This was the first that was known of any generalized or local spasm or convulsion. However, inquiry of the husband revealed the fact that there had been about six apparently similar seizures during the past five months but he had made light of them with his wife, as she was "too nervous as it was." He had not told his doctor. The family physician was aware of the attacks for the first time when told of the hospital convulsion. Shortly after returning home, the patient had several seizures, one of which was witnessed by the family doctor who likened it to that of idiopathic epilepsy.

Postoperative examination. Upon returning for the postoperative examination, the patient seemed quite confused, disturbed, and blind, save for poor light projection. Ophthalmoscopic examination revealed clear media but a papilledema of considerable amount with parapapillary venous engorgement without hemorrhages. Visual fields were markedly constricted, a small central area remaining. At first it was believed, because of the mental state of the patient, that the poor vision and constricted visual fields were exaggerated. But repeated examinations during the course of the ensuing week gave the same results. Papilledema was also found, although seen indistinctly in the right eye, with loss of sight and constricted fields. X-rays of the skull, orbit, and intracranial contents were normal.

Neurologic examination. The patient was referred to a neurologist. His first office examination was not conclusive enough for diagnosis and the patient was hospitalized for further study.

During the three weeks after the last cataract operation, the patient's behavior changed. Mental symptoms appeared, with nervousness, change of temperament, irritability, and irrational periods. During this time, several attacks of generalized convulsions were reported. During the 24 hours prior to hospital admission, there was continuous twitching of the entire body with spasms of fingers and toes, and generalized convulsions and involuntary defecation were reported. On the day of admission, the calcium was at 6.5 mg. and the phosphorus at 2.35 per 100 cc. of blood. The white blood count was 15,700, the red 4,220,000. All other laboratory tests were negative.

Outcome. Immediate improvement began with the administration of dihydrotachysterol and calcium lactate. Convulsions and twitching ceased after the first day. The mentality cleared. The visual fields improved and the papilledema, though still present, seemed at the end of the first week to be reduced. Vision in the left eye, at the end of the first week, had improved somewhat. There may still be further improvement, although some pallor of the disc has appeared.

Cataract of parathyroid deficiency

The cataract produced by parathyroid deficiency is of relative frequent occurrence and has been reported extensively and in detail by ophthalmologists who specifically have recorded normal fundi in many instances. The ocular syndrome of cataract and papilledema is rare, having been reported in the literature infrequently. Albrecht collected eight cases and added one of his own.[1] Barr and his co-workers reported two cases.[2] Leonard reported one case and referred to seven others.[9] Lillie reported a case having "optic neuritis and cataracts."[10] The patient whose history is herewith presented brings the total to 21 cases.

The probable reason for the rarity of papilledema in parathyroid deficiency is the fact that the severity required to produce this condition is seldom encountered. Perhaps it is occasionally overlooked.

Causes of parathyroid deficiency

There are several causes of parathyroid deficiency. Sufficient for the purpose of this presentation is the classification into idio-

pathic and postoperative types. The idiopathic type may be the result of lack of growth or degeneration of the glands. Intoxication may play an uncertain role. Infections, local or general, hemorrhage, and factors which may cause an inactivation of the products of the parathyroid glands may result in parathyroid priva.[15]

The exact action of the reduced functioning of the parathyroid glands upon the body structure, resulting in the varied symptoms, is unknown. There is an increase in the neuromuscular irritability which is reflected in both the somatic and visceral systems. The ectoderm, both somatic and neural, is affected. The condition exists in the latent and in the manifest stage and may occur in an acute, subacute, or chronic form.

Symptoms of latent stage

The latent stage shows symptoms of excitability only upon local nervous stimulation or irritation and is usually restricted to the muscle or muscles innervated by the nerve stimulated. This stimulation may be artificially induced, as is seen in the tests used for the purpose of diagnosis. It may also be the result of local irritation or inflammation, as is seen in the spasm of the eyelids and face and probable ciliary spasm following eye operations. The most common reaction is the spasm of the striated somatic musculature. Usually, with the latent stage, there is an involvement of the surface ectodermal structures.

Symptoms of manifest stage

The manifest stage is characterized by generalized spontaneous convulsions, possibly of central origin, in addition to the ectodermal changes and the symptoms of neuromuscular irritability which may appear spontaneously. The manifest stage also introduces the neuroectodermal symptoms: mental disturbances, increased intracranial pressure with papilledema, and increased cerebrospinal fluid pressure. The few autopsies performed upon these patients revealed the presence of generalized cerebral edema.[1, 11]

Diagnosis of parathyroid deficiency

The diagnosis of parathyroid deficiency in either latent or manifest forms is made through laboratory tests of the blood calcium and phosphorus and through signs of excessive neuromuscular irritability elicited through clinical tests and symptoms of ectodermal (both surface and neural) involvement.

The normal calcium content of the blood varies within the limits of 9 and 11 mg. per 100 cc. Usually, in latent tetany or parathyroid deficiency, the level is about 7 to 8; in manifest tetany from 4 to 6. The phosphorus content, which normally is between 2 to 4 mg. per 100 cc. of blood, is relatively or absolutely increased in proportion to the calcium content.

Clinical symptoms and tests

The usual tests made to determine the hyperneuromuscular excitability are:

1. Chvostek's sign, which shows the hyperexcitability of the muscles innervated by the facial nerve when it is tapped just anterior to the tragus of the ear above the condyloid process of the mandible (the point of injection for O'Brien's akinesia). The response is a momentary contraction of the facial muscles, including those of the eyelids.

2. Trousseau's sign (or phenomenon) is produced by pressure upon the brachial artery at the bend of the elbow, resulting in a contraction of the hand and fingers.

3. Erb's phenomenon is the result of neuromuscular response to a weaker galvanic current than is usually required to produce a normal reaction.

There are other tests and signs of lesser importance. The clinical symptoms are:

Ectodermal trophic changes resulting in alopecia, dry skin, brittle nails, ridged teeth, and cataract.[7]

Causes of lens changes

Authors differ as to the causes of lens changes. Some attribute them directly to tetanic convulsions with possible ciliary spasm. However, these lenticular changes have been seen in patients in which there have been no local or general spasms. Others attribute the lens opacities to the result of low calcium or lack of specific parathyroid secretion.[6]

The opacities usually begin as individual points in the cortex beneath the posterior (occasionally the anterior) capsule of the lens which develop into threads and riders, finally coalescing. A few crystal-like opacities of denser appearance may be present. In the idiopathic form, which may be seen in the young, possibly acquired congenitally, opacities may be seen deeper in the cortex, evidence of involvement during the developmental stages of the lens.[12]

These lenticular changes somewhat resemble, and therefore should be differentiated from, those produced in diabetes and other toxic conditions and from types of radiation, myxedema and other dermatogenic cataracts.

Neural symptoms

The neural (neuroectodermal) symptoms are:

1. Spasms which may be local or general. They may be induced for purposes of diagnosis. They may be the result of irritation or inflammation or they may be spontaneous, in which case they are usually found in the manifest stage.*
2. Sensory affections of tingling, boring, or numbness may be complained of.
3. Symptoms of irritability, headache, and dizziness may be present.
4. Convulsive seizures or epileptiform attacks occur.
5. Mental disturbances may be present with depression, dullness, and personality changes.
6. Symptoms pointing to hypothalamic affection have been reported.[16, 17]

Accompanying these symptoms indicative of cerebral involvement, increased intracranial pressure, as is evidenced by brain edema, papilledema, and increased cerebrospinal fluid pressure, is found.[1, 11]

X-ray films frequently show symmetrical shadows in the area of the basal ganglia. Blood vessels in the vicinity may at first be surrounded by colloid deposits which undergo calcification.[6]

Other symptoms of apparently lesser diagnostic importance, including extrinsic ocular muscular weakness and eyestrain, strabismus, nystagmus, and anisocoria, have been reported. Spasm of the ciliary muscle and iris is found. The smooth muscles innervated by the autonomic nerves are probably more frequently involved in tetany than is commonly appreciated.

Differential diagnosis

Differential diagnosis must be made from idiopathic epilepsy and brain tumor. The former may be the tentative diagnosis of the general practitioner who first sees the patient in convulsions. The latter may be the diagnosis of the neurologist who sees the patient's confused mental state, with convulsions and increased intracranial pressure as evidenced by papilledema and increased cerebrospinal fluid pressure.[1, 11] Perhaps, as there is rapid loss of vision along with swelling of the optic-nerve head, the ophthalmologist may consider optic neuritis along with papilledema in the ophthalmologic diagnosis.[10]

Conclusion

The reason for this presentation lies in my desire to recite my clinical experience and to review the pertinent literature of this con-

* A patient is recalled who, about two hours after cataract extraction, suffered extreme local pain with spasm of the facial muscles and of the eyelids and probable ciliary spasm with redness and profuse lacrimation, evidently as a result of irritation induced by the operation. She had undergone thyroid operation several years before and had developed tetany cataracts.

dition. If there is anything of worth to be gained from the report of this case, I believe it is revealed in the necessity of keeping all patients with parathyroid deficiency under constant surveillance in order to prevent the latent affection from becoming manifest.

THE EXTRACTION OF CATARACT IN THE PRESENCE OF FLUID VITREOUS*

DANIEL B. KIRBY, M.D.
New York

Nearly all cataract surgeons have had experiences with the complication of fluid vitreous which has replaced the normal gel vitreous, but very few have recorded them. In some cases, the fluid vitreous remains behind the capsulozonular hyaloid barrier, while in others it is in free communication with the anterior chamber. There are means of recognizing both, although not in every case the latter, and the surgeon may be surprised to see fluid vitreous flow immediately after the section has been made. The profession in general is not aware of the possibilities of recognizing the condition before operation. I have had some gratifying and interesting experiences with such cases and have made some observations and speculation on the nature and cause of the condition and the method of handling the extraction of the cataract.

"When a dissolved state of the vitreous body exists, as it often does in old persons, the section of the cornea is perhaps no sooner made than the cataract, along with a greater or less quantity of the vitreous humor, bursts from the eye; or, the cataract sinking down behind the iris, a large quantity of vitreous humor alone bursts out. If the dissolution of the vitreous body be great, it will be evacuated wholly or in large quantity, and the eyeball may thus be destroyed, notwithstanding the utmost dexterity, delicacy, coolness, and circumspection on the part of the operator."[1]

Weeks[2] said that "in case of fluidity of the vitreous the tension of the eye may be reduced but it is not always so nor can we say that it is the rule. Such cases present complications when operative procedures necessitating the opening of the globe are undertaken."

Hundt[3] said that Peters had had a favorable outcome in a case of fluid vitreous from which he had removed a cataract. Peters assigned him to investigate the subject. I will quote Hundt at length. "The first information available on synchysis of the vitreous is the writings of the anatomists, Rosinius and Morgagni. The latter frequently found in post-mortem examinations that the vitreous had been completely replaced with a transparent fluid.

"Ophthalmologists such as Ammon, Himly and Wardrop added nothing new to this. An investigation of the subject was made by von Graefe who said that it was important to distinguish between a simple liquefaction of the vitreous and flocculent dissolution.

"Arlt, in his book (1856), divided fluid vitreous into five groups, the first in which the liquefaction followed mechanical injury to the vitreous, the second due to a drop in the pressure in the vessels of the interior of the eye. This he named *hydrops ex vacuo.* A third group of cases of fluid vitreous were observed associated with iritis, especially in the chronic cases. He noted that the vitreous liquefied more often in older people, whose lenses were either opaque or on the way to becoming so. He finally stressed especially the fact that eyes with high myopia and stretching of the posterior pole of the eye often had a fluid vitreous.

"In like manner do other older writers express themselves on fluid vitreous. Stellwag (1867) mentioned the occurrence of liquefaction following massive loss of vitreous. He divided fluid vitreous into (1) simple liquefaction without any solid particles and (2) a flocculent type in which the

* Presented at the 83rd annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June, 1947.

fluid contains degenerated products of inflammatory lesions, groups of cells, clots, pigment clumps, single or clumped cholesterol crystals, fat droplets, and so forth. Simple synchysis without preceding inflammatory processes is represented as a separate entity. He differentiated between liquefaction of the vitreous and separation of shrunken vitreous from the retina by serous exudate."

Hundt goes on to quote de Wecker, telling how he stressed "(1) chronic uveitis as a forerunner of fluid vitreous, (2) the liquefaction of the vitreous which follows direct injury to the vitreous by introduction of a foreign body and especially by *couching* of the lens, (3) senile degenerative changes accompanied by opacities in the vitreous, (4) poor nourishment of the tissues as related to diseased vitreous."

Fuchs was quoted as stating that the fluid which runs out in cataract surgery in such cases isn't always liquefied vitreous but may well be serous exudate which has accumulated between the retina and the vitreous. Fuchs also brings out the fact that operations in the latter cases may be followed by detachment of the retina and atrophy of the globe.

Von Michel is mentioned as having ascribed the cause of some cases to previous hemorrhage. Elschnig's study of fluid vitreous in myopes is mentioned with his conclusion that myopia can cause it but that the vitreous does not always liquefy in myopia. Behse studied 10 myopic eyes (up to 20D.) and found that in none of them was the vitreous normal. Seefelder found fluid vitreous in congenital hydrophthalmos. Naumoff stated that when the vitreous is fluid only in the center part one is suspicious that the change in consistency is recent. Hundt adds that the peripheral vitreous is normally firmer and would be the last to yield to liquefaction.

Hundt enumerates the significant sequels to fluid vitreous as follows: "(1) No effect on vision from fluid vitreous unless there are also floating particles which may be disturbing to the patient, (2) probably no effect on refractive index, (3) lens nutrition may suffer from chemical changes in the vitreous and a posterior cortical lens opacity may develop and this may or may not spread to the rest of the lens, (4) predisposes to dislocation of the lens, (5) fluid vitreous is of greatest significance when surgery is required, especially in cataract extraction."

Arlt is quoted as saying that you can expect a restoration of vision only if the loss of fluid vitreous is not more than one third of the total. Other authors, especially Czermak, are less conservative. Czermak attaches little significance to fluid vitreous. According to his experience the wound closes well and the globe soon resumes its normal volume. Also, according to Zehender, the eye from which fluid vitreous has been lost is less likely to have an inflammatory reaction after cataract extraction than eyes from which normal viscid vitreous has been lost.

Arlt is quoted as recommending that "In order to avoid loss of vitreous in patients with fluid vitreous they should be in bed when operated instead of sitting up. He added, however, that unfortunately it is seldom possible to establish in cataract patients a diagnosis of fluid vitreous. And, therefore, one will occasionally be surprised, at operation, by a total loss of the fluid vitreous which so radically alters the eye that restoration to its former shape seems doubtful, yet this is often very easy to achieve by filling the empty space with normal saline.

"The credit for the use of saline goes to Hermann Knapp who, in 1899, during a cataract extraction, noticing an unusually deep indentation of the cornea and subsequent infection, made the proposal that in such cases the anterior chamber be filled with physiologic saline in order to prevent infection while the anterior chamber was reforming. Since this method proved utterly harmless in another case of deeply indented

cornea after extraction, Knapp extended the recommendation for its use in cases where the globe collapsed completely after the corneal incision."

Hundt goes on: "It is noteworthy that this very worthwhile suggestion of Knapp's had very little attention; at least I found only two cases in the literature in which this method was used. Thus, Andrews reports that he succeeded in getting uneventful healing and good vision by injecting saline into an eye which had undergone severe loss of vitreous during the extraction of a traumatic cataract.

"Elschnig brought out this point again at a meeting in Heidelberg with a paper recommending in cases with vitreous opacities or hemorrhages treatment of partial withdrawal of the vitreous and replacement with physiologic saline.

"After Axenfeld had remembered that Knapp had recommended this procedure 10 years earlier, Elschnig reported that he, too, had had occasion to replace escaped vitreous with physiologic saline in a case of traumatic perforation of the globe with extensive loss of vitreous and retinal detachment. He reported that he obtained an excellent result."

Hundt goes on to report Peters' case: "It concerned a 65-year-old patient who, in addition to high myopia and a beginning cataract in one eye and a fully developed one in the other, also showed fluid vitreous. When the cataract incision was made, a large amount of entirely fluid vitreous flowed out, so that the sclera above showed a deep depression and the iris dropped back in a funnel-shaped position. The lens disappeared entirely so that the cornea's upper margin was dipping down perpendicularly. It was attempted to fill the globe with this saline. It was, however, impossible to overcome the deep groove in the sclera. The next day the shape of the globe was entirely normal and the anterior chamber was closed. Peters obtained a good result."

Elschnig[4] has reported that in 85 cases of highly myopic eyes intracapsular extraction was successful, 11 capsules ruptured but were extracted, that he was unable to grasp the capsule or that it had already ruptured in the anterior chamber in 18 cases. One eye was lost. "A comparison shows that in highly myopic eyes intracapsular extraction is much superior to extracapsular extraction in respect to all complications. In comparison with extraction in nonmyopic eyes, the danger of prolapse of the vitreous body is a little greater."

Meller[5] states that "Quite unavoidable is the prolapse of vitreous in the presence of complicated cataracts, when the zonule is ruptured or when the vitreous has lost its normal consistency."

Schoenberg[6] said that detachment of the vitreous is recognizable with the ophthalmoscope by the bright reflex in front of the retina. In some cases the vitreous shrinks and becomes detached, ordinarily at its posterior portion, while that part in contact with the ora serrata and ciliary body remains adherent.

Troncoso[7] said "Synchysis can be recognized more easily when the eye is rotated. There may be liquefaction of the vitreous with more or less complete destruction of the framework of fibers, and the appearance of adhering to the fibers or floating in the spaces between." Troncoso agrees with the classification of Bachstez of the lipid and nonlipid bodies moving in the vitreous as follows:

"(1) Bodies in the fluid vitreous: synchysis. (a) synchysis scintillans, (b) synchysis nivea or albescens; (2) Bodies in nonfluid vitreous: (a) asteroid hyalitis, (b) poorly defined flakes of unknown chemical nature."

Troncoso goes on: "*Synchysis scintillans.* This is a special degeneration of the vitreous which appears with the ophthalmoscope as a beautiful shower of sparkling gold particles rising with movement of the eye but sinking rapidly to the bottom. These glistening crystals consist of cholesterol (Clapp), and

appear sometimes in otherwise healthy eyes, especially in aged persons, without deterioration of the central vision. More frequently, however, they are signs of choroiditis occurring as the result of syphilis, arteriosclerosis, metabolic diseases, or trauma. The disease may appear in one or both eyes.

"*Synchysis niva or albescens.* The floating bodies appear as small, white, spherical opacities of a dull white color (Bachstez). They are probably leucine needles, tyrosine or phosphates.

"*Asteroid Opacities.* This is also a degenerative condition with deposits in the vitreous or numerous particles which, instead of being brilliant like the crystals, appear as small, spherical, isolated, white globules resembling snowballs (Holloway). Sometimes clusters of these balls may appear in the periphery. The white opacities are fixed, or move very slightly when the eyeball is rotated, as the vitreous is not liquefied. Benson gave this condition the name of *Asteroid hyalitis,* comparing the fundus picture to the sky studded with numerous stars. Verhoeff had the opportunity, in 1921, to examine chemically the snowball opacities and concluded that they consist chiefly of calcium soaps, calcium carbonate, and a certain amount of fatty or lipid substances. The source of the lipids seems to be, in part, the vitreous lipid. According to Krause, the lipid particles enter the vitreous from other tissues; it is probable that migratory leukocytes pass into the vitreous and die there, disintegrate and leave the lipids as inert particles floating in the vitreous."

Duke-Elder[8] said that "liquefaction of the vitreous body (Synchysis. Syn, together; Cheo, to pour) is the most common feature of degeneration, occurring in senile and myopic conditions and after contusions as well as in most degenerative and inflammatory states of the eye. It is due to a conversion of the colloid gel into a sol and is usually associated with the development of ophthalmoscopically visible opacities formed by the colloidal micellae which aggregate together in dustlike particles, strands or membranes. In a sense it is probably a dehydration rather than a hydration in so far as it represents the loss by the micellae of their water of absorption which becomes free intraocular fluid, leaving the protein residue shrunken and agglutinated. Such a breakdown may be due to purely physicochemical factors but may also be conditioned by enzymic digestion of the protein basis of the gel.

"Fluidity of the vitreous calls for no treatment; its clinical significance lies in the demonstration of degenerative changes in the eye, and in the possibility of serious complications occurring in intraocular operations, for in these eyes the zonule also is usually weak, and a dislocation of the lens and prolapse of the vitreous may easily occur."

The natural conclusion to be drawn from the last paragraph of Duke-Elder's statement is that there should be prophylaxis against luxation of a cataract when fluid vitreous is known to be present. It will be best judgment not to permit a cataract to become hypermature and risk luxation when it may be easily removed at a convenient time.

Arnold Knapp[9] said, "The question whether fluid vitreous is a contraindication is often raised. I am not convinced that this is a contraindication, if it is assumed that its presence can always be recognized beforehand."

Cataract in the presence of fluid vitreous

The presence of fluid vitreous (synchysis) in a case of cataract may therefore indicate the need for a special handling of the eye and use of a special operative technique for extraction of the cataract. The preliminary examination of the eyes before cataract surgery may disclose whether or not the vitreous is fluid instead of being in its normal gel or viscid state. It may be discovered that it is well contained behind the capsulo-

zonular hyaloid barrier or on the other hand it may be in communication with the anterior chamber.

Viscid and semiviscid vitreous

If, directly after the section has been made and the aqueous evacuated, it is observed that the anterior chamber has reformed, it is an indication that a rupture of the hyaloid capsulozonular barrier had preëxisted or had developed during the section and the viscid or semiviscid vitreous had moved forward into the anterior chamber. Even the normal cornea with normal elasticity will collapse somewhat upon evacuation of aqueous. Therefore, if the chamber has deepened and the corneal shape has been restored, the only inference is that as given above. A loop or spoon extraction of the cataract is probably the only resort, as the viscid or semiviscid vitreous will interfere with the grasp of the interior lens capsule by forceps or other device. In some cases of semiviscid vitreous approaching the semifluid stage it may be possible to clear it from the capsule with a suitable applicator but not so in cases of viscid vitreous.

The escape of fluid vitreous

The effect of loss or evacuation of the normal amount of aqueous humor upon cataract section is well known. There is no rapid reformation of aqueous and no continued loss evident in the average case. Therefore, if a continued loss occurs, if fluid seeps away and continues to seep away, flowing out in a thin stream from part or all of the incision, the only inference is that it is fluid vitreous that is escaping. The fluid may be colorless or it may be slightly straw-tinged.

Intracapsular extraction indicated

A condition of hypotony will exist which will make ineffective any manipulation requiring pressure over the globe. Intracapsular rather than capsulotomy extraction will be indicated and necessitate the use of traction, rotation, and under certain conditions direct rupture of the zonule by separating or stripping it from its attachment to the capsule of the lens for the removal of the cataract with the least effort, trauma, and danger.

In the latter group of cases of fluid vitreous it must be inferred that a dehiscence or hole or tear in the hyaloid capsulozonular barrier was present before the section was made or that the zonule being fragile it developed because of the relatively minor trauma of the fixation or of the section or because of the change of hydrostatic pressure inside the eye.

The normal hyaloid capsulozonular barrier

Embryology. The lens plaque arises in the embryo as a result of contact between optic vesicle and surface ectoderm. There develop protoplasmic adhesions between the cells of the primordial lens and the optic vesicle, later the optic cup. As the lens develops, these adhesions are stretched out to form the zonular fibers. The latter in the adult extend between the ora serrata, accounting for its serrated form, and the equatorial portion of the lens capsule, running in and forming the ciliary valleys with secondary fibrillar attachments to the ciliary processes. Mann[10] said, "The primary vitreous is added from retinal ectoderm. The fibrils of the zonule, or tertiary vitreous, arise later from the ciliary epithelium." I have found by microdissection of living chick embryos that strong adhesions which may well be the anlage of the zonular fibers exist at all times after the contact of optic vesicle and lens ectoderm. Further observations should be made on fresh human embryos by microdissection. I believe that as revealing differences will be found between fresh and fixed specimens of the zonule at the different stages of development as are evident in the examination of fresh and fixed preparations of the adult zonule and its lamella. At the time of development of the tertiary vitreous the zonular lamella may be added to the zonular fibers.

Anatomy. In the fresh normal human eye, the zonule consists of (a) an orderly array of fibers and (b) a thin interfibrillar lamella which in clinical surgery gives the zonule the appearance of a membrane. It is not a true membrane like Descemet's but it may well act, when normal, to prevent the passage of particulate bodies from the vitreous to the posterior aqueous chamber. It may have some semipermeable quality, although this is very dubious. It is probably like the vitreous and is a condensation between the zonular fibers. The lamella is of the same index of refraction as the aqueous and is not visible in the living human eye when surrounded by the normal fluids of the eye, as, for example, in colobomas, either congenital, traumatic, or surgical. The zonular fibers are visible under these conditions. The lamella becomes visible when magnified and exposed to the air as, for example, in the surgery for removal of cataract. It disappears during the preparation of stained microscopic specimens, thus leading to the confusion of descriptions of fresh and fixed specimens. The normal hyaloid, zonule, and the lens in its capsule constitute in effect a barrier between the vitreous and the aqueous chambers. The hyaloid enclosing the vitreous anteriorly is separated from the posterior lens capsule by a thin film of aqueous, while in the periphery there is a greater depth of aqueous between the hyaloid and the zonule. The normal vitreous is fluid in the small central region of the canal of Cloquet. The greater portion is normally viscid.

Pathology. In pathologic conditions of the eye, there may be (a) absence or disinsertion of the fibers of the zonule, resulting in luxation or subluxation of the lens. This picture is familiar in congenital, degenerative, and traumatic conditions. In such cases there may be viscid or fluid vitreous in the anterior chamber. In congenital conditions, disinsertion is at the ora and ciliary body, whereas in traumatic, degenerative, and surgical conditions it is at the insertion into the capsule. There may be degeneration and perforation of the zonular lamella and hyaloid but intact zonular fibers. In all of these conditions, particulate bodies from the degenerated vitreous may enter the anterior chamber. When, in addition to the fact that the vitreous is fluid in a case of cataract, there are signs that the hyaloid capsulozonular barrier is missing, perforated, or ruptured, the surgeon is forewarned and may well be prepared for escape of the fluid vitreous immediately after the section has been made. I have observed such cases before and after surgery.

Fluid vitreous well contained behind an intact hyaloid capsulozonular barrier. There are relatively more cases of fluid vitreous well contained behind the hyaloid capsulozonular barrier than those in which a communication of the fluid vitreous exists with the anterior chamber through dehiscences in the barrier. The latter may appear to be a form of low-grade uveitis, in which there is no congestion but in which pigmented and nonpigmented particulate matter circulates in the aqueous and is deposited on the endothelium. I had in such cases considered this material evidence of degeneration rather than of inflammation, but I had not linked up with the possibility of this particulate material coming from the region posterior to the capsulozonular barrier. There is need for the recognition and differentiation of such cases from uveitis due to infection and inflammation. In the group in which the hyaloid capsulozonular barrier is intact, one may find signs of degeneration the same as in the lesser group but there may be no floating debris in the aqueous.

Preoperative examination of the eyes. Preparation for any cataract surgery should include details of examination with the ophthalmoscope, slitlamp, microscope, and tonometer. In cases in which the lens opacity is sufficiently dense to preclude the possibility of direct examination of the vitreous, its condition may be inferred, although not always correctly, by examination of the pa-

tient's fellow eye. One particular lead is to look for signs of degeneration of tissue in all cases of cataract before surgery.

THE SIGNS OF OCULAR DEGENERATION

The absence of congestion. In cases of degeneration alone there will be no congestion of the vessels unless there is consequent inflammation. It is well known that necrosis of degeneration may set up an aseptic inflammation. Congestion of the eye from any cause is an important sign of bad omen in relation to cataract surgery.

Tonometry. The intraocular pressure as indicated with the aid of a reliable tonometer may, if low, and particularly if there is hypotony, indicate that degeneration and fluidity of the vitreous may be expected. The prognosis for successful healing of a very low-pressure eye after cataract extraction when the tension with the Schiøtz tonometer is less than 8 mm. Hg is not good, and surgery, therefore, may well be avoided if possible in such cases. If the hypotony is of lesser degree, between 8 and 12 mm., the condition is less grave but there is a definite indication for particular care in the avoidance of trauma as in all ocular surgery. It has been said that in such eyes the extracapsular operation is indicated, but comparative results show that these eyes do not heal gracefully in the presence of retained cortex which is slow in absorption and productive of irritation, inflammation, and after-cataract; whereas, in my experience, intracapsular extraction has produced gratifying results.

Ophthalmoscopy. Sufficiently strong light should be used with the ophthalmoscope to pierce the lens opacity, if at all possible, and various dioptric values used to detect movement of the vitreous on rotation of the globe, its rate, and the presence of vitreous opacities. The rate and degree of disorderly movement of particulate bodies or opacities in the vitreous indicates the degree of fluidity of the vitreous. It may be possible to demonstrate increased fluidity of the anterior or central vitreous while the posterior or peripheral vitreous remains viscid. The binocular ophthalmoscope is particularly useful in examination of the vitreous.

Biomicroscopy. 1. The vitreous and zonule. Monocular and binocular loupes and the slit-lamp microscope are useful in the examination of the anterior vitreous. The appearance of the magnified normal vitreous with its beautiful transparent curtains and folds, with its undulatory controlled movement on rotation of the globe is a familiar picture. In cases of degeneration, the normal structure will be absent, and in its place there will be observed opacities of various pigmented and nonpigmented forms, dots, strings, conglomerate nebulae, or constellations which the patient may perceive as certain figures or as a jumble of moving clouds which disturb the clarity of his vision. These the ophthalmologist may see moving and swirling in disorganized fashion much more rapidly than any single opacity or group of opacities in the gel state of the normal vitreous, the rapidity of movement being an index of and in proportion to the fluidification of the vitreous. The vitreous may be found to have degenerated from the normal viscid gel to a semiviscid, semifluid, or completely fluid state. Particular examination for the presence of degenerated vitreous mixed with the aqueous or in the anterior chamber should be made in all cases of iridodonesis and inequality of depth of the anterior chamber as indicative of subluxation of the lens. In such cases it is known that there is a dehiscence or break in the zonule. It is a familiar phenomenon in congenital and traumatic luxation or subluxation of the lens to see viscid gel vitreous in the anterior chamber or at the side of the lens. In cases of senile deterioration or degeneration of structure, a minor trauma may cause a break in the zonule and evidence of fluid vitreous mixed with the aqueous may be present. The zonule is known to be fragile in such cases, and it is inferred to be fragile in cases of fluid vitreous because of coinci-

dent degeneration of structure of somewhat similiar origin and nature.

2. The deposits on the endothelium of the cornea. Differentiation should be made between the deposits of inflammation and those of degeneration in cases in which dehiscences in the hyaloid and zonule permit continuity between the aqueous and the fluid vitreous. The typical mutton-fat deposits of inflammatory uveitis have been well described elsewhere and are well known. They bear no resemblance to the deposits found in cases of degeneration. These are fewer in number, are not greasy, are not in clumps, and they do not assume the typical triangular pattern of those of inflammatory origin. They apparently have less cohesive and adhesive equality and appear to be resting on the endothelium, not adherent to it.

3. Particulate bodies in the aqueous. Opacities resulting from degeneration found floating in the convection currents of the aqueous are similiar to the deposits on the endothelium. The plasma clot of acute uveitis is never found in the cases of moderate degrees of degeneration, but one should not mistake the particulate floating bodies of inflammatory uveitis for those of degeneration.

4. The aqueous beam. The aqueous beam exhibits slightly more relucency than normal in case of fluid vitreous in the anterior chamber indicating the slightly greater protein content of the aqueous because of the admixture of the fluid vitreous. In cases, however, in which the beam is in excess of slightly more relucent than normal there should be a grave suspicion that the case is more complicated than can be explained by the presence of fluid vitreous mixed with the aqueous. A moderately to greatly increased protein content of aqueous may point to important complications of serious detachment of the vitreous, uveitis, serous exudate, and detachment of the retina. The sign of increased relucency of the aqueous combined with hypotony with faulty light projection and color perception is of serious omen in establishing the prognosis of complicated cataract.

The form of the cataract. The form of complicated cataract, not always however associated with fluid vitreous, may be that of (a) the postcortical or saucer-shaped variety. It may have the iridescence described by Vogt and this may be a sign of a particular degeneration but the use of the term "complicated cataract" in this connection does not necessarily mean that useful vision cannot be obtained after removal of the cataract. The complication may be only in the lens, zonule, or vitreous and not particularly in the uvea, retina, or nerve. (b) The anterior and posterior subcapsular form, which may be regarded as a variety of the posterior-cortical. In some cases the number of lens globules and the pattern of the anterior opacity may be as great as that of the posterior. Cortical and nuclear haze develop sooner, the onset of intumescence is earlier, and the progress of development of the complete opalescent or dull gray white opacity of the lens is more rapid in the second form. Not all cataracts which develop rapid intumescence are complicated. During surgery the taut capsule of a swollen lens may be found to be rubbery, thick, and tough, or it may be very thin and fragile. The zonule may be resistant or fragile. The well-known forms of presenile and senile cataract, nuclear, corticonuclear, and cortical, immature, mature, and hypermature may all be associated with fluid vitreous and fragile zonules.

Other signs of degeneration. Other signs of coincident ocular degeneration should be looked for and evaluated as, for example, fragility of the conjunctiva, atrophy of the sclera, arcus senilis, dystrophy of the endothelium of the cornea, atrophy of the iris, and exfoliation of the most superficial lamella of the anterior lens capsule. An inference that may well be drawn in the presence of any sign of degeneration is that other structures of the eye may be degenerated. There may be in the presence of cataract, and any or all of the signs enumerated, sclerosis of the cells of the iridocorneal angle, fragility of the zonule, and fluid vitreous.

The recognition of fluid vitreous in communication with the aqueous before operation. The determination of fluid vitreous by ophthalmoscopy and biomicroscopy when the lens is sufficiently clear is relatively easy. It is also possible to recognize the condition of communication of fluid vitreous with the anterior chamber without evident subluxation of the lens and to differentiate it from uveitis due to inflammation. It must again be asserted that the process of degeneration may in itself produce inflammation, although this will usually be different than that engendered by infection, and it must be repeated that signs of severe or extensive degeneration with fluid vitreous, particularly with hypotony and increased aqueous flare, even though the light perception and projection are fairly accurate, must give a poor prognosis.

The Cause of Cataract, Fragility of Zonule, and Fluid Vitreous

The coincidence of cataract, fragility of zonule, and fluid vitreous connotes deterioration of the substance of the crystalline lens, zonule, and of the vitreous humor, and may be regarded as a dystrophy or degeneration dependent on faulty nutrition, abiotrophy and senescence of ocular tissues which may be local or part of a general condition, hemorrhage into the vitreous, myopia, trauma, inflammation, and detachment of the retina.

1. Faulty nutrition. The lens, zonule, and vitreous may suffer from faulty nutrition because of degeneration of ciliary body and the production of poor-quality aqueous. The proper utilization of vitamins, proteins, fats, carbohydrates, and minerals is important in the maintenance of nutrition, health, and transparency of the lens, zonule, and vitreous. Faulty blood supply to the eye, particularly to the ciliary body, may produce faulty nutrition of the lens, zonule, and vitreous and consequent cataract, fragility of zonule, and fluidification of the vitreous.

2. Abiotrophy and senescence. Abiotrophy and local senescence of tissue may be a factor in the development of cataract, fragility of zonule, and fluid vitreous. The span of life and function of these tissues of ectodermal origin may be less than that of the rest of the eye or body and thus be the reason for their earlier deterioration. Other examples of abiotrophy in the eye, such as the degeneration of the pigmented and nonpigmented cells of the posterior surface of the iris and of the ciliary body in certain cases of glaucoma, of the pigment epithelium of the retina and of the choroidal blood vessels in retinitis pigmentosa, may be cited. The eye and its tissues share in the process of general senescence. A large percentage of all elderly persons have some signs of cataract and degeneration of lens capsule and zonule, but relatively few develop fluid vitreous.

3. Hemorrhage. Hemorrhage into the vitreous may be a cause or an accompaniment of the degeneration of the vitreous.

4. High myopia. Progressive myopia leading to the higher degrees of myopia, although it may be caused by a number of factors, may in some instances be regarded as a dystrophy or degeneration in which the lens, zonule, and vitreous suffer. From the mechanical viewpoint, the self-limited vitreous gel sufficient to fill a normal eye is incapable of expanding to the size of the highly myopic eye. The balance of the space is filled with fluid. The remaining gel may tend to liquefy so that the whole may eventually become fluid. Fluid vitreous may well be expected in all cases of high myopia, although as shown in Elschnig's and in my series of cases the vitreous may be retained behind an intact hyaloid and be no contraindication to intracapsular extraction.

5. Trauma. Contusion trauma sufficient to rupture the normal zonule from its attachment to the lens capsule must be relatively great. It is remarkable that the eye as a whole can stand such injury. If the lens is luxated into the vitreous by trauma it may act either with its capsule ruptured or intact as a foreign body and, in addition to its potentialties of exciting aseptic inflammation, may cause degeneration of tissue and fluidification of the vitreous. Even without

gross rupture of the globe, contusion trauma may produce degeneration of the ciliary body, hypotony, cataract, and fluid vitreous.

6. Inflammation—Uveitis due to infection. Any case of uveitis, particularly of cyclitis and choroiditis, may develop cataract and fluid vitreous as a complication or consequence of the inflammation. All cases of cataract should be examined with magnification to determine whether or not there are signs of causative or complicating uveitis. Excluding the active congestive states of acute uveitis, one should look for the insidious quiet cases which may show (1) a few typical mutton-fat deposits on the endothelium of the cornea, (2) particulate bodies either floating in the aqueous or fixed in a plasma clot in the anterior chamber, (3) increased relucency of the aqueous, (4) ciliary congestion, (5) posterior-cortical form of cataract, (6) opacities in the vitreous, and (7) signs of coincident or consequent degeneration.

If degeneration of the lens, vitreous, and uvea develops rapidly or extensively, there may be engendered an inflammatory reaction because of the nature of the toxic necrotic material which must be absorbed and in the process proves irritating to the uvea. Such a reaction may be entirely similar to that produced by an infection to which the uveal tissues may have become sensitized.

7. Detachment of the retina. When detachment of the retina first develops, the vitreous may be quite normal and viscid. If the detachment exists for a length of time or becomes extensive, degeneration and liquefaction of the vitreous will ensue. Hence, it is of particular importance in each case of cataract and fluid vitreous to exclude detachment of the retina by objective examination and by subjective tests before surgery. On the other hand, if detachment of the retina does not exist at the time of surgery it has been my experience in this series, except in one case, that it has not developed after the extraction of the cataract even when the fluid vitreous has escaped and later been replaced by normal saline or by natural restoration of intraocular fluid.

Indications and prognosis in cases of cataract and fluid vitreous. Degeneration of the normal gel viscid vitreous at the time of cataract surgery may have caused it to become semiviscid, semifluid, or completely fluid. Degeneration of the lens, zonule, and vitreous does not necessarily indicate an accompanying degeneration of the retina, nerve, and uvea. Eyes in which the latter is not present and from which the cataract has been removed may heal well after surgery and maintain good function, central form and color and peripheral field vision for years afterward. They seem to do so well after the indicated nontraumatic intracapsular cataract extraction that it may be judged that the cataract had been liberating toxic bodies, freedom from which has a salutary influence.

I believe that extracapsular extraction is contraindicated in such cases because it has been common experience that cortical remnants do not absorb gracefully when mixed with vitreous, normal or in any stage of degeneration. The cataract may be removed fairly easily in the capsule because of the fragility of the zonule. Minor subluxations do not alter the prognosis. Complete luxation into the anterior chamber or into the fluid vitreous complicates the condition. When fluid vitreous is recognized, the cataract should be removed before hypermaturity makes probable the development of complete luxation. One should not be deceived in the interpretation of signs of degeneration or inflammation and give a good prognosis when other serious complications are present.

The disaster of the loss of viscid vitreous. Nothing that is said in this paper should be taken to minify the bad effects of the loss of normal viscid vitreous in cataract surgery. Eyes in which normal viscid vitreous is extruded may be lost through infection, uveitis, through faulty healing, or by detachment of the retina. More such eyes are lost when the

hyaloid ruptures inside the eye than when the hyaloid remains intact but incarcerated in the healed incision. Disaster usually attends the rupture of the hyaloid and extrusion of viscid gel vitreous into the anterior chamber or actual loss and incarceration of the fibrillae. The methods of prevention or of successfully dealing with this complication when it is imminent or when it has actually happened have not been developed. This is one of the real problems of the future in cataract surgery.

The removal of cataract in the presence of fluid vitreous

The recognition of fluid vitreous before operation, whether apparently well contained behind the hyaloid capsulozonular barrier or in communication with the anterior chamber, need not deter the surgeon from removing the cataract whether it be completely luxated, partially subluxated, or with the lens in proper position. I have several private communications from surgeons who abandoned the operation after the section had been completed and fluid vitreous found. It is technically possible to remove such lenses best in their capsules without undue trauma and to have good visual results, provided the functional tests of the eyes are good before the operation and there are no other insurmountable local or general complications.

1. The removal of cataract luxated into the anterior chamber in the presence of fluid vitreous. If the cataract is found in the anterior chamber, preplaced sutures and a small limbus incision enlarged by scissors, avoiding injury to the lens capsule, may allow the lens to escape. If not, a loop or forceps may be used to remove it. If the cataract has been in the anterior chamber for some time and adhesions have formed with development of increased intraocular pressure, the problem is greater and more unsatisfactory in its solution.

2. The removal of cataract completely luxated into fluid vitreous. In the presence of fluid vitreous a completely luxated cataract may be found floating about with the motion of the eye, settling down when the eye is quiet, and tending to become adherent to the retina or ciliary body. A cataract completely luxated into the vitreous may or may not be readily detected and localized. Ophthalmoscopy and direct observation with the aid of the Hildreth or Hague ultraviolet lamps, which with a filter utilize the natural fluorescence of the lens tissue for its visual demonstration, may help. If the cataract is adherent to the ciliary body, it may not be visible.

Luxated lenses are said to float up and forward directly after the incision has been made, thus obviating any necessity of fishing for them, but this behavior only applies to cases in which viscid or gel vitreous is back of the subluxated lens. As soon as the section is made, such viscid vitreous itself moves forward, bringing the lens with it. If the lens is freely movable in fluid vitreous, the effect of having the patient lie prone on the abdomen and with dilatation of the pupil, trying to coax the cataract into the anterior chamber, imprison it there by the use of miotics contracting the pupil, from which it may be more easily removed. By experience, however, it is known that it is difficult to keep the lens in the anterior chamber during the steps preceding the extraction.

If the luxated cataract cannot be gotten into the anterior chamber, I would recommend that the surgeon should not fish around blindly with a spoon or loop for the cataract or lift it off the retina, on which it may have settled. This may be productive of severe reaction and probable loss of the eye. A floating lens may be carefully picked up on a loop and removed.

There are two very ingenious methods which have been described in which success has been achieved in the removal of luxated cataracts from fluid vitreous: (1) the technique reported by Verhoeff,[11] who described how he made the incision, lifted the corneal flap, directed a stream of saline into the fluid

vitreous, causing the loose lens to float up from the retina into a position from which it could be removed and (2) the method of Bracken,[12] who inserted corneoscleral sutures, made the incision, then had the table elevated, the specially robed and draped patient turned over from the supine to the prone position, so that the lens dropped into the anterior chamber from which it was easily removed with a loop. It need not be assumed that all of the fluid vitreous would run out under such conditions. Saline may be used to replace some of the fluid vitreous which escapes after the patient has been returned to the supine position. Then the toilet of the operation may be completed.

3. The removal of subluxated cataract in the presence of fluid vitreous. If it is known beforehand that the lens is partially subluxated and that fluid vitreous is in communication with the anterior chamber, then sutures may be placed before or after the section has been made, a loop passed through the opening in the zonule behind the lens to support it, bringing it forward and removing it if the zonule is very fragile. If the remainder of the zonule displays any resistance, I believe it best not to use traction alone with the loop to remove the cataract, but, having lifted it up into position, to grasp the anterior capsule with forceps and then slip the loop around the zonule to rupture it directly by separating or stripping it from the capsule, thus freeing the lens for nontraumatic delivery.

4. The removal of cataract in the presence of fluid vitreous when the zonule is intact and the lens is in normal position. Preparation for surgery. The usual preoperative preparations of sedatives, cultures, atraumatic cleansing of the field, asepsis, and so forth, are all indicated. Local anesthesia is employed by instillation, and by injection, avoiding retrobulbar injection except in patients who have good blood vessels. Intravenous anesthesia in the hands of some, and with selected patients, may have very desirable features, but it is not without complications and dangers. Complete akinesia is desirable and if the patient is not confident and relaxed, various delays or changes with the addition of more sedatives may be resorted to until he is quiet.

Incision. A speculum, such as the Lancaster smooth, solid blade properly supported by an assistant, is preferred to lid sutures or metal retractors. Lateral canthotomy is done if there is any lid pressure upon the globe. Fixation is taken lightly on the medial rectus tendon. A narrow point of fixation is preferred to a broad one. The conjunctiva may be severed from the upper limbus by peritomy so that there will be no flap to interfere with the manipulations of extraction or the firm closure of the corneoscleral incision. A beveled corneoscleral section with a narrow conjunctival flap is made with the Graefe knife from about one quarter to one third of the circumference of the limbus. It is enlarged with the scissors on each side to two fifths, usually to one half, of the limbus circumference according to the size of the cataract, care being taken not to buckle the tissues or to cause pressure during any maneuver.

Sutures. If preplaced sutures are indicated, I prefer the Suarez de Mendoza[13] or the McLean[14] type. I have found by experience that corneoscleral sutures may be efficiently placed after the section, except in cases of presentation, prolapse, or loss of viscid vitreous. As previously described, three accurately placed radial appositional atraumatic 5-0 black silk sutures are inserted with a small, sharp-cutting 3/8 curve needle, using a standard Kalt needle holder and special forceps designed for the purpose. The central of the three sutures is at first passed through only the outer half of the corneal edge and is used for traction and direct exposure of the iris and lens. It is completed and passed through the outer half of the scleral edge after the extraction of the lens. The ease of insertion of such sutures with proper instruments, the airtight or watertight quality of the anterior chamber

produced by the proper apposition of incision edges after such suturing, the retention of saline or air which may be injected into the anterior chamber after the extraction have made the use of radial appositional sutures valuable in the presence of fluid vitreous. The loose conjunctiva is sutured separately after the corneoscleral sutures have been tied.

Intraocular pressure after corneoscleral section. Immediately after the corneoscleral section has been made in the average eye for the removal of cataract, the intraocular pressure drops to that of the surrounding atmosphere, unless there is present increased intravitreous, uveal, or retrobulbar pressure. The eye retains its contour, particularly if the sclera and cornea have their normal tissue resiliency, elasticity, and structure. The surgeon may feel assured if he notes a little dimpling or falling in of the cornea, denoting the fact that the cataract, vitreous, and uvea are remaining in their normal positions and that the eye will behave well under the manipulations of cataract extraction.

When, however, after the corneoscleral section, the aqueous has escaped and fluid vitreous seeps out and continues to flow away in a thin stream, and the globe appears to collapse somewhat, the lens and iris falling to a deep posterior position, then the surgeon may well show concern because of the evident hypotony and difficulty of extraction of the cataract, particularly in a case in which the condition was not diagnosed before operation. Such a state is not the dreaded complication of the lens becoming completely luxated and falling deep or out of sight into the vitreous, but it may be possible for this to occur through injudicious handling of the case, as, for example, by an attempted loop extraction, passing the instrument through a portion of the zonule which is intact. Certainly pressure upon the exterior of the globe for intra- or extracapsular extraction in this predicament is inadvisable, inefficient, and contraindicated for removal of the cataract because of the evident hypotony, the impossibility of rupturing the zonule by pressure, or of expressing the lens nucleus if the capsule has been opened, and the evident escape of more fluid vitreous with each pressure manipulation.

The handling of the iris. The criteria used previously for the handling of the iris apply to cases of cataract with fluid vitreous. If the pupil will dilate to but 4 mm., a complete iridectomy is necessary. If it will dilate to 5 mm., a small cataract may be removed through the round pupil. If to 6 mm., the removal of any size cataract through the round pupil is feasible. Peripheral iridotomies, two in number and placed between the central and lateral sutures, are desirable.

The experience of distortion of the pupil, drawing up of the iris and ciliary body by a mass of viscid vitreous or by strands of semiviscid vitreous does not apply to cases of fluid vitreous. The pupil and iris may be as free and perfect as after an uncomplicated case in which the hyaloid remained intact and in normal position.

The removal of cataract in the presence of fluid vitreous. A redescription of the maneuvers used in my system of intracapsular cataract surgery[15] seems desirable in this paper. If the fluid vitreous is well contained behind an intact hyaloid, all of the procedures may well be applied although one should be cautious of the use of any pressure on the globe. The condition of the eye in which fluid vitreous has seeped away immediately after the section makes it evident that pressure should not be used even for a preliminary test of conditions. The tension is very low and the resistance found in the average case with intact vitreous and hyaloid is not present. The iris and the lens or cataract fall well back into the eye. The lifting or elevation of the corneal flap permits the surgeon to assay the conditions present. My experience has shown that I may reach in with a suitable intracapsular forceps, place it ever so lightly on the capsule, close the forceps to the stop which prevents too firm a closing, get a proper grasp of a sufficient

portion of the capsule, preferably just anterior to the superior equator of the lens, and lift the lens to the level of the open incision where I can manipulate it. I need not fear loss of viscid vitreous for there may be none or, if there is any, it may be well back in the posterior portion of the eye. I can calmly make traction to one side, putting the zonule under tension, and, with a blunt instrument such as the loop or the elbow of the lens expressor hook, separate or strip off a small area of zonule to start the process of direct rupture of the zonule. Further rotation may tear the hole in the zonule larger, or I may use the blunt instrument more to separate the zonule farther. When more than 120 degrees of zonule have been removed, the balance may be torn circumferentially by rotation first to one side, then to the other, and the lens wheeled out to one side or the other. If need be, the grasp of the forceps may be released and reapplied or a second pair of forceps may be applied to provide further rotation.

If subluxation of the lens is present before the incision is made or if it develops because of manipulations in such an eye in which the vitreous is fluid and the zonule fragile, then it may not be safe or feasible to place the forceps on the lens capsule. I have in such cases placed a wire loop behind the lens, introducing it advisedly through the area in which the zonule is already missing or ruptured rather than going through the typical textbook manipulations of the introduction of the loop from above, endangering, in a case in which the upper portion of the zonule is the only intact part, complete luxation and a more difficult task of removal of the lens. When once the loop has been placed behind the lens, it may easily be removed by direct traction with the loop if the zonule is fragile, but if not, the loop should be used first to bring the lens forward and support it, while the corneal flap is elevated and forceps applied to the lens capsule. Then, with the forceps holding the lens, the loop may be used for direct rupture of the zonule by separating or stripping it from the capsule to provide easy delivery.

I would not advise the use of a barbed vectis for direct traction under any conditions. The experience of some in using a flat or shallow concave spoon as a sliding plane, holding it still while pressure through the cornea causes the lens to slide up and out, has met with success except when the zonule is resistant. The use of the suction cup or erisophake does not seem advisable if there would result aspiration of the intervening fluid vitreous before the lens capsule is engaged.

Direct rupture of the zonule by separating or stripping it from the capsule has been previously reported as a feasible, desirable, efficient, and conservative procedure in cases in which the zonule has proved to be more elastic, resilient, and resistant than that found in the average cataract case, and in which an average or safe amount of pressure, traction, and rotation has failed to deliver the cataract. The further application of these principles and maneuvers to cases of cataract in the presence of fluid vitreous was a natural one. It was definitely indicated because of the inadvisability of using pressure, the futility, faulty judgment, inefficiency, and even hazard of pressure or traction alone if they be applied in such a case. Experience with its application in these complicated cases has been gratifying.

Toilet of the incision and completion of the operation. If the iris is not caught between the edges of the incision, the iris repositor need not be used. The lateral sutures are tied with three square reversed loops. Then the central suture is completed and tied.

Transplantation or replacement of vitreous. It has not seemed nor been found necessary to replace the fluid vitreous, which has escaped, by transplantation of vitreous or replacement with fluid other than normal saline, which was used in relatively few of the cases.

A suture is placed between the skin of the

upper and lower eyelids to splint them and to be sure that the eye is kept closed. Physostigmine sulfate (½ to 1 percent) in aqueous solution is instilled. A single or double eye dressing and mask is applied, according to the behavior and coöperation of the patient. Atropine-sulfate solution is used at the first and subsequent dressings as indicated.

The vitreous after intracapsular cataract extraction. After removal of a cataract in the capsule in the otherwise normal case with gel vitreous, the latter may be seen delimited from the aqueous by the hyaloid. It may be on a plane posterior to the iris, protruding slightly through the pupil or prolapsed into the anterior chamber.

The prolapse and loss or incarceration of normal gel vitreous will usually result in an updrawn pupil, even more so when an iridectomy has not been performed, and the incarceration of the hyaloid and of the vitreous fibrillae in the healed incision. The complications attendant upon such an event have been described.

In cases of semiviscid vitreous, there may be found isolated strings of vitreous substance, one or more of which may become incarcerated. After removal of cataract from cases of fluid vitreous, there may be no gel vitreous to be seen, only fluid similar in all respects to that of the anterior chamber.

In addition to the cases in which there are manifest evidences of dehiscences in the hyaloid and zonule before the section is made, there are those of known fluid vitreous often in high myopia in which during and after the procedure of extraction the hyaloid has not been ruptured and has remained intact, still containing the fluid vitreous.

Opinions concerning the handling of such cases vary much. Some say that preliminary iridectomy and capsulotomy and removal of the lens nucleus and cortex by expression are indicated. One illustrative case of recurrence of secondary membranes (Case 4, L. B. in Series 1) after extracapsular extraction is given to illustrate one of the complications. Discission of such membranes as found necessary in many cases of extracapsular extraction produces the communication between the fluid vitreous and the anterior chamber which it was the purpose of the procedure to avoid. My experience has shown that such eyes react well to intracapsular extraction with emphasis on traction and rotation for the delivery rather than pressure in the eye that usually has low tension. If the cataract does not come away easily with traction and rotation then direct rupture by separation or stripping of the exposed zonule has served a very useful purpose.

Case reports

Series 1

Case 1. C. E. A., a white woman, aged 68 years, was an artist. She had been myopic since the age of nine years. Vision was: O.D., with a −17D. sph. = 1/6; O.S., with a −21D. sph. = 1/10. The cataracts were corticonuclear. The vitreous was fluid with opacities. The fundi showed large areas of myopic degeneration and posterior staphyloma, particularly in the left eye. Intraocular pressure measured: O.U., 16 mm. Hg (Schiøtz). On January 10, 1944, an intracapsular extraction with iridectomy was performed on the left eye without any presentation of vitreous. On April 27, 1944, vision was: O.S., +4.25D. sph. ⊂ +1.50D. cyl. ax. 155° = 4/6. The same operation was performed on the right eye on November 14, 1944. On January 23, 1945, vision was: O.D., +3.75D. sph. ⊂ +1.25D. cyl. ax. 25° = 3/6; O.S., +4D. sph. ⊂ +1.25D. cyl. ax. 170° = 4/6. One year later, a macular, retinal hemorrhage developed in the right eye which reduced the central vision to 2/6.

Case 2. C. H., a white woman, aged 70 years, was a nurse. She had been myopic in her right eye and worn glasses since the age of 34 years. On October 16, 1944, vision was: O.D., −6D. sph. = 4/6; O.S., −4D. sph. = 3/100. A partial cataract was present in the right eye. The fundus of the left eye could not be visualized and there was a partially complete cataract. An intracapsular extraction through a round pupil was performed on the left eye. On December 28, 1944, vision was: O.S., +12.5D. sph. ⊂ +3D. cyl. ax. 30° = 4/6. There was further development of the lens opacity in the right eye, and the same operation was performed on this eye on March 12, 1945. On April 12, 1945, vision was: O.D., +8.5D. sph. ⊂ +2D. cyl. ax. = 3/6. On May 21, 1945, vision was: O.D., +7.5D. sph. ⊂ +2D. cyl. ax. 140° = 3/6; O.S., +12D. sph. ⊂ +2.50D. cyl. ax. 32° = 4/6.

Case 3. C. H., an actor, aged 66 years, had, on September 28, 1942, lost the sight of his left eye through inflammation, detached retina, and glau-

TABLE 1

SUMMARY OF REPORT OF CASES OF FLUID VITREOUS WITHOUT ESCAPE AT TIME OF SURGERY FOR REMOVAL OF CATARACT*

Case	Name	Age	Tension	Refraction Before Operation	Eye	Refraction After Operation	Vision	Pupil
1.	C. E. A.	68	16	−17.00	O.D.	+3.75 +1.25 ax. 25	2/6	Coloboma

* Twelve cases reported, 20 eyes operated upon. Ages 45 to 70 years. Tension from 7 to 18 mm. Hg Schiøtz. Nearly all myopic Postoperative acceptance in proportion to previous axial and lenticular myopia. Vision obtained from 1/10 to 7/6. Three patients had 1/10, 1 had 1/6, 2 had 2/6, 3 had 3/6, 7 had 4/6, 1 had 5/6, and 1 had 6/6. One developed anterior synechia and glaucoma and glaucoma controlled by miotics. Most of the cases had areas of degeneration of choroid and retina. In no instance did detachment of the retina develop.

coma. There was no light perception. Vision in the right eye was: −4.5D. sph. ⊂ −2.5D. cyl. ax. 20° = 1/6. Tension of the right eye measured 18 mm. Hg (Schiøtz). On November 10, 1942, an intracapsular extraction with peripheral iridotomy was performed on the right eye without any presentation of vitreous. During convalescence, due to the strain of vomiting, peripheral anterior synechia developed superior nasally over one sixth of the angle circumference. On December 11, 1942, vision was: O.D., +10D. sph. ⊂ +0.5D. cyl. ax. 95° = 4/6. On December 12, 1942, there was a transient attack of glaucoma with tension measuring 50 mm. Hg (Schiøtz). The attack subsided under treatment with pilocarpine and mecholyl. On December 19, 1942, vision was: O.D., +8D. sph. ⊂ +1.5D. cyl. ax. 100° = 6/6. Tension was normal. Vision was the same on November 20, 1946.

Case 4. L. B., a white woman, aged 70 years, was an artist. Vision was: O.D., −16D. sph. = 2/100; O.S., −21D. sph. = 1/8. Intraocular pressure was: O.U., 12 mm. Hg (Schiøtz). On May 22, 1935, a capsulotomy extraction with iridectomy was performed on the right eye. On November 13, 1935, vision was O.D., +1.0D. sph. ⊂ +4D. cyl. ax. 20° = 1/10. Discission of after-cataract of the right eye was done on November 26, 1935. A capsulotomy extraction with iridectomy was performed on the left eye on December 2, 1935. On March 13, 1936, vision was: O.D., −1.5D. sph. ⊂ +3.5D. cyl. ax. 20° = 3/6. On January 2, 1938, vision was: O.D., with the same acceptance, 1/6; O.S., with the same acceptance, 5/100. Discission was performed on both eyes and, on June 2, 1944, was repeated because of reformation of after-cataract. With the same acceptance, vision in each eye was 4/6. Semifluid vitreous with opacities could be seen through the discission openings.

Case 5. A. L. B., a white man, aged 57 years, a broker, was first seen on October 19, 1944. He had had uveitis in both eyes for years. This condition had been treated with old tuberculin by the oculist who referred him for surgery. Vision in the right eye was hand movements with good light projection and perception of colored light. Vision in the left eye was 1/6 with a +1.5D. sph. ⊂ −3.5D. cyl. ax. 155°. There was a corticonuclear cataract in the right eye, and a partial cataract in the left eye. Intraocular pressure was: R.E., 20 mm. Hg (Schiøtz); L.E., 16 mm. Hg. An intracapsular extraction with peripheral iridectomy and no escape of vitreous was performed on November 20, 1944. On December 21, 1945, vision in the right eye was 1/6 with a +10D. sph. and there were many large opacities in the fluid vitreous. On March 15, 1945, vision in the right eye was 3/6, with a +10.5D. sph. ⊂ +0.75D. cyl. ax. 135°. On June 27, 1945, the vitreous of the right eye was quite clear, and vision with the same acceptance was 3/6+. The vision of the left eye has become quite poor through further development of lens opacities. Intraocular pressure was: O.D., 16 mm. Hg (Schiøtz); O.S., 18 mm. Hg. Late in 1946, vision in the right eye had improved to 5/6, and the same operative procedure was used for the left eye with equally promising results.

Case 6. G. B., a white woman, aged 64 years, was a housewife. When she was first seen on June

12, 1937, she stated that she had always been myopic. Vision was: O.D., —10D. sph. = 1/6; O.S., —10D. sph. = 3/6. Interior fluid vitreous was present, and there was a myopic fundus. An intracapsular extraction with peripheral iridotomy was performed on the right eye on September 14, 1937. On October 5, 1937, vision was: O.D., +3D. sph. ⊂ +2.5D. cyl. ax. 150° = 2/6; and on October 29, 1937, vision in this same eye was 4/6— with a +2.75D. sph. ⊂ +2.75D. cyl. ax. 175°. Vision in the left eye, with acceptance, was 1/6. On November 8, 1937, the same operation was performed on the left eye. On December 16, 1937, vision was: O.D., +2.5D. sph. ⊂ +2.75D. cyl. ax. 175° = 4/6; O.S., +4D. sph. ⊂ +2.5D. cyl. ax. 150° = 4/6.

Case 7. G. L. H., a white woman, aged 45 years, was a secretary who had always been myopic. When first seen on February 3, 1947, there were old, interstitial corneal opacities; cause not determined. There were partial lens opacities in each eye. Vision was: O.D., —14D. sph. ⊂ —5D. cyl. ax. 165° = 1/6; O.S., —13D. sph. ⊂ —4D. cyl. ax. 165° = 2/6. Semifluid vitreous was present. The fundi could not be visualized well, but no areas of degeneration were seen. The fundi were seen with a —24D. sph. Intraocular pressure was: O.U., 12 mm. Hg (Schiøtz). An intracapsular extraction with peripheral iridotomy was performed on the left eye on March 8, 1937. The same operation was performed on the right eye on June 14, 1937. On December 1, 1937, vision was: O.D., —1.0D. cyl. ax. 135° = 1/6+; O.S., —1.5D. cyl. ax. 180° = 1/6. By February 5, 1938, vision was much better. The patient can now see to read and work. On June 13, 1940, vision was: O.D., —1.0D. cyl. ax. 135° = 2/6+; O.S., +1.5D. sph. ⊂ +2.5D. cyl. ax. 180° = 4/6.

Case 8. C. F., a white woman, aged 60 years, a housewife, was first seen on March 6, 1935. She had always been myopic. At this time vision was: O.D., —25D. sph. ⊂ —0.5D. cyl. ax. 180° = 1/6; O.S., —19D. sph. ⊂ —1.0D. cyl. ax. 105° = 1/6. Fluid vitreous with large opacities was present in both eyes. There were partial nuclear cataracts, marked chorioretinopathy, and myopic degeneration. Intraocular pressure was: O.U., 7 mm. Hg (Schiøtz). On May 13, 1937, more lens opacities were seen, particularly in the right eye. At this time, vision was: O.D., —28D. sph. = 1/6—; O.S., —20D. sph. = 1/6. By February 2, 1938, there were more nuclear opacities in both eyes. Intracapsular extraction with complete iridectomy was performed on the right. There was one secondary hemorrhage in the anterior chamber and in the vitreous. On March 5, 1938, vision was: O.D., —3D. sph. ⊂ +4D. cyl. ax. 150° = 1/6. On March 10, 1939, vision was: O.D., —2.25D. sph. ⊂ +3.5D. cyl. ax. 155° = 3/6; O.S., —20D. sph. = H. M. On April 5, 1939, an intracapsular extraction with iridectomy was performed on the left eye, with no vitreous loss. On May 29, 1939, vision in the left eye was 1/6 with a +0.5D. sph. ⊂ —3.5D. cyl. ax. 45°. On December 21, 1941, vision was: O.D., —2.25D. sph. ⊂ +3.25D. cyl. ax. 160° = 3/6; O.S., +0.5D. sph. ⊂ —4D. cyl. ax. 55° = 1/6.

Case 9. Mrs. G. B., a white housewife, aged 71 years, was first seen on August 5, 1943. She had always been myopic. Vision at that time was: O.D., —18D. sph. = 1/100; O.S., —20D. sph. = 5/100. A nuclear cataract was present in each eye, as were fluid vitreous with opacities and myopic chorioretinopathy. Intraocular pressure was: O.U., 10 mm. Hg (Schiøtz). Central scotomas were present in both eyes. An intracapsular extraction with iridectomy was performed on the right eye on September 14, 1943. On October 22, 1943, vision was: O.D., —1.0D. sph. ⊂ —1.0D. cyl. ax. 90° = 1/10+. On January 10, 1944, the capsule ruptured during an attempted intracapsular extraction with iridectomy of the left eye. Operation was followed by uveitis and after-cataract, and there was a slow convalescence. On March 27, 1944, the membrane and capsule were removed with a Tyrell hook through a linear section in the left eye. By June 10, 1944, vision was: O.D., —0.5D. sph. ⊂ —1.5D. cyl. ax. = 1/6; O.S., —2D. sph. ⊂ —1.5D. cyl. ax. 100° = 1/20. On September 10, 1945, vision was: O.D., —1.0D. sph. ⊂ —2.0D. cyl. ax. 95° = 1/10; O.S., —1.5D. sph. ⊂ +3.5D. cyl. ax. 25° = 1/10.

Case 10. B. C., a white mechanic, aged 53 years, was first seen on February 26, 1940. He had always been myopic. Vision at this time was: O.D., —13.5D. sph. ⊂ —7D. cyl. ax. 175° = 1/10; O.S., —8.5D. sph. ⊂ —4.5D. cyl. ax. 165° = 3/6. The interior of the right eye showed a dense nuclear cataract. There was a partial cataract in the left eye. Fluid vitreous with opacities and myopic fundi were also present. The intraocular pressure was: O.U., 18 mm. Hg (Schiøtz). On January 5, 1942, an intracapsular extraction with peripheral iridotomy was performed on the right eye. Vision on January 27, 1942, in the right eye was 3/6— with a +1.0D. sph. ⊂ +3D. cyl. ax. 95°. On August 12, 1943, vision was: O.D., +2.25D. sph. ⊂ +1.25D. cyl. ax. 110° = 4/6; O.S., +2D. sph. ⊂ —4.5D. cyl. ax. 155° = 2/6—. The left eye has not been operated on since the patient is satisfied with the use of the right eye.

Case 11. M. F., a white woman, aged 66 years, had been nearsighted for years. Vision was: O.D., —19D. sph. ⊂ —1.0D. cyl. ax. 180° = 6/100; O.S., —20D. sph. ⊂ —1.5D. cyl. ax. 165° = 6/100. Intraocular pressure was: O.U., 14 mm. Hg (Schiøtz). There were vitreous opacities, the vitreous was fluid, and posterior staphylomas were present. An intracapsular extraction with no escape of vitreous was performed on the right eye on December 10, 1946. Vision was 20/40 in the right eye on March 28, 1947, with a +3.5D. sph. ⊂ +3.25D. cyl. ax. 15°. The left cataract was removed by the same operative procedure in May, 1947.

Case 12. A. F., a white woman, aged 65 years, had always been nearsighted, but now there had been a constant fog before the left eye of 3 to 4 years' duration. The right eye had been blind for

some years due to an old uveitis with degeneration. Tension in the left eye was low, 8 mm. Hg (Schiøtz). The central light and color perception was faulty. Vision was less than 1/100. Projection was good. There was a dense, brownish nuclear opacity in the lens. The vitreous was evidently fluid, for very high myopia and a degenerated uvea were present. Intracapsular extraction with complete iridectomy were performed with no escape of vitreous and with the hyaloid remaining intact. Two months after the extraction, vision was 10/100 with a —4D. sph. The intraocular pressure was still 8 mm. Hg (Schiøtz). There was no detachment nor other untoward development. The patient was pleased with the improvement in her vision.

Case reports

Series 2

Report of surgery of cases of cataract and fluid vitreous and dehiscence of hyaloid capsulozonular-barrier with escape of fluid vitreous at the time of extraction of the cataract.

Case 1. W. B., was a white man, aged 39 years. The vision of the right eye had never been good, while that of the left eye had become poor within the past year. Physical condition showed a typical case of Marfan's syndrome of arachnodactyly with bilateral subluxation of the lenses and recently developed anterior and posterior subcapsular cataracts and recognizable fluid vitreous. Vision was: R.E., 1/100, with a —2D. sph.; L.E., 3/100, with a —10D. sph. ⊂ —2D. cyl. ax. 10°. Intraocular pressure was: O.U., 16 mm. Hg (Schiøtz). On December 19, 1945, an intracapsular extraction with use of forceps and loop was done on the right eye, and on January 3, 1946, the same operation was done on the left eye. Resulting vision was: R.E., +8D. sph. ⊂ +1.0D. cyl. ax. 90° = 2/6; L.E., +9D. sph. ⊂ +1.0D. cyl. ax. 90° = 6/6. The left eye was used alone as it had been previous to the operations. Exotropia of 40 degrees of arc continued.

Case 2. E. C., a white woman, aged 41 years, was first seen on August 6, 1942. She had always been nearsighted, but within the past two years her vision had become so poor that she could hardly get about by herself. History was negative except for a rather severe chronic purulent pansinusitis which every general and local effort had failed to cure. Physical examination showed a well nourished woman of middle age.

Vision was: R.E., 1/16 with a —7D. sph. ⊂ —1.0D. cyl. ax. 180°; L.E., 1/12 with a —12.D. sph. ⊂ —1.0D. cyl. ax. 180°. Corticonuclear cataracts were more dense in left eye. The color perception and peripheral fields for light and form were normal. The pupils measured 3.5 mm., reacting 1 mm. They dilated well with homatropine and paredrine to 8 mm. Tension was 18 mm. Hg (Schiøtz), O.U. Examination with slitlamp microscope was essentially negative. There were no deposits on the endothelium of the cornea except some old fine pigment dots; no floaters; no iridodonesis. Iris structure was normal. There was no heterochromia. Operations: O.S., intracapsular extraction with peripheral iridotomy on November 13, 1942; O.D., May 11, 1943. Then lens capsule was ruptured with the wire loop which was being used to strip off the zonule. Not all of the adherent cortex was removed. It was thought that a great part of the inflammation which developed in the right eye in the postoperative course was due to the toxic effect of the degenerated lens protein. In January, 1945, two months after the extraction, vision in the left eye was 6/6 — 1 with a +6.25D. sph. ⊂ +1.5D. cyl. ax. 53°. In January, 1944, six months after operation, vision in the right eye was 3/6; while one year after the surgery, vision in the right eye was 4/6 with a +8.5D. sph. ⊂ +2D. cyl. ax. 90°. In 1947, she had 6/6 vision in each eye with binocular single vision and stereopsis. The right iris was slightly atrophic, and there were some posterior synechias to a portion of the anterior lens capsule. The left iris appeared normal. The vitreous became quite clear in each eye.

Case 3. A. A., was a white man, aged 44 years, whose left eye had always been weak. For the past six years the vision of each eye had been practically useless. Vision was: R.E., 1/6 not improved by glasses but with good color perception and form field. The left eye had light perception, good light projection, and color perception. An operation on the left eye on March 20, 1945 combined an intracapsular extraction with peripheral iridotomy. The same was done on the right eye, September 11, 1945. The left eye had 6/12 vision in three months, with a +8.25D. sph. ⊂ +1.5D. cyl. ax. 15°. The right eye had 6/12 vision in two months with a +8D. sph. ⊂ +2D. cyl. ax. 175.° The irides appeared normal and in good plane, with no synechia apparent; the fluid vitreous was clear with no opacities.

About fifteen months after the extraction from the left eye and nine months after the extraction from the right eye, the ophthalmologist who had referred him to me and who had been very pleased with the result found that the intraocular pressure was elevated to nearly 60 mm. Hg (Schiøtz). There was very little redness and the vision with correction was reduced to 20/70 in the right eye, and 20/200 in the left eye. My associate in my absence found that medication failed to reduce the tension and performed a cyclodialysis with iridectomy in each eye. The tension in two months was: O.D., 22 mm. Hg, and O.S., 24 mm. Hg. Di-isopropyl-fluoro-phosphate (0.1 percent) was used later when the tension was found nearer 30 mm. Hg, with not very satisfactory results as far as normalizing of the tension was concerned. This has remained about 25 to 28 mm. Hg (Schiøtz), but the vision of the right eye with correction has been 3/6, and that of the left eye 2/6.

Case 4. A. E., a white man, aged 55 years, was first seen on April 30, 1945. His right eye had been normal, while his left eye had had an ulcer of the

cornea following a foreign body 18 years ago. Five years ago, while pounding on pipe, a piece of iron had injured but had not entered the left eye. X-ray films showed no intraocular foreign body. Recently the vision of the left eye had been very poor. Seven months ago he was told that he had a hemorrhage in the eye. He had been disturbed by large clouds before the left eye. The left eye was not congested. The cornea was clear except for minute pigment deposits on the endothelium. The aqueous was clear. There were no floaters; iris was normal; there was a small sized dense brownish cataract. Pupils were equal and both reacted to direct light. Vision was: L.E., good projection, with good light projection and perception of colored lights, R.E., 6/6 with a −0.25D. sph. ⊂ −0.37D. cyl. ax. 70°. Tension was 16 mm. Hg (Schiøtz) in each eye. Intracapsular extraction with peripheral iridotomy was performed on the left eye. The first test of vision was three months after the operation when it was: O.S., +8.5D. sph. ⊂ +3D. cyl. ax. 60°, 4/6+. The plane of the iris was normal. The aqueous was clear. The vitreous opacities were well posterior. The anterior vitreous was clear.

Case 5. L. B., a white man, aged 64 years, had always been quite myopic. Recently vision even with best correction was very poor. Vision was: R.E., 1/16 with a −20D. sph., L.E., 1/100 with a −14D. sph. Pupils were equal and reacted well to light. His general condition was excellent. Corticonuclear cataracts were denser in right eye. There was fluid vitreous with many fine and course floating opacities. Tension was 20 mm. Hg (Schiøtz) in each eye. An operation was done on the right eye, November 14, 1944. The seeping away of fluid vitreous continued until the lens was out, then viscid vitreous presented in the superior temporal portion of the incision. None was lost but the vitreous became incarcerated in the lips of the incision and upon healing the pupil was drawn up and displaced in this area. The vision of the right eye with a +1.0D. sph. ⊂ +2D. cyl. ax. 45° was 2/6 one month after operation. Because of the behavior of the right eye at the time of surgery it was decided to do an inferotemporal, posterior, scleral drainage of the left eye immediately before the extraction of the cataract from the left eye. On March 2, 1945, an operation on left eye was planned as above. Viscid vitreous was found in the posterior scleral drainage area. Fluid vitreous seeped away anteriorly after the incision and during the delivery of the cataract, but no viscid vitreous was lost or incarcerated. In two months the vision of the left eye was 1/5 with a −2.5D. cyl. ax. 175°. The final vision in each eye was very satisfactory. One year after operation vision was: R.E., 4/6 with a +0.75D. cyl. ax. 10°; L.E., 5/6, with a +2.25D. cyl. ax. 180°. The after history of the left eye is very interesting. On May 9, 1947, over two years after the extraction, the patient came to me complaining of loss of vision in his left eye. He had been performing extremely arduous labor, lifting heavy cases and helping to move machinery of great weight. Detachment of the retina was found. This was the only case in which this condition developed. The factor of the creation of an opening in the retina through which an attempt was made to drain the vitreous may well have been the cause. Surgery for reattachment of the retina is to be done. Certainly patients who have had a successful result after cataract surgery should be warned, as was this one, of the bad effects of undue strain upon an aphakic eye.

Case 6. W. J. W., a white man, aged 49 years, was first seen September 28, 1945. He was a clerical worker who had always been myopic. Vision was: O.D., −5.5D. sph. ⊂ −3D. cyl. ax. 10° = 1/12; O.S., −6D. sph. ⊂ −3D. cyl. ax. 180° = 2/6. On November 20, 1945, an intracapsular extraction with peripheral iridotomy was done on the right eye. No gel vitreous was seen. On December 10, 1945, vision was: O.D., +4D. sph. ⊂ +1.75D. cyl. ax. 100° = 4/6; December 21, 1945, O.D. +4D. sph. +2D. cyl. ax. 105° = 6/6.

Case 7. L. B., aged 60 years, rapidly developed cataract in the right eye. The left eye had been blind for 10 years from endophthalmitis, detached retina, secluded pupil, hypotony, cause unknown. The right eye showed no congestion; dystrophy of the endothelium with deposits of degeneration was present, as were floaters and slightly increased relucency. There was complicated cataract. Tension was 12 mm. Hg (Schiøtz). There was partly fluid vitreous with opacity and a tremulous lens. A few months after the first observation the cataract rapidly became complete; there were more floaters and more relucency of the aqueous. Light projection and color perception was not perfect. Due to the nature of the case, operation was decided upon. After cataract extraction which was easily accomplished and in which fluid vitreous seeped away, the eye appeared to heal well anteriorly but a detachment of the retina, which may well have been present at least in part before the extraction, was evident. The aqueous floaters and relucency were in this case significant of the pathologic condition in the posterior segment. The eye did not respond to later efforts to reattach the retina.

Case 8. E. R., a woman, aged 64 years, had a record of having been refused cataract operation for her better right eye by a number of surgeons because of ophthalmoscopic evidence of arteriosclerotic degenerative chorioretinopathy in the left eye. Her vision was: O.D., 10/200 with a −11D. sph., and O.S., faulty light projection. Tension was 13 and 12 mm. Hg (Schiøtz). Diagnosis of fluid vitreous was made. There were tremulous lenses. It was decided to remove the left lens first to learn the reaction of the eye. It healed well with a round pupil, despite escape of much fluid vitreous. Then the cataract was removed from the right eye with a good result of 6/9 vision with correction.

Case 9. E. McE., a white man, aged 62 years, had good functional tests and no remarkable evidence of degeneration before surgery. Tension was: O.U., 16 mm. Hg (Schiøtz). At the time of opera-

tion on each eye, excess fluid came away, apparently from the area anterior to and around the gel vitreous which presented but did not escape in either eye. Healing and vision after surgery were good. He had worn: O.D., —0.75D. sph. ⊂ —1.75D. cyl. ax. 45° = 1/100; O.S., —2D. sph. ⊂ —0.50D. cyl. ax. 20 = 6/100. The acceptance six months after operation was O.D., +7.5D. sph. ⊂ +3D. cyl. ax. 160° = 5/6; O.S., +7D. sph. ⊂ +2D. cyl. ax. 70° = 5/6. In 1946, he had 6/6 vision in each eye.

Case 10. M. R., aged 52 years, had had intumescent cataract of the left eye operated upon unsuccessfully, with loss of viscid vitreous complicated by iridocylitis (not of the sympathetic type) resulting in loss of the eye. Enucleation had been performed. Upon development of a cataract of the same type in the right eye, six months later, extra precautions were taken, including a preliminary iridectomy at the time of which fluid vitreous flowed away through the keratome incision. Tremulousness of the lens had been a constant feature since then. There were fine deposits on the endothelium (none of the mutton-fat type). The aqueous beam was normal. An occasional floater of varied type was seen. The subsidence of the intumescence for an easier intracapsular extraction was awaited and extraction was performed on May 6, 1947. Direct rupture of the zonule was necessary to effect delivery in the capsule because of the low intraocular pressure.

Comment

It is evident from analysis of these two groups of cases that there are points of difference. In the first group, the fluid vitreous was a complication of high myopia except in two cases, in whom the myopia was moderate, and in one, in whom uveitis caused the complicated condition. The second group are younger with an average age of 48 years. If Case 4, in which trauma was a factor, and Case 5, in which high myopia was present in an older individual, are excluded, the average age was 46 years. The visual results after operation in each group were remarkably good considering the complications.

Summary and Conclusions

Fluidification (synchysis) of the vitreous may complicate the formation of cataract. The degeneration of the vitreous may proceed from the normal viscid gel to a semi-

* 10 cases reported, 16 eyes operated upon. Ages 39 to 64 years. Tension from 8 to 20 mm. Hg (Schiøtz). Refraction from approximately −1.00 to −20D. sph. with cylinders. The average would be that of the lower degrees of myopia. The acceptance after extraction was corresponding. The degree of central vision was good after extraction, considering the type of cases and the complications. After healing, one patient had hand movements, one had 1/100. Both of these cases had known retinal pathology. One other eye had 2/6, 4 had 3/6, 4 had 4/6, 3 had 5/6 and 1 had 6/6. In the case of one patient, secondary glaucoma reduced the vision of one eye from 3/6 to 3/6—1 and of the other to 2/6—1. One eye with fluid vitreous has had only preliminary iridectomy, not having had the extraction of the cataract as yet. One patient evidently had detached retina before the extraction, which seemed indicated because of the complete blindness of the indlvidual. One patient developed detachment of the retina two years after extraction. The factors of excessive strain of heavy lifting and arduous labor may have been at fault, but it is significant that in this case alone was the procedure of posterior drainage of the vitreous resorted to before the extraction.

viscid, semifluid, and fluid state. A portion of the vitreous may remain viscid or semiviscid, surrounded by fluid. The vitreous may be contained behind an intact hyaloid capsulozonular barrier or the latter may also be degenerated and a direct communication exist with the aqueous in the posterior and anterior chambers. The signs for recognition of both of these conditions are described. Particular stress is made of the signs of degeneration of the ocular tissues, hypotony, the type of deposits on the endothelium, the aqueous floaters and relucency, the form of the cataract, the character of the vitreous. The particular lead is to look for signs of degeneration of tissue before surgery for removal of cataract. If they are found, the inference should be drawn that the zonule is fragile and that the vitreous may be fluid. The causes of degeneration and fluidification of the vitreous—faulty nutrition, abiotrophy and senescence, myopia, trauma, inflammation, and detachment of the retina—are discussed in relation to the condition. The literature is cited, particularly in relation to the prognosis, surgical treatment, and results obtained.

The recognition of abnormal fluidity of the vitreous before operation or encountered at the time of surgery is a direct indication, in my experience, for intracapsular extraction. The usual tests of light and color perception and projection should be made and the prognosis based upon them and the objective condition of the eye. Hypotony with intraocular pressure below 8 mm. Hg (Schiøtz) and definitely increased relucency of the aqueous are signs of ill-omen. The cataract should be removed before hypermaturity and complete luxation, because of the attendant fragility of the zonule. The flowing away of the fluid vitreous and the partial collapse of the globe may cause some surgeons to abandon the extraction of the cataract after the section has been made, but in my experience atraumatic intracapsular extraction has given good results. The zonule is uniformly fragile in such cases. Extracapsular extraction is contraindicated in cases of fluid vitreous in communication with the anterior chamber, because of the hypotony which makes useless any maneuver involving pressure and because the eye does not heal as well with retained irritating cortex. If the lens is luxated into the anterior chamber, it can be removed directly. If luxated into fluid vitreous, the maneuvers of coaxing it into the anterior chamber or the methods of Verhoeff or Bracken may be used. If the hyaloid capsulozonular barrier is intact and the vitreous fluid, there is no contraindication to intracapsular extraction, with retention of the intact hyaloid even in cases of high myopia. When there are dehiscences in the barrier, with or without subluxation, intracapsular extraction with traction by forceps and direct rupture of the zonule by separating or stripping it from the capsule with a blunt instrument, such as the elbow of a lens expressor hook, has produced good results. In cases of subluxation, the loop or spoon may be used but it should be passed through an already existing break in the zonule and used to support the lens until the forceps grasp the lens capsule and support it while the loop or spoon is used to separate the zonule from the capsule.

I would not use direct traction with loop or vectis to rupture the zonule nor would I use pressure from without to slide the lens out on a flat spoon, except when the zonule is fragile. The use of the suction cup or erisophake is not indicated in cases of fluid vitreous in communication with the anterior chamber. It may be contraindicated if a direct application of the cup to the capsule is not feasible before the suction is applied. Preplaced sutures are not necessary or even indicated, as shown by experience, in the presence of fluid vitreous. Sufficient time may be taken for a calm, unhurried performance of the surgery, particularly in the toilet of the incision. A complete iridectomy is not necessary in cases of fluid vitreous, as the round pupil may be re-

tained, using two peripheral iridotomies. There need be no drawing up of the iris if there is no incarceration of viscid or semiviscid vitreous. Transplantation of viscid vitreous or replacement with spinal fluid or even with saline is apparently not necessary, although the latter may be used if there has been collapse of the globe. Two cases of detachment of the retina were observed in this series, but the condition in one existed prior to the development of the cataract. In the other, the detachment developed over two years after the extraction. The factors of heavy lifting and the presence of a hole in the retina produced by purposeful drainage of the vitreous prior to the extraction of the cataract from this eye have to be evaluated as the cause of the detachment. One case of bilateral postoperative glaucoma developed. This was only partially controlled by surgery and the use of di-isopropylfluorophosphate (0.1 percent).

A report of 10 case histories with operations on 16 eyes in which fluid vitreous was in communication with the aqueous and of 12 cases with operation on 22 eyes in which the hyaloid was intact is made. The results obtained indicate that in cases of fluidity of the vitreous with cataract in which the degeneration has not progressed too far and in which there is not a preëxisting detachment of the retina or severe hypotony the cataract may be removed by an atraumatic intracapsular technique with gratifying results.

Nothing that is said in this paper on fluid vitreous should be taken to minify the disastrous results of the rupture of the hyaloid and the loss of viscid vitreous.

NOTES, CASES, INSTRUMENTS

AN UNUSUAL CASE OF LEPTOTHRICOSIS CONJUNCTIVAE*

ALFRED KANT, M.D.
Boston, Massachusetts

A 32-year-old white housewife was first seen at the out-patient department of the Massachusetts Eye and Ear Infirmary on December 25, 1946, complaining of itching of the right eye of two weeks' duration and redness of the eye associated with a painful lump in front of the right ear of three days' duration. She had been treated by her own physician for the past five days with ointment and drops without improvement.

Ocular examination revealed vision to be: O.U. 20/30—. The right eye showed slight redness of the lids with moderate swelling of the lower and marked swelling of the upper lid to the extent that the upper fornix could not be prolapsed. There was a scant, stringy mucoid discharge.

There was marked chemosis and swelling of the fornicial conjunctiva. The palpebral conjunctiva was congested and swollen. In the center of the palpebral conjunctiva of the lower lid was a grayish white, semitranslucent, mushroomlike, nonulcerated nodule measuring 3 by 2 mm. with a collarette of smaller daughterlike grayish deeper excrescences.

Several small follicles were seen near the outer canthus of the lower lid. The cornea was clear and did not stain with fluorescein. Findings in the remainder of the eye were negative. The right preauricular node was tender and swollen, measuring 1 by 1 cm. The left eye was entirely negative. Temperature was 99.2°F. A diagnosis of Parinaud's oculoglandular syndrome was made.

Laboratory findings. Conjunctival smears and scrapings were negative. Culture revealed nonhemolytic streptococci. Urine was negative.

Blood was: W.B.C., 8,300—77-percent polymorphs, 14-percent lymphocytes, 9-percent monocytes. R.B.C., 4,200,000; Hgb., 12.2 gm.

X-ray films of chest, teeth, and sinuses were negative.

Agglutination tests for brucella and tularemia were negative. T.B. skin test (1/20,000) was negative. Serology was negative.

Course. Three days after the initial visit, hemorrhage occurred into the nodule and it was removed for biopsy. The sections were reviewed by Dr. F. H. Verhoeff, who found the typical histologic picture and organisms of Leptothrix infection.

The tributary adenopathy became progressively more marked and diffuse. Thirteen days after first being seen at the clinic, the preauricular node measured 2 by 3 cm., and the whole right cervical chain was visibly enlarged and tender. The overlying skin was reddened. No definite fluctuation could be made out at this time, although the surgical consultants were of the opinion that the patient had a definite and marked cervical adenitis.

The blood at the height of the adenitis revealed a leukocytosis of 12,400 with 77-percent polymorphs and no eosinophiles. The adenopathy gradually regressed from below, but the preauricular node remained visibly and painfully enlarged. Approximately six weeks after the first visit, the preauricular node spontaneously discharged some "matter" while at home. The following day 3-cc. thin, greenish purulent material were aspirated from it. This material was bacteriologically sterile. Modified Verhoeff gram staining revealed no filaments or other organisms, and special cultures for Leptothrix were negative after one month's incubation. Guinea-pig inoculations of the aspirated material were negative for tuberculosis. The preauricular gland gradually regressed in size and again spontaneously drained some pus about one month later. Three months after the onset of the dis-

* From the Massachusetts Eye and Ear Infirmary.

the gland was still slightly enlarged and indurated but no longer painful.

The eye signs of redness, chemosis, and edema gradually regressed so that five weeks after the onset of the disease the lids were normal and only slight chemosis and simple conjunctival injection remained. This had cleared completely three weeks later.

During the illness the patient's temperature had ranged from 98.6°F. to 100°F., being highest at the height of the cervical adenopathy. General symptoms—mild lassitude, chilliness, and headache—closely paralleled the temperature variations. With the exception of the ocular and associated findings, physical examination was negative.

Treatment. This was symptomatic and consisted of aspirin, cold compresses to the glands, and zinc and adrenalin eye drops.

Comment

This case of leptothricosis conjunctivae was of particular interest to us for the following reasons:

1. The occurrence of suppuration of the preauricular node, which does not usually occur in this condition, and the spontaneous drainage, which to our knowledge has not been previously reported.

2. The occurrence of hemorrhage into the conjunctival nodule which we have not seen before either in this condition or in tubercle of the conjunctiva.

PARALYSIS OF SUPERIOR RECTUS AND INFERIOR OBLIQUE FROM DIABETES MELLITUS

Henry L. Hilgartner, M.D.
Austin, Texas

Paralysis of the superior rectus and the inferior oblique muscles in one or both eyes is relatively rare. In cases in which ocular paralysis does occur, one immediately thinks of syphilis as the etiologic agent. Until the Wassermann test was developed, all cases of ocular paralysis in the adult were considered syphilitic in origin unless other definite causes could be established.

In 1930, James Collier reported a number of cases of paralysis of the oculomotor nerve-trunks in diabetes, and I wish to report one case in which paralysis of the superior rectus and inferior oblique muscles developed in a diabetic who had syphilis some 15 years previously. In discussing diabetic involvement of the oculomotor nerve trunks, it is well to remember that diabetes also affects the retina and the optic nerve rather frequently.

White reported on the paralysis of the superior rectus and the inferior oblique muscles of the same eye, in 1941. He stated that paralysis of both elevators of one eye, although one of the less common palsies, is not infrequently seen and is generally, if not always, congenital. His discussion dealt with the surgical treatment of these cases, and the patients were all children.

Report of a case

J. H., a Negro man, aged 62 years, was first seen on January 7, 1947, with the complaint that he was unable to open both eyes simultaneously. About December 1, 1945, the patient suddenly noticed that when he opened the right eye, the left upper lid would close, and vice versa. He was able to open both eyes at times, but saw double. There was no pain at any time. His only other complaint was that the stump of his left leg, which had been amputated, was painful.

History. The patient was first seen at the Brackenridge Hospital Clinic in 1931, complaining of a urethral discharge of three weeks' duration. The patient underwent proper gonorrheal treatment and was cured. A Wassermann test made at the time showed a plus-four, positive reaction. He was treated

regularly for syphilis in the Clinic, and the blood and spinal fluid became negative.

In 1935, the patient's left leg had to be amputated above the knee, following an accident. He had had a great deal of trouble with a painful stump, which had been operated on several times.

About 1940, the patient developed a severe diabetes and had been treated in the Brackenridge Hospital Diabetic Clinic since then. Insulin and diet had been more or less effective in keeping the blood sugar near normal levels. Occasionally he would break his regime, and the blood sugar would go up to over 200 mg. per cc.

Eye examination. Vision was: R.E., 20/60; L.E., 20/20. The eyes were normally prominent, and the pupils reacted to light and accommodation. When the patient opened the right eye, the left upper lid closed, and vice versa. By raising the right upper lid manually one noticed that the pupillary levels of the eyes were not the same. On having the patient look in the cardinal directions, the left eye moved normally. The right eye moved normally in the horizontal axis and in the lower-temporal, lower-central, and lower-nasal directions. He was unable to elevate the eye above the midline. Both fundi were essentially normal except for moderate arteriosclerosis.

Laboratory reports. On January 7, 1947, a blood Kahn and Wassermann were run and reported negative.

On January 16, 1947, spinal fluid was examined for syphilis and reported negative. Spinal-fluid sugar was 198 mg. percent. On January 21, 1947, the patient was placed on Mead's brewers yeast tablets, four times daily after meals, in addition to the insulin and diet regime that he had been on.

By March 11, 1947, the patient could open both eyes simultaneously, alone, with no effort. He did this, however, only when requested. The right eye could be elevated slightly above the horizontal line.

Fig. 1 (Hilgartner). (Left). Usual appearance with right eye closed and left eye open. (Right). Appearance when right eye is opened. Left upper lid practically closes, and left eye turns up.

Fig. 2 (Hilgartner). (Left). Forcing both eyes open. Note wrinkling of brow, turning up of left eye, and drooping of left upper lid. (Right). Looking to right in midline. Right eye can be seen moved to the right.

Fig. 3 (Hilgartner). (Left). Left eye elevated up and out. Right eye extended nasally but not above the midline. (Right). Left eye extended up. Right eye not elevated above the midline.

Diagnosis. Paralysis of superior rectus and inferior oblique due to diabetes.

Comment

In conclusion, a case of paralysis of the superior rectus and the inferior oblique muscles of the right eye, due to diabetes, has been reported. Contrary to the statement of Collier that most of these cases improve on regular diabetic treatment, this patient has not improved up to the present time.

202 West 13th Street.

A MODIFIED ERISOPHAKE*

ALAN E. BELL, M.D.
Key West, Florida

A modification of the erisophake is reported, which has the following advantages:

1. It is light, small in size, and easy to handle.
2. The suction is easily controlled.
3. It is simple and inexpensive.

The tip is modeled after those of Dimitry and Castroviejo, and either of these tips

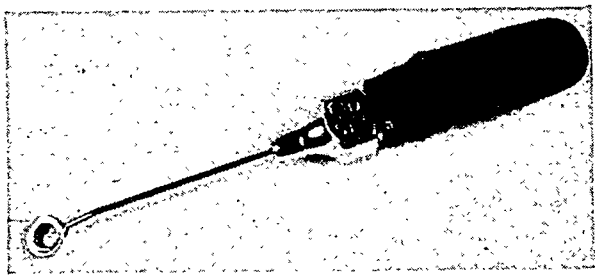

Fig. 1 (Bell). A modified erisophake.

may be used. The suction is provided by a small rubber bulb made from a contact-lens holder by cutting off the flexible lip. The working volume of the bulb (approximately 0.25 cc.) is ample, if the instrument is filled with normal saline solution prior to grasping the lens. The maximum vacuum is 60 to 70 cm. Hg, approximately equal to that provided by the Barraquer and Castroviejo vacuum pumps. The bulb is rugged and inexpensive and will stand many boilings. To sterilize them, the tip and nipple should be disassembled and boiled. If assembled when boiled, the rubber bulb will tend to adhere to the metal tip.

Before the operation, the instrument should be assembled and completely filled with normal saline. This is important, because if any air remains in the instrument, it will prevent the attainment of a high vacuum, and bubbles of air will be introduced into the anterior chamber, obscuring the operator's field of vision. The bulb should be squeezed, expelling as much of the saline as possible, when grasping the lens. This will provide a better grasp on the lens, as well as clear the anterior chamber of any blood or iris pigment and sweep the iris anterior to the erisophake cup.

U. S. Naval Hospital.

A SCREEN FOR PRISM COVER TEST

CHARLES T. MEACHAM, M.D.
Stamford, Connecticut

The screen about to be described was designed primarily for the prism (alternate) cover test, but may also be used to measure the near point of convergence or PcB.

It is 6-cm. wide and 15-cm. long, made of black X-ray film, with rounded corners. Notches on the sides mark it off in centimeters. Each fifth notch is deeper so that the right measurement may be quickly read in any position.

The advantages are many. The screen does not look soiled with handling. The width is just enough to occlude the eye properly, without requiring too much accuracy so that full attention may be devoted to observing ocular movements. The length is convenient not only in manipulation but in giving an even number of 5-cm. (notch) gradations so that measurements can be easily read off from any position or angle without the use of printed numbers or calculation.

Over-exposed X-ray film is plentiful, costs nothing, and is easily and quickly shaped into the above design.

Bradding together two films for increased rigidity, and using numbers or pinholes instead of notches were among the variations tried. None, however, were found so handy or practical as the simple model described.

65 South Street.

A SIMPLE METHOD OF PHOTOMICROGRAPHY*

EDWIN S. WRIGHT, M.D.
Los Angeles, California

At present, photomicrography is usually confined to the larger institutions where costly equipment may be found and special technicians are maintained. Such laboratories frequently use the optical bench to produce the photographs. Good photomicrographs can be taken with relative ease, with a minimum of equipment, and in little time.

Theoretically, all one needs is a microscope and a camera. Light rays emerging from the ocular of the microscope are parallel, if the observer is emmetropic or rendered so by the proper spectacle lens. When the camera focused for infinity is set on top of the microscope the rays of light should focus exactly on the film. In practice, this method is wasteful of time and film since the observer is rarely exactly emmetropic and the slightest error produces a blurred picture. A focusing apparatus that permits a direct view of the slide to be photographed is advantageous.

EQUIPMENT

The Exacta and other reflex cameras permit such a direct view and their use speeds the work. However, these cameras are very expensive and not readily available so that for ordinary use a copy attachment has been chosen as the simplest method. The apparatus chosen has the following advantages:

1. All around usefulness of 35-mm. equipment.
2. Direct-view focus of the slide.
3. Simplicity of lighting system.
4. Relatively inexpensive equipment.
5. All materials are readily available.
6. Photomicrographs in true color are as easy to take as black and white.
7. The same equipment may be used to photograph the anterior segment (fig. 3A).

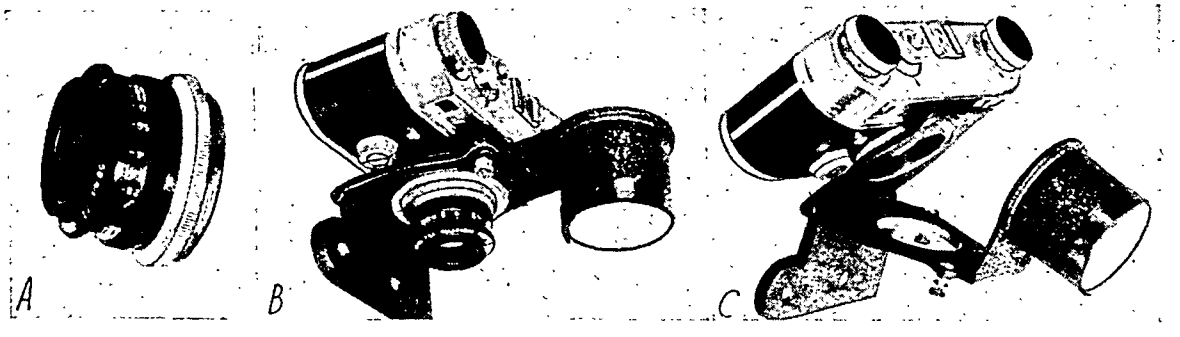

Fig. 1 (Wright). (A) Lens barrel dismounted from camera. (B) Lens mounted in lens plate of copy attachment. (C) Camera back mounted on camera plate of copy attachment.

The necessary items are:

1. A 35-mm. camera with focal plane shutter.
2. Copy attachment, preferably hinged type.
3. Camera support.
4. Connector.
5. Number-one photoflood bulb in any kind of lamp socket.
6. Ordinary microscope of standard make.

METHOD

After loading the camera with the desired film, the lens barrel (fig. 1A) is unscrewed from the camera and mounted in the lens plate of the copy attachment (fig. 1B). The camera back is mounted on the camera-back

* From the Department of Ophthalmology, Northwestern University Medical School.

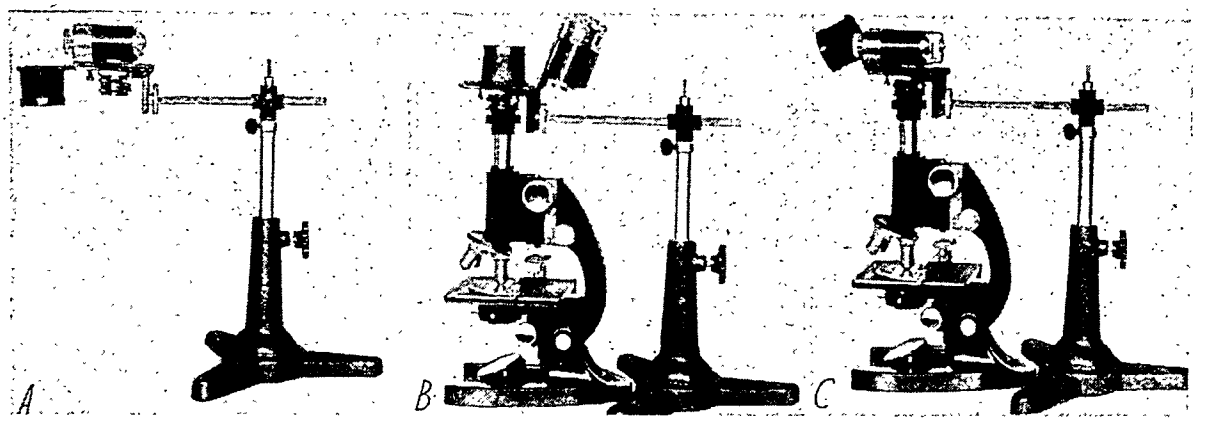

Fig. 2 (Wright). (A) Assembly mounted on support. (B) Focusing with ground-glass image. (C) After focusing, the ground glass is raised and the camera back is lowered into position.

plate of the copy attachment (fig. 1C). The assembly is mounted on the support (fig. 2A). The slide is placed on the stage and roughly focused on the desired area. The camera-copy assembly is gently lowered to the microscope connector and the slide is focused by means of the ground glass on the copy attachment (fig. 2B). The ground glass is raised and the camera lowered into its place and the picture made (fig. 2C).

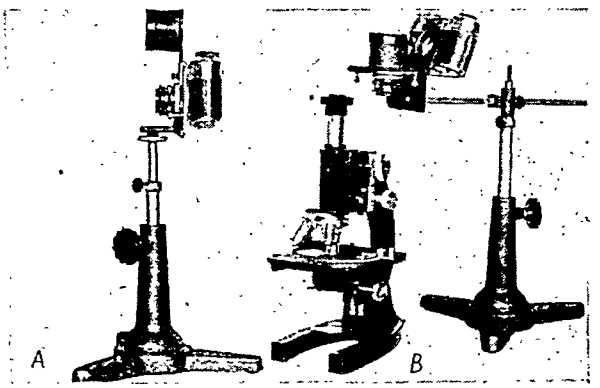

Fig. 3 (Wright). (A) Camera is set up for anterior-segment photography. (B) Shows camera assembly, microscope, and connector.

The light system is a number-one photoflood lamp placed about three feet from the concave mirror of the microscope whose condenser is opened fully and then closed until the light in the field of view just begins to dim. For black and white, using Eastman Super-XX film, about 1/30 of a second is required for a slide of average density. For Kodachrome type-A film, about one-half second of exposure is required. Thin slides require 1/5 second. These slides project nicely.

The connector is a short metal tube, or it may simply be a piece of black paper pasted around microscope and camera lens (fig. 3B). It need not be absolutely light tight. Pictures taken with high or low power require the same time of exposure, although the diaphragm of the condenser must be opened wider for high-power photographs. Critical focusing with the ground glass is facilitated by study of the ground-glass picture with a hand magnifying lens.

511 South Bonnie Brae.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

April 7, 1947

DR. BENJAMIN FRIEDMAN, *president*

This meeting, the annual round-table discussion, was devoted to the discussion of the "Clinical Aspects of Ocular Pathology." Questions were submitted before the meeting, and were edited and divided among the following ophthalmologists, who comprised the panel of experts: Dr. J. Arnold de Veer, Dr. Joseph Igersheimer, and Dr. Algernon B. Reese. Dr. Benjamin Friedman acted as the moderator.

IN WHAT WAY MAY ENDOPHTHALMITIS PHACO-ANAPHYLACTICA BE RELATED TO SYMPATHETIC OPHTHALMIA?

DR. J. ARNOLD DE VEER said that there are several respects in which injury of the lens may contribute to the development of sympathetic ophthalmia. The proponents of the "infectious" theory of sympathetic ophthalmia have occasionally referred to the possibility that lens substance may serve as a culture media for bacteria and so play a role in the development of sympathetic ophthalmia.

Inclusion of lens capsule in a wound has repeatedly been mentioned, along with inclusion of uveal tissue, as a possible factor. Long before Verhoeff and Lemoine attributed certain inflammatory conditions to an "anaphylactic" reaction to lens protein, it was well known that protracted inflammations occasionally followed retention of lens material after cataract extract and that whatever can cause an iridocyclitis can indirectly bring about sympathetic ophthalmia. So, in a nonspecific way, the lens has been thought to be concerned in sympathetic ophthalmia by a number of observers.

Before 1940, no one had suggested that sensitization to lens protein might be a direct precursor of sympathetic ophthalmia in certain cases. In these cases, there has usually been one or more injuries or operations involving the liberation of lens protein. Inflammation in one eye has been followed by irritation or inflammation of the other eye. Examination of the enucleated, exciting eye has shown features both of endophthalmitis phaco-anaphylactica and of sympathetic ophthalmia. The theory advanced by Dr. de Veer is chiefly on morphologic evidence. It is that these people had first become sensitized to lens protein, and developed an allergic type of uveitis and subsequently became sensitized to uveal pigment. This theory still awaits serologic or experimental proof. Dr. de Veer stressed that the lens may play an important role in the development of sympathetic ophthalmia, whether as a source of antigen, as food for infection, as a toxic irritant, or in other ways.

Discussion. Dr. Joseph Igersheimer asked Dr. de Veer whether he would comment on the conception of autoanaphylaxis and its relationship to endophthalmitis phaco-anaphylactica.

Dr. de Veer replied that lens protein is one of the antigens described as organ specific rather than species specific. The idea that certain inflammatory lesions of the eye might be the result of sensitization of the individual to its own lens protein was advanced by Verhoeff and Lemoine, in 1916, and has never been fully accepted, chiefly because lens substance is a weak antigen, and it has been impossible to produce any convincing experimental support of the theory. In 1934, however, Berkey struck upon

a method of augmenting antigenicity by the use of some adjuvant substance, notably staphylococcus toxin. By the intradermal inoculation of rabbits with lens antigen and this toxin, either in separate skin sites or combined, he succeeded for the first time in rendering rabbits highly sensitive to beef lens substance. When the lenses of these rabbits were then needled, so that some of their own lens substance was released, intense inflammations ensued rapidly. Sections of these eyes were reported by Friedenwald to show changes resembling endophthalmitis phaco-anaphylactica in man.

With this experimental support and the histologic evidence furnished by clinical material, there has been rather general acceptance of the fact that reactions of the type described by Verhoeff and Lemoine have at least an allergic aspect, although infection and toxicity of lens substance may also be concerned in the pathogenesis of the lesion. Dr. de Veer said that he believed that sensitization to lens protein plays the predominant role in endophthalmitis phaco-anaphylactica and that sensitization to uveal pigment and sympathetic ophthalmia may supervene. In other words, people who have become sensitized to lens antigen are more prone to develop sympathetic ophthalmia than those who have not suffered such an immunologic disturbance.

Is sarcoid a type of tuberculosis?

Dr. Joseph Igersheimer said that his personal experience with sarcoid is very limited and he felt that this is true of most ophthalmologists. Very few cases of sarcoid of the eye have been studied anatomically and published. The whole question of the relationship between sarcoid and tuberculosis cannot be decided by the microscopic picture alone.

The histologic picture of Boeck's sarcoid is characteristically nodular in form. It is composed mainly of epithelioid cells with a few giant cells, lymphocytes, and marked fibrosis. The lack of caseation or necrosis is particularly suggestive.

Heerfordt's uveoparotid fever and Mikulicz's syndrome belong to the same group as Boeck's sarcoid. The fact that all these diseases show a tuberculoid formation cannot be used as positive evidence that they have a tuberculous origin since we know that allergic reactions in general often cause nodules of epithelioid character.

It is not the pathologic picture alone but the combination of the clinical entity plus the microscopic changes which are important in the pathogenesis. The negative tuberculin reaction in high concentrations, the absence of Koch's bacilli, and the lack of any form of caseation are the main but not the only facts which suggest that sarcoid and similar diseases are not due to an infection caused by Koch's bacillus, but to another infectious agent which we have not yet discovered. On the other hand, it must be admitted that in a relatively small number of cases of sarcoid, tubercle bacilli are found, inoculations are positive, and caseation is present. Therefore, the whole question of the relationship between sarcoid and tuberculosis cannot be answered in a positive way.

Can malignancy be diagnosed on a study of the subretinal fluid?

Dr. Algernon B. Reese said that Meissner, Rintelen, and others have been able to demonstrate the presence of cancer cells in the centrifuged subretinal fluid in cases of malignant melanoma of the choroid. Tumor cells cannot get into the subretinal fluid in cases of melanoma of the choroid until the tumor has perforated the lamina vitrea. In early cases this has not taken place, and it is these cases which may be difficult to diagnose.

Dr. Reese said that there are pigment epithelial cells which proliferate readily in the subretinal fluid and which he felt would be difficult to distinguish from tumor cells. He did not believe that the withdrawal of

subretinal fluid for the purpose of identifying tumor cells was of any value diagnostically.

Cibis found a positive melanin test for the subretinal fluid in cases of malignant melanoma of the choroid. Similar tests were negative for the aqueous, vitreous, and subretinal fluid in idiopathic detachments. Cibis felt that this test was of diagnostic value. Dr. Reese said that he has never used it and doubted its validity.

Dr. Reese said that it is sometimes advantageous to drain the subretinal fluid in order to unmask a melanoma lurking in the choroid. Sometimes this can be accomplished by putting the patient to bed with absolute rest for several days and in rare instances it is advisable to withdraw the fluid with a syringe.

Discussion. Dr. Benjamin Friedman asked if, when the eye is tapped, there is any danger of cells being left in the conjunctiva and whether these cells could lead to a secondary growth in the conjunctiva. Dr. Reese replied that he did not believe that there was any danger of this happening.

Pathologic findings in cases of retained nonmetallic foreign bodies

Dr. J. Arnold de Veer said that he believed it to be axiomatic that even the most inert foreign bodies excite some foreign-body granulomatous reaction. The more intense inflammations come from foreign substances that are more or less soluble in tissue juices, but even such insoluble substances at talc, glass, or coal dust call forth a mobilization of macrophages that leads to fibrosis. Infection may, of course, be carried into the tissues with the foreign bodies, and the traumatic hemorrhage, necrosis of tissue, hyperemia, and edema incident to the entrance of the foreign body furnish food for the infecting organism.

Although infection may not be introduced at the time of entrance of a foreign body, the fibrosis that results from the trauma of introduction, plus the fibrosis about the foreign substance itself, present areas of modified circulation and other structural and functional abnormalities that may invite endogenous infection.

Many nonmetallic foreign substances may be tolerated within the eye for indefinite periods of time. The clinician must weigh the risk of removal against the risk of leaving the foreign body within the eye.

A type of delayed, posttraumatic glaucoma is known to occur occasionally months or years after introduction of a "nonirritating" foreign body of even minute size.

The problem of identification of a nonmetallic foreign body in an enucleated eye may tax the diagnostic acumen of the pathologist. Glass, cilia, or displaced fragments of lens are relatively simple. Various vegetable structures call for a knowledge of plant histology.

Are there any histologic ocular findings that one can definitely classify as exclusively luetic?

Dr. Joseph Igersheimer replied that there are no histologic findings exclusively characteristic of syphilis. In the early stages, plasma cells are often present abundantly and, in the later stages, giant cells and vascular changes are often found, but all such findings are not pathognomonic.

Discussion. Dr. de Veer remarked that, if there is a real gumma in the eye, you can often give a histologic diagnosis of lues. He said that his reports usually read, "infectious granuloma, probably lues or tuberculosis." Then a serologic or bacteriologic confirmation is sought.

Histologic criteria in determining rate of growth of choroidal sarcoma

Dr. Algernon B. Reese said that Callender gave a cytologic classification of melanomas of the uvea into spindle-cell A and B, fascicular, necrotic, epithelioid, and mixed. The spindle-cell and fascicular types were

the least malignant and the epithelioid and mixed types the most malignant.

Wilder has reported the use of the reticulum content of melanomas as a criterion. Tumors in which the reticulum content or argyrophile fibers are greatest are less malignant than the tumors in which the reticulum content is less. The principle involved here is that the more rapidly a tumor grows the more anaplastic it is, and the less the cell produces its by-product.

The melanomas of the uvea are divided into the neurogenic and the chromatogenic melanomas.

Incidence of intraocular tumors in blind eyes

Dr. J. Arnold de Veer said that he was not able to answer the question from the standpoint of personal experience of any statistical value. The question of etiologic factors in development of malignant melanomas arises in these cases. Leber and Krahnstöver, in 1898, reported 22 cases in which inflammation seemed to have preceded development of the tumor. In most instances, however, the tumor has been the cause of the phthisis.

Dr. de Veer said that it can be stated without exception that phthisical eyes always show inflammation. He said that he had seen many examples of malignant melanoma in phthisical eyes, and felt that chronic inflammatory and profound local metabolic disturbances in some of these cases may have been casually related to the development of malignancy just as chronic irritation is believed to cause malignant changes in nevi of the skin.

The question of the relationship of injury and the development of malignant melanoma is a difficult one. If, as is commonly thought, partial removal of a pigmented mole of the skin may cause the remaining nevus cells to take on a malignant character, perhaps an injury that produces blindness can be credited with the subsequent development of an intraocular tumor. There is a tendency today to view this question of activation of growth of nevi, by operation or other trauma, in a different light than heretofore. It is thought that the nevus that shows obvious malignancy after incomplete removal was probably already malignant at the time the operation was undertaken.

At any rate, continued Dr. de Veer, the fact that a malignancy, impossible to detect early, may develop into a hopelessly blind eye is one of the best reasons for urging removal of such eyes. Furthermore, the phthisis may have been caused by an unsuspected malignant tumor. Estimates of the incidence of malignant tumors in phthisical eyes run as high as 10 percent. For similar reasons, eyes with absolute glaucoma in which the fundus cannot be seen, may harbor malignant tumors and so should be enucleated.

Discussion. Dr. Joseph Igersheimer said that it would be wise to consider the possibility of an intraocular tumor when one eye is blind and when the fundus is not visible. E. von Grosz published, in 1929, the following interesting figures: Among 4,004 enucleations during a period of 25 years, there were 200 eyes which were diagnosed as having uveal sarcoma. In 68 cases of blindness, there was only a suspicion of a tumor, and a tumor was found in 26 of these cases. Among the enucleated blind eyes with no suspicion whatsoever of a tumor, 25 cases of sarcoma of the uvea were found anatomically.

Why do inflammatory lesions of the posterior segment heal with fewer complications than those located anteriorly?

Dr. Joseph Igersheimer said that we must first consider the uvea, because the consequences of healing the exudative stage are most important. The dangers of a fibrinous exudate getting into the anterior and posterior chambers from the vessels of the iris and ciliary body are well known, and it is not necessary to describe them. In the choroid, these exudates are generally very limited in

size and space. If they are in a small area and the inflammatory process extends to the pigment epithelium and the outer surface of the retina, a microscopic retinal detachment may be present. Large exudates and large detachments as in Harada's disease are very infrequent occurrences. Even if involvement of the retina takes place in many small areas, as in disseminated choroiditis, the lasting visual disturbances are generally not great, unless the macular region is involved.

Several factors, anatomic as well as physiologic, are probably instrumental in causing the difference in behavior of the anterior and posterior segments of the uvea.

Anatomically, it is the glass membrane bordering the choroid which resists the spread of inflammation to a rather high degree, as does Descemet's membrane in corneal infiltrations. The iris and the ciliary body do not have such a natural barrier.

Physiologically, the pressure on the outside of the blood vessels may play a role in the amount of fluid and fibrin passing through the vessel wall. It is apparent that the choroid is naturally compressed by the sclera on one side and the pigment epithelium plus the retina on the other side. In the iris there is no counterpart on either side; in the ciliary body, on one side only. This point may be of some importance in cases where the inflammatory process is very severe, but is mainly restricted to the uveal tissue itself. Tuberculous nodules for example generally grow larger in the anterior uvea than in the choroid.

In discussing the posterior segment, inflammatory processes in the retina proper must be considered. Here the inflammation can be very severe, as in endophthalmitis. Necrosis of the retinal elements follows quickly, and the healing consequences are as bad as in the anterior segment. If the inflammation is mild and is restricted to some septic emboli, the complications may be insignificant because the tissues of the retina have little or no inflammatory response, and the little embolus may cause only a microscopic necrotic reaction in its surroundings.

Discussion. Dr. J. Arnold de Veer commented on the apparent ease with which exudate gets out of the ciliary body and into the vitreous, particularly from the pars plana and the region of the ora serrata. Why that should be so is not entirely answered by the statement that there is a glass membrane behind the ora serrata and none anterior to it. The two layers of the lamina vitrea are represented in the ciliary body, but there is a connective-tissue layer interposed between them. If these two membranes, the cuticular and the elastic membranes, are as represented in the textbooks, it is remarkable that cells can migrate through them in their separated positions any more easily than through the lamina vitrea, where these two layers are fused. Perhaps the answer is that these glass membranes in the orbicular region of the ciliary body are fenestrated, or perhaps they are easily broken during inflammations, so that inflammatory cells stream out into the vitreous, pass forward along the zonular fibers, and give rise to the cyclitic membranes that are so destructive.

Dr. de Veer concluded that an investigation of the glass membranes in the ciliary body, by means of maceration preparations, would be worth while.

Potential Malignancy of Pigmented Lesions of Conjunctiva

Dr. Algernon B. Reese said that there are two types of tumors to be considered here. One is the nevus and the malignant melanoma which arises from it, and the other is precancerous melanosis and the malignant melanosis which arises from it.

The nevus is a congenital tumor, extremely common, and it is an extremely rare occurrence that it gives rise to a malignant melanoma. When this does occur, the malignant tumor is localized and elevated.

Precancerous melanosis is an acquired lesion, usually appearing at the age of from 40 to 50 years. It is diffuse and nonelevated

and characteristically gives rise to a malignant melanosis in from 5 to 15 years. This tumor stems from the basal layer of the epithelium.

Dr. Reese said that, in his experience with these tumors, he has found that cancerous melanosis which arises from a precancerous melanosis is at least 15 times more common than the malignant melanoma which arises from a nevus.

Clinical criteria for differentiating benign from malignant tumors of the iris

Dr. J. Arnold de Veer said that there should be close and careful observation of all nevi. Those in the iris should be under the observation of an ophthalmologist. Notations should be made of size, shape, color, exact location, and degree of vascularity. Continued growth, especially after a period of quiescence should be viewed with suspicion. Changes in the degree or pattern of the vascularity or the development of glaucoma in such an eye should arouse great suspicion. The nonpigmented nevus should be watched as carefully as the pigmented one.

Dr. de Veer said that he was glad to see the designation "pigmented nevus" replacing the term "melanoma" in ophthalmic literature. Melanoma for several decades has been used in general pathology to designate a malignant tumor of melanoblastic cells. The addition of the word malignant would seem a wise precaution. The designation "melanosarcoma" is being dropped from ophthalmic parlance and that of "malignant melanoma" substituted. The term "leukosarcoma" is also troublesome. In general oncology it means lymphosarcoma accompanied by a leukemic blood picture. The name "nonpigmented malignant melanoma" should replace that of "leukosarcoma" in referring to pigment-free malignant melanoblastic tumors of the eye.

Differentiate histologically between luetic and tuberculous keratitis

Dr. Joseph Igersheimer said that the opportunity to examine an interstitial keratitis histologically is extremely rare. If only the cornea is examined under the microscope, it may not be possible to decide whether the keratitis is of luetic or tuberculous origin. Nevertheless, there is a great difference between the two and this can be understood best if the problem is approached from an experimental angle.

If luetic material is injected into the cornea of a rabbit, an interstitial keratitis will develop after a certain incubation period. This keratitis is generally not in the region of the injection. If tubercle bacilli are injected into the cornea, a yellowish infection will appear at the site of the injection after a few days; this infiltration becomes larger and nodular and may be followed by ulceration or perforation of the cornea.

If spirochetes are inoculated into the anterior chamber a typical interstitial keratitis results; whereas, after inoculation of tuberculous material a specific nodular process develops first in the iris, and later on a caseating process develops in the cornea.

If the syphilitic infection is made somewhere else in the body, as in the testis, and if the eye becomes involved, a typical interstitial keratitis appears after several weeks. Often no other pathologic condition of the eye can be found even histologically. If tubercle bacilli are injected intravenously, a uveal tuberculosis frequently results, but very rarely and only in severe tuberculosis of the anterior uvea does the cornea become involved. In such a case, the corneal disease can have the clinical and histologic appearance of an interstitial keratitis.

With rare exceptions the same process exists in pathologic conditions in human beings. According to his experiences, Dr. Igersheimer said that a luetic interstitial keratitis is primary, which means it is independent of

other inflammatory foci in the eyeball. Tuberculosis affects the cornea either in the form of a nodular keratitis or an interstitial keratitis, but this interstital keratitis is always secondary to a specific process in the sclera or the anterior uvea. Dr. Igersheimer demonstrated a case of interstitial keratitis with tuberculosis of the iris.

Dr. Igersheimer also demonstrated with lantern slides one histologic peculiarity of luetic keratitis. He said that experimentally, as well as in human cases, he had found new formations on the posterior surface of the cornea. They appeared clinically like large Descemet precipitates, but histologically they were proliferations of the corneal endothelium. The interesting point was that in several of the experimental cases, a large number of spirochetes could be detected in these endothelial new formations.

Intraocular complications in cataract extractions

Dr. Algernon B. Reese said that the following complications were common to both intracapsular and extracapsular cataract extraction:

1. Choroidal detachment. The immediate type is due to loss of volume in the eyeball. The late type, which comes on several weeks or more following the operation, is probably due to a leaky wound.

2. Epithelization of the anterior chamber. This may be in the form of a localized cyst due to the impregnation of isolated epithelial cells in the anterior chamber. It may be in the nature of epithelium lining a portion of the anterior chamber or the posterior chamber. This is due to the ingrowth of epithelium at the wound and is perhaps encouraged by the incarceration of iris or capsule in the wound.

3. Various types of operative sections.

4. Glaucoma.

5. Postoperative inflammation, which may be early and ectogenous in character, or late and endogenous in character.

6. Prolapse of the iris.

In regard to the extracapsular extraction, by far the most common and serious complication is capsule in the wound. The subcapsular epithelium proliferates into large plaques of metaplastic tissue and gives rise to various types of complications.

In regard to the intracapsular extraction the following were discussed by Dr. Reese:

1. The protrusion of the anterior hyaloid membrane across the anterior chamber to touch the corneal surface.

2. Adhesion between the lens capsule and the anterior hyaloid membrane (ligamentum hyaloidea capsularis). When actual adhesions exist between the two, an intracapsular extraction causes a tearing of the anterior hyaloid membrane and thus gives rise to loss of vitreous.

3. A detachment of the retina due to the fact that the dislocation of the lens causes a hole to be pulled in the retina at the ora serrata because some of the zonules insert into the ora.

Obligations of pathologist to furnish unprejudiced opinions and of clinician to provide adequate clinical information

Dr. J. Arnold de Veer said that it has been the custom for many years to examine gross and microscopic sections without any clinical notes whatever. After gross and microscopic examinations are completed, he considers the clinical data in order to reach a diagnosis that is compatible with all the facts in the case.

Only when the complete clinical picture is known, can the globe be sectioned in the proper planes to yield the most information. Dr. de Veer said that he believed that many valuable specimens have been ruined because the clinician has not given enough data to the pathologist. The attending physician

should see to it that the proper information accompanies the specimen to the laboratory.

Sudden degeneration of the optic nerve and its clinical implications

Dr. Joseph Igersheimer discussed his experiences with rapid degeneration of the optic nerve, which are not generally mentioned in the textbooks.

The first group of such cases concerns papilledema. Dr. Igersheimer had the opportunity to follow up a large number of papilledema patients before and after decompression operations and also to examine histologically the whole peripheral visual apparatus of many such cases. Among these cases there were many patients who had normal visual functions before the operation which remained after the decompression. Others showed, even before the operation, a certain grayish discoloration of the disc and a slight decrease of the visual functions. Some of these latter patients demonstrated a rapid deterioration of their vision after the decompression. He recalled the case of a young girl who became totally blind a few days after the operation. She died shortly thereafter, and the microscopic examination showed total Marchi-degeneration of the optic nerve in its entire cross section. This should serve as a warning signal for recommending a decompression operation if the optic nerve already shows clinical signs of beginning atrophy.

A second group with sudden decrease of visual functions was demonstrated by a patient who was studied clinically and anatomically. This patient felt absolutely well until he suddenly developed a mist in front of each eye. The borders of the discs were hazy and the vision was beginning to fail. During the next two weeks, the vision decreased rapidly and the disc showed some grayish discoloration. In the retina there were some small hemorrhages with a tiny star figure on one side. The retinal changes could not explain the visual disturbances. The spinal pressure was normal. There was general hypertension and nephrosclerosis. The patient died practically blind four weeks after the beginning of the eye symptoms as a result of cerebral hemorrhage. Anatomically there was a degeneration of all optic-nerve bundles as shown by the Marchi-method. At the distal end of the optic nerve there was an increase of glial cells. Dr. Igersheimer showed by means of slides that both central vessels had normal lumen. There was no definite pathologic process apparent in the smaller vessels. The cause of the sudden degeneration in this case and in similar cases is not clear, but it must lie in the optic nerve itself. Dr. Igersheimer said that it was probably due to a circulatory damage, since the patients all seem to suffer from a general hypertension or severe atherosclerosis.

Tabetic optic atrophy can, in rare instances, also show a very rapid progression. A 25-year-old woman, who came to the clinic with early visual symptoms, was blind in both eyes six weeks later. Recently Bruetsch has also described such an experience. No case of this type has been studied microscopically as yet.

Differential diagnosis of retinoblastoma

Dr. Algernon B. Reese said that the important characteristics of retinoblastoma which are helpful in making a diagnosis are as follows:

1. The color of the tumor.
2. The identification of calcium in the tumor either by ophthalmoscopic examination or by X ray.
3. Globules of tumor tissue in the vitreous.
4. Implantation growths along the anterior surface of the iris or elsewhere in the eye.
5. A normal size eye.

Dr. Reese said that retinoblastoma must be differentiated from the following conditions:

1. Retrolental fibroplasia. In this condition the color of the lesion, the long ciliary processes, the anterior concavity of the lesion, its presence in an eye that is smaller than normal, and the premature birth of the patient are all important features.
2. Metastatic retinitis.
3. Massive retinal fibrosis.
4. Coats's disease.
5. Dictyoma.
6. Astrocytoma.
7. Extensive medullated nerve fibers.

CLINICAL PROGRAM

(Presented by the staffs of Children's Memorial, Michael Reese, and Mount Sinai Hospitals)

ERYTHEMA EXUDATIVUM MULTIFORME

DR. MARTHA RUBIN FOLK presented Mrs. L. K., seen first in consultation at Mount Sinai Hospital on July 25, 1945. Two days before admission, the patient experienced pain in the left shoulder and hip, for which her family physician gave her an injection of a gold preparation for rheumatism. On leaving his office she experienced a feeling of tightness around her mouth and an increase in saliva. Within a few hours an eruption appeared, covering the eyelids, conjunctiva, and most of the skin of the face, the dorsal part of the arms, chest, abdomen, legs, and feet.

History. Past medical history was not significant except for the story of an ulcer on her leg 20 years ago which healed slowly. Serologic tests were positive.

Physical examination showed an extensive eruption of macular, papular, and vesicle lesions scattered over the entire body with a predilection for the extremities. Many of the lesions had crusts of a violescent hue, and some coalesced into large erythematous patches. A profuse muco-frothy discharge was present on the lips. The buccal mucous membrane, bladder, and rectum were ulcerated. Blood pressure was 217/110. The heart was slightly enlarged. The Kahn test gave a positive result. The blood count was within normal limits. The urine showed a trace of albumin.

Eye findings. Vision was: R.E., 0.8; L.E., 5/200. The skin of the eyelids showed many crusts of various sizes, some of which oozed serum. The lids were adherent; a profuse mucopurulent discharge was visible between the palpebral fissures, which were narrowed to 2 mm. in size. After careful cleansing of the lids, pontocaine (1 percent) was instilled and some adhesions were broken so that the fundi might be examined. Many fine ulcerations were present on the palpebral conjunctiva, which was moderately injected. The cornea was clear but the fundi could not be satisfactorily examined.

Under hospital treatment for three weeks, the lesions of the skin cleared, leaving dark, pigmented patches. The palpebral fissures became larger, but some bands of adhesions near the canthus remained.

At this time there is still a scanty mucoid discharge present from the conjunctival sac. The patient has been receiving antisyphilitic treatment. Cultures and smears show many dead epithelial cells and a few Staph. aureus. No fungi were found. The obliteration of the conjunctival fornices persisted. On several occasions the cornea, stained with fluorescein, showed many punctate ulcerations. On slitlamp examination, both lenses showed grayish opacities and golden brown posterior cortical opacities. The right disc showed a temporal pallor. In the left macular

region, there was a pigmented patch the size of the disc, with others smaller in size. There were various changes in the blood vessels, some tortuosity and nicking of the veins by the arteries at the crossing.

Diagnosis. (1) Erythema exudativum multiforme, which caused scarring of the conjunctiva. (2) Bilateral incipient cataract. (3) Right partial optic atrophy. (4) Left central choroiditis—syphilitic. (5) Hypertensive retinopathy.

This patient is still under weekly observation.

SCIENTIFIC PROGRAM

1. Testing School Children with Massachusetts Vision Tests.—Mrs. B. H. Gray*

2. Toxoplasmosis.—A. C. Krause.

3. The Sodium Vapor Lamp and its Use for Refraction. (See Am. J. Ophth., 30: 1527 (Dec.) 1947).—Stefan Van Wien.

4. Streptomycin Therapy in Ocular Infections. (See Am. J. Ophth., 30: 1215 (Oct.) 1947).—John G. Bellows, and Chester J. Farmer.*

Richard C. Gamble,
Secretary.

* By invitation.

HISTORICAL MINIATURES

Toward the end of the middle ages one finds extensive efforts to elaborate a system of optics. The names of Alhazen (965-1038), Roger Bacon (1214-1291), and John Peckham (1240-1294) are well known. The work of Vitellio (1220-1280) is less well known, although he was highly appreciated in his time and during the Renaissance. Leonardo da Vinci thoroughly studied his book, Frederic Risner praised it extravagantly and Johannes Kepler, in 1604, entitled his treatise on optics: *Ad Vitellonem Paralipomens.*

The blackness of the pupil was so much taken for granted that the importance of Mery's demonstration of the visibility of the eyeground in an excised eye that is immersed in water was not recognized. In his student days Adolf Kussmaul not only recognized the importance of the problem of the blackness of the pupil but correctly formulated its details, although it remained for the genius of Helmholtz to provide the solution.

KATHERINE FERGUSON CHALKLEY, *Manuscript Editor*
Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 700 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

RETROLENTAL FIBROPLASIA

In infants, and especially in those that are premature, blindness due to the presence of opaque tissue in the vitreous is assuming tremendous importance. The condition does not seem to be a new one, but merely represents an increased incidence of a lesion which has always appeared sporadically and has been called by various names. Terry, who coined the term "retrolental fibroplasia" to designate the lesion, gave great impetus to its study. He appreciated the lately increased incidence and was the first to concern himself regarding it.

At The Institute of Ophthalmology, New York City, we have seen 136 cases, and 89 of these have been seen in the past three years. At the Massachusetts Eye and Ear Infirmary, 165 blind preschool children are recorded as residing in Massachusetts, and in 108 of these the blindness is due to retrolental fibroplasia.

As the high incidence of the disease has occurred only in the past 10 or more years, and as the disease prior to this period was extremely rare, ophthalmologists over the country have not all incorporated the diagnosis in their repertoire. It is difficult, there-

fore, to arrive at a true estimate of the lesion's incidence because all statistics must be based on eye reports from ophthalmologists. The United States Public Health Service has no statistics on the subject. This is also true of many state and local organizations concerned with health statistics.

Figures on the incidence of the disease are available in five states. The reports from four of these states are as of April, 1947, ("The Blind Preschool Child," New York, American Foundation for the Blind, Inc., 1947, pp. 46-51).

The Division for the Blind, Department of Public Welfare, Chicago, Illinois, reported a total of 109 blind preschool children known in the state, and remarked "a more adequate coverage of the state would, we feel, reveal considerably more cases." Out of this total of 109, eye reports were available for only 48. Of these 48, 20 gave retrolental fibroplasia as the cause of blindness.

The New Jersey State Commission for the Blind reported 96 blind preschool children all of whom were covered by eye reports, and 28 of that number gave retrolental fibroplasia as the cause of blindness. Since this report, the New Jersey State Commission has listed a total of 135 cases under their supervision. This rise, within the last nine months, may be real, apparent, or both.

The New York State Commission for the Blind reported 115 cases, of which 93 were covered by eye reports; 20 of them are cases of retrolental fibroplasia.

The Wisconsin School for the Visually Handicapped reported that 58 visually handicapped preschool children were known to the field service of the Department of Public Instruction, and added "information included on causes of blindness is not too reliable as less than 40 percent of the cases are based on direct medical reports." Eight of the 58 cases had retrolental fibroplasia.

The Division of the Blind, Department of Education of the Commonwealth of Massachusetts, reports as of January 1, 1948, that 148 preschool blind children are recorded and that 82 of these have a diagnosis of retrolental fibroplasia.

The figures quoted from The Institute of Ophthalmology, New York City, and from the Massachusetts Eye and Ear Infirmary are not representative: they give too high an incidence of retrolental fibroplasia because both these institutions have manifested particular interest in the disease. On the other hand, the figures available from the four states show too low an incidence of retrolental fibroplasia, because all the ophthalmologists, upon whose certificate the statistics depend, are not diagnosing this condition which has only recently assumed importance. Eye reports covering a larger number of preschool children and better case-finding methods of the organizations interested in the blind would lead to the discovery of many more blind preschool children. Available statistics show that retrolental fibroplasia is by far the commonest cause of preschool blindness. I feel that a fair estimate is that one third of all preschool blindness now is due to retrolental fibroplasia. Furthermore, there are indications that the incidence not only has increased in the past decade or more, but has shown a particular increase in the last few years.

An important factor in this increased incidence is the decrease in mortality of premature infants. The pediatricians now are saving premature babies that formerly were lost. This may not, however, be the sole factor.

There is evidence indicating that the disease may result from an infection of some nature. In support of this it can be said that the incidence of the disease seems to vary in different localities. In one Boston hospital the incidence of retrolental fibroplasia has been found to average 18 percent of all premature births during the past eight years (King, M. J., The Blind Preschool

Child, 1947, pp. 138-142), while in some other localities, the incidence seems lower. My colleagues in other countries, including France, Austria, and Australia, tell me that they do not encounter the condition except as a rare sporadic case. Furthermore, in the fundi of these patients there are clinical manifestations over the areas accessible to examination which indicate that a choroiditis of a mild nature has existed. This manifests itself as a diffuse, mild, pigment disturbance. Also, some of the eyes having retrolental fibroplasia show evidence of an iridocyclitis. This manifests itself as posterior synechiae, atrophy of the iris, and the sequela of exudate around the pupillary margin of the iris. Moreover, from 40 to 60 percent of the mothers of these patients give a history of vaginal bleeding during pregnancy, and some give evidence of having had infection of some kind during their pregnancies. This may be a history of fever or of intercurrent infection such as brucellosis, German measles, ulcerative colitis, and so forth.

It is known that certain mild clinical, or even subclinical, infections of the mother affect the offspring. Toxoplasmosis is a subclinical infection of the mother which produces in the offspring chorioretinitis as well as congenital anomalies. Measles, and perhaps other virus diseases of the mother, can produce abnormalities in the offspring. There must be still other clinical and subclinical infections of the mother acting in similar fashion. In retrolental fibroplasia, therefore, it seems reasonable to postulate that a maternal infection of some nature is responsible for the variations in the incidence in different localities, for the vaginal bleeding and consequent premature birth, and for the signs of inflammation in the eyes of the offspring such as chorioretinitis and iridocyclitis. As pediatricians now save premature infants which would previously have been lost, the sequelae of this maternal infection on the infant now manifests itself as an increased incidence of this lesion which formerly appeared only sporadically. The increased incidence might also be attributed in part at least to an increase in the prevalence of some maternal infection.

The problem of retrolental fibroplasia is the most acute one in ophthalmology today. Is there not some way we can prevent the birth of so many blind infants whose parents, too frequently young and of modest means, can ill afford to have their resources decimated and to carry the tremendous burden of such a child? Often the affected child is the first one of young parents who, though they accept their plight, are terribly handicapped and plan to have no more children. Those concerned in this problem, including the ophthalmologist and the various public organizations and institutions, are not sufficiently aroused to, or conscious of, the importance of the problem. One of the first steps toward clarifying the issue should be a thorough and accurate accounting of premature children with regard to the incidence of retrolental fibroplasia, mental retardation, and other abnormalities. Then it can be decided whether or not the saving of premature infants should be entered on the credit or debit side of medicine.

Algernon B. Reese.

THE WILMER RESIDENTS ASSOCIATION MEETING

The seventh annual meeting of the Wilmer Residents Association was held at the Wilmer Ophthalmological Institute, Johns Hopkins Hospital and University, on April 14, 15, and 16, 1948. The total registration, including guests, was 181. Those privileged to attend came from many places in the United States.

The Residents Association is composed of former residents of the Wilmer Ophthalmological Institute. The purpose of their annual clinical meeting is to provide an opportunity for the returning residents, former house officers, assistant residents, and guests

to review the work done in the Wilmer Institute during the past year, and to follow the activities of the former residents. It has been the custom to invite a number of ophthalmologists from other cities to attend these meetings.

There were 26 papers or presentations by former residents, past and present members of the staff, and from members of other departments of the university. Thus, a most impressive array of authors and subjects was paraded before the keenly interested audience during the three delightful days of the meeting.

The quality of the work and its importance to ophthalmology was most striking. It is impossible here to do adequate justice or to describe in detail the individual contributions. Many of them will appear in subsequent issues of the JOURNAL. However, the papers by Woods on "Antibiotic and Chemotherapy in Experimental Ocular Tuberculosis," Owens and Owens, on "Retrolental Fibroplasia," Walsh on "Nasopharyngeal Carcinoma," Woods and Wood on "Bacterial Hypersensitivity and Its Relation to Ocular Disease," and Kuffler on "Synaptic Transmission with Reference to the Retina," were particularly worthy of note.

Dr. Alfred Blalock discussed the "Surgical Treatment of Coarctation of the Aorta and Pulmonic Stenosis," and showed a breath-taking motion picture in Kodachrome of his spectacular and life-saving operation in these conditions. Dr. Jonas Friedenwald brilliantly presented some of his recent work on "Enzymatic Histochemistry and Its Applications to Ophthalmic Research," and did his best to simplify the complexities of the subject for his overwhelmed listeners. Dr. William G. Marr debunked and devastated the cyclodiathermy operation for glaucoma. Dr. Samuel D. McPherson, Jr., and Dr. Ronald Wood exhibited convincing evidence that solutions of the usual drugs used in ophthalmology in 1:5,000 Zephiran remain sterile for weeks thereafter. Dr. M. Elliott Randolph read an excellent paper on "Recurrent Erosion of the Cornea," and suggested the value of histamine desensitization for this stubborn condition. The paper by Bruno and McPherson, Jr., on "Harada's Disease," was thought-provoking and stimulating. These and the other papers on the program showed careful observation, work, and skill in presentation. One cannot praise the meeting too highly.

There were many lighter moments and times for relaxation and entertainment during the evenings. A skit, ably performed by the active house officers and residents, poked harmless fun at their betters (in age at any rate) and slyly probed into the foibles and dignities of their directors. The actors' lines were clever and were relished by the onlookers, particularly those who were not in the line of fire. Derrick Vail.

CORRESPONDENCE

REPLY TO DR. CRISP

Editor,
American Journal of Ophthalmology:

In the March issue of the *American Journal of Ophthalmology,* there appears an editorial signed by Dr. W. H. Crisp, in which decided exception is taken to certain portions of an address delivered by me in Chicago at the recent meeting of the American Academy of Ophthalmology and Otolaryngology.

Dr. Crisp elected to express his disapproval through the medium of an editorial rather than take the more conventional method of a letter to the editor. In adopting this more formal and official approach he avails himself of his position as consulting editor of the *Journal* and in his use of the pronoun "us" implies general editorial approval. Thus his criticism immediately passes the boundary of personal disagreement and assumes the tenor of an official rebuke. Inasmuch as I have a natural reluctance to endure chastisement meekly, and am moreover quite unrepentant, may I take this opportunity to point out certain points

in Dr. Crisp's presentation where his argument appears to me difficult to follow?

In the address delivered in Chicago I endeavored to give full recognition to the solid accomplishments of the American Board of Ophthalmology and to the high character of their aims and purpose. Four adverse criticisms were offered, all of which I believe to be constructive and calculated to provide better internes, stimulate investigation, and to advance ophthalmology as a whole. These four criticisms concerned, first, the required year of general interneship; second, the so-called basic-science requirements; third, the principle of hospitals and institutions requiring certification of a specialty board as a prerequisite to appointment and promotion; and lastly, a question of the policies of the national ophthalmologic societies, wherein the certificate of the specialty boards is a prerequisite for membership. Dr. Crisp states that these criticisms might, if taken seriously, endanger the whole fabric of the Board's endeavor. I cannot agree that the Board's fabric of endeavor is so thin and tenuous that it is unable to stand constructive criticism. I considered the Boards established in a much more solid basis, and frankly said so in my address.

Dr. Crisp takes exception to three of the above criticisms. The first of these relates to the requirement by the Board of a preliminary year's interneship in a general hospital. This he admits is a debatable question. In essence he defends this requirement with a statement, that considering all phases, the rule is more frequently wise than foolish, that a waste of time is more or less unavoidable, that this is exemplified by the activities of student nurses, and indeed he suggests that my own internes in The Johns Hopkins Hospital are guilty of the same practice. Quite probably Dr. Crisp is correct in this accusation, but is this any argument in favor of waste of time? Dr. Crisp further asks if an understanding of the relation of ophthalmology to general medicine is not desirable. Obviously, everyone must answer this question in the affirmative. This, however, is not the point. The pertinent question is who shall initiate the instruction of the future ophthalmologist in this relation—an internist, a surgeon, a gynecologist, an obstetrician who knows little or nothing of ophthalmology, or a competent ophthalmologist who has spent his life in the study of the question? If the ophthalmologic service can provide this instruction, as any well-organized service should be able to do, I believe they should be entrusted with the task. In his concluding sentence Dr. Crisp states the duty of the American Board is to satisfy the clinical needs of the general community. On this point at least we see eye-to-eye. I expressed it slightly differently in saying that the Board is nothing more or less than an agency to determine the clinical fitness of practitioners of ophthalmology.

Dr. Crisp's next criticism involves the principle that hospitals should make Board Certification a requisite for appointment and promotion. Dr. Crisp states that my condemnation of this principle is extended to include the action of the Veterans Administration in requiring that persons appointed to its attending and consulting staffs be diplomates of the Boards representing their specialties and also in granting a 25-percent increase in salary to members of the full-time staff who obtain certification. In stating that I condemned this practice, Dr. Crisp makes an unwarranted assumption. In my address, I cited this action of the Veterans Administration as a contribution to the power, strength, and prestige of the Boards and as an example that Board certification might well mean actual dollars in the pockets of the diplomates. In no place in my address did I condemn this action of the Veterans Administration. Further on in Dr. Crisp's editorial, returning to the same subject, he refers to the action of the Medical Board of The Johns Hopkins Hospital in which that body refused to accede to the principle that certification by any specialty board be a condition of appointment or promotion

to any position on the staff of The Johns Hopkins Hospital, and their subsequent circulations of this resolution. This action Dr. Crisp characterizes as a "rather unpleasant slap at standardization." It is peculiar, however, that in his discussion and criticism Dr. Crisp does not similarly indict the Council of Medical Education and Hospitals and the House of Delegates of the American Medical Association, who somewhat belatedly have expressed similar views and have now taken official action condemning this practice.

For some peculiar reason Dr. Crisp appears somewhat puzzled that I did not adversely criticize the American Board of Otolaryngology, whose certificate Dr. Crisp states is "usually rather easier of attainment." I confess this did not occur to me, nor is it altogether clear even now why I should assail the Board of another specialty, about which I know nothing. The dual membership of the Academy and the relative severity of the two Boards were not subjects of my address.

Dr. Crisp next accuses me of an exaggerated fear that the application of the principle, presumably of the requirement of certification for appointment, will endanger the research institutions. I assure Dr. Crisp I have no such fear. Fortunately, the research institutions of the country are, far and large, under the control of intelligent men. In my address I merely speculated on what would be the effect did institutions accept such a stifling stricture.

Dr. Crisp's concluding charge concerns my opinion of the present policies of the national societies in which Board certification is made a prerequisite for membership. Here I stated, "If I am correct in my idea of the lines along which ophthalmology must henceforth develop, the present policies of the national societies lie squarely across this pathway." Here Dr. Crisp accuses me of exaggeration. He presents no arguments controverting my views on the future development of ophthalmology, although here there is obviously ground for differences of opinion, and it is quite probable Dr. Crisp and I may hold radically different views. Dr. Crisp contends that the national societies already fully comply with my "desideratum," and that no scientist can be regarded as an ophthalmologist unless he possesses the knowledge of clinical ophthalmology demanded by the American Board. On these conclusions, I am in complete disagreement with Dr. Crisp. I am prepared to admit that our concepts of the future development of ophthalmology, and our definitions of an ophthalmologist, may be so different there is no probable meeting of minds. I fail, however, to see where fundamentally different concepts of a problem justify the charge of exaggeration.

Baltimore, Maryland.

An answer to Dr. Woods

Editor,
American Journal of Ophthalmology:

I am glad to have an opportunity to glance through Dr. Wood's comments. Incidentally I notice that, because I once used the word "us" in referring to my colleagues in ophthalmology, Dr. Woods assumes that I am indulging in the editorial "we" and therefore imply general editorial approval. Dr. Woods should know by this time that the policy of the *American Journal of Ophthalmology* has been to encourage each editorial writer to express his own individual opinions. As to Dr. Wood's lightly expressed suggestion that I was availing myself of editorial privilege, the editorial writer is surely no more privileged than an Academy president whose presidential address is not open to discussion.

In a general way I believe I correctly interpreted the tenor of Dr. Wood's remarks concerning the American Board of Ophthalmology. I may have gone astray a little as to his attitude with regard to the Veterans Administration and its beneficial recognition

of those having certificates from the Boards. The atmosphere created by the context led me to assume that this was among the disapproved activities of the Boards. I have met others who received the same impression.

Dr. Woods is certainly mistaken in supposing that I was accusing his internes of wasting time. Mere inspection of my question (Am. J. Ophth., 31:348 (Mar.) 1948—first paragraph, column 2) will indicate that I referred to systems rather than to persons. Oft-repeated performance of routine duties inevitably involves waste of time so far as the education of the individual is concerned.

My remarks about the certificate of the American Academy did not criticize the Board of Otolaryngology but suggested a certain result in regard to the Academy's certificate of membership.

I am content to have my editorial read in conjunction with the presidential address itself and with Dr. Wood's present letter. My purpose was not to find fault but to analyze the situation.

Denver, Colorado.

The serology of trachoma

Editor,
American Journal of Ophthalmology:

In 1944, I made serologic investigations upon trachoma patients. The number of these investigations was small, but in the following years I did not have an opportunity to go on with the work. I am, therefore, reporting the results already obtained in the hope that someone will be interested in continuing these studies.

I shall explain briefly what has already been done and what I intended to do. The supposition is not an entirely new one. For some time the connection between trachoma and the lymphatic apparatus has been well known (Angelucci, Kuhnt, and so forth). In my opinion, trachoma does not rank as an independent disease of the lymphatic system, but is rather only a symptom of one general lymphatic disease.

Both microscopically and clinically, trachoma resembles other diseases of the lymphatic system. The vascular picture in the conjunctiva is frequently strikingly similar to that in lymphatic leukemia. True acute trachoma is very like the "drüsenfieber" of Pfeiffer.

TABLE 1
Results of the Paul-Bunnel test in 32 cases of known trachoma

No. of Patients	Reading	Percent
8	1:112	25
4	1:224	12.5
5	1:28	15
1	1:448	3
12	1:56	37.5
2	1:896	6

* It is generally stated and accepted that a reading up to 1:56 is normal; over 1:56 is positive.

TABLE 2
Results of the Paul-Bunnel test in 11 cases known to be free from trachoma

No. of Patients	Reading	Percent
1	0:00	9
1	1:14	9
4	1:28	36
5	1:56	46

With these thoughts in mind, the Paul-Bunnel test was made in 32 cases of trachoma. As controls, the same serologic tests were made of 11 cases in which no trachoma was present but in which the following eye diseases had been diagnosed—3, serpent ulcers; 1, acute glaucoma; 1, keratoconjunctivitis sicca; 1, keratitis lymphatica; 1, wound from BB-shot; 2, marginal ulcers; 1, hematoma of the lids; 1, interstitial keratitis. The results are given in Tables 1 and 2.

Since many of my patients were young soldiers, some of them may have been artificially infected with trachoma. It was intended, therefore, as the next step to make serologic examinations of numerous patients with trachomatous pannus, as well as

of patients in whom trachoma had been positively diagnosed (MacCallan).

It was further intended to do a number of animal experiments, using the Paul-Bunnel reaction. Someone who reads this may be interested in developing these ideas.

LUMINOUS CROSS FOR FIXATION

Editor,
American Journal of Ophthalmology:

I have not seen the following idea published, yet it has proved valuable in my practice. It is difficult to do a fundus examination on old persons with small pupils, who cannot fix the eyes on an object. With nothing to fixate on, they continue to move their eyes.

I bought a small bottle of luminous paint and a brush, then painted two pieces of adhesive tape. On the wall directly in front of a chair in the dark room, I pasted these two pieces of tape in the shape of a cross. The cross was then covered with Scotch tape to hold it in better position and to keep the surface clean.

Fall River, Massachusetts.

BOOK REVIEWS

TABULAE BIOLOGICAE. Volume XXII (Oculus). Pars I. Uitfeverij, Dr. W. Junk, Amsterdam, 1947.

Of this monumental collection of biologic data, a volume of 408 pages, the first part of four on the eye, has appeared. It is fittingly prefaced by an appreciation of the work and enthusiasm of Kurt Steindorf, without which this great undertaking could never have been launched. Three other parts are in preparation in which data on vegetative physiology and physiologic optics will be presented. Like its predecessors the book is intended for reference, and, as a repository of every imaginable fact that can be expressed in numbers, it could not be surpassed.

This volume presents in tabular form all available data arranged in several chapters each of which has a most extensive list of references. In the first chapter, Hermann Kahmann deals with the eyes of invertebrate animals. Fifty pages of tables record such facts as the number and position of eyes, size and position of various ocular structures, and extent of visual fields of innumerable species of animals. The second chapter of more than a hundred pages by Stefanie Oppenheimer deals with metric and descriptive characteristics of the human and animal eye. The section which deals with the measurement of the bony orbit of primates is accompanied by 54 figures on 11 plates. The other part of the chapter deals with the lids and most extensively with the color of iris in relation to race, heredity, age, and pigmentation of hair.

In the third brief chapter Dejean and Granel describe the eye of the vertebrate embryo; 12 pages suffice for this. The fourth chapter by Steindorff presents the descriptive anatomy of the eye of vertebrates and man in 126 pages of tabulation and an extensive bibliography. In the remaining pages Nordmann discusses the anatomy and physiology of the pupil in vertebrates, and Ascher discusses the intraocular pressure and intravascular pressure in the eyes.

The index also lists those contributions in Volumes I to XXI of Tabulae Biologicae which refer to the eye.

F. H. Haessler.

AN INTRODUCTION TO THE PRESCRIBING AND FITTING OF CONTACT LENSES. By Dickinson and Hall. London, England. Hammond and Hammond and Co. Ltd., 1946. 168 pages. Index and 97 illustrations, Price, one guinea.

This publication, the first to be written in England on the subject of contact lenses, contains general information on the methods of fitting of molded and ground contact lenses. It contains chapters on the history, optical principles, and sphere of utility of the contact lens. There is a great deal of pertinent material as to the fitting of contact lenses and their usefulness.

While this book may give the ophthalmologist and optician an overall picture of contact lenses, there are many who feel that the techniques more recently evolved permit more rapid and accurate fitting than those described in this book. The chapter on the sphere of utility needs more strict scientific direction.

Francis W. Parker.

BULLETINS ET MEMOIRES DE LA SOCIÉTÉ FRANÇAISE D'OPHTHALMOLOGIE Published by the Members of the Board. Volume 59, 1940-1946.

This volume contains the membership lists of the Société Française d'Ophthalmologie, the transactions of the scientific sessions, and the minutes of the meetings from May 20, 1946, to May 23, 1946.

The first part contains the discussions about G. Renard's new ophthalmoscopic atlas and seven lectures about various fundus diseases. A. Fritz's paper, concerning the relation diameter of retinal veins and arteries has to retinal metabolism is one of the most interesting. So is Mme. S. Schiff-Wertheimer's and Mlle. G. Gaillard's study of the intravenous use of novocaine in thrombosis of the retinal veins. The authors use 1-percent novocaine solution of which as much as 10 cc. is injected very slowly. Improvement should be noticeable on the same day. If it is not, the injection should be repeated, at first daily, later two or three times per week, until 10 injections have been given. The prognosis of branch thrombosis is most favorable with this treatment.

The second part includes 16 lectures on corneal and conjunctival diseases and their treatment and it brings many interesting details, especially the symposium on corneal surgery. P. Sourdille's paper on complete keratoplasty, M. Franceschetti's study on the technique of this operation, and L. Paufique's comparison between complete and incomplete keratoplasty are valuable contributions.

The third and fourth parts record papers on varied topics. The biochemistry of the lens, the familial incidence of glaucoma, the symptomatic and surgical treatment of glaucoma were described at length. Special emphasis should be given to Kalt's lecture on iridencleisis, Coppez's lecture on microdiathermy puncture with the pyrometric electrode, Szymanovky's lecture on demi-Elliot, and Mme. Schiff-Wertheimer's symposium on the complications of diathermy coagulation in retinal detachment. Drouet, Thomas, Herbenvol, and Henry reported on five cases of recurrent vitreous hemorrhage which were caused by intestinal parasites (ascarides). A cutaneous reaction was helpful in the diagnosis. Verrey's study on the cytology and bacteriology of the aqueous may elucidate the etiology of uveitis and the detection of latent focal infections.

The etiology of uveitis was widely discussed. J. Babel discussed benign ocular leptospiroses. R. Nertoux and R. Chercheque reported their investigation of blood cultures from the gums in uveitis associated with alveolar pyorrhea. Amsler described, once more, his experiments on a blood-aqueous barrier, using the same equipment and technique as in earlier work described in Ophthalmologica 111:155, 1946. A. Franceschetti and V. Bischler analyzed the pharmacodynamics of Adie's syndrome. C. E. Joyle and A. G. Ourgand discussed retinal adaptation.

Alice R. Deutsch.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjuctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

1
ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Deller, J. F. P., O'Conner, A. D., and Sorsby, A. **X-ray diameters of the living eye.** Proc. Roy. Soc., S.B. 134:456-466, Sept. 30, 1947.

To measure the diameters of the globe the subject undergoes 15 minutes preliminary dark adaptation. He is then seated facing the x-ray apparatus in a darkened room with his head immobilized in a clamp. A slit beam of Roentgen rays 0.5 by 50 mm. is projected so that it traverses the eyeball with the plane of the beam at right angles to the diameter to be measured. This excites the sensation of vision where the beam transects the retina. By moving the beam from side to side without changing its direction with respect to the diameter and questioning the patient as to his visual sensations, it is possible to determine a position where the beam is tangential to the retina, that is, the position where the reported sensation is that of a point of light. This position is marked by an exposure on a film introduced in front of the eye. The beam is then moved until it is again tangential at the opposite pole and its position again marked. On the developed film the distance between the two images gives the length of the diameter; thus any selected diameter can be measured provided its ends abut on the retina. As to the axial length, this is measured by determining the lateral projection of the posterior pole of the eye on a film by the method already described. A true lateral radiograph of the cornea is then taken on a dental film held at the inner canthus. A special cone is used carrying a cross-wire in its central ray, which impresses its image on both films. After development, the films are related to each other by superimposing the images of the cross-wire and the axial length measured between the corneal image and the slit image. Measurements may be regarded as accurate to the extent of ± 0.5 mm., the width of the slit.

A series of tables is presented. One displays the findings in 45 eyes of which routine clinical examination of refraction was combined with the measurement of the three diameters of the eye. A second shows the relation of diameters to each other and deviation from spherical shape in relation to refractive state; a third shows the volume of globe calculated on the assumption that the eye is ellipsoidal

(ratios of log. of volume/log. of the individual diameters). A fourth shows the volume in a series of eyes measured by L. Weiss (1897), assessed against the present series, the validity of the assumption as to calculated ellipsoid volume, and the application of the formula of ratio of log. of volume to log. of axial length. The fifth shows the relation of the computed total refraction to the axial length.

Theodore M. Shapira.

Wolff, Eugene. **A note on the attachments and action of the ciliary muscle.** Tr. Ophth. Soc. U. Kingdom 65:164-169, 1945.

The author attempts to describe the relationships of the origin of the ciliary muscle, the scleral spur and the ligamentum pectinatum. They all develop from a continuous mass of mesodermal cells in the neighborhood of the future angle of the anterior chamber. In the adult the tendinous fibers of the ciliary muscle arise partly from the scleral spur and from the ligamentum pectinatum. The percentage of origin from each structure seems to vary in different eyes and in different portions of the same eyes. In many cases the fibers of the ligamentum pectinatum pass outwards to give a tendinous attachment to some of the circular fibers and also to some of the radial fibers of the muscle, which form a tendinous ring.

The most posterior muscle fibers give place to the delicate muscle stars of Salzmann and are attached to fine elastic fibers continuous with the lamella of the suprachoroid. These posterior attachments of the ciliary muscle, consisting largely of delicate elastic tissue, seem to be adapted to allow the posterior ends of the muscle to pass forwards during contraction and to guide them back to their original positions on relaxation. Because of this, the action of the ciliary muscle causes as little disturbance to the choroid as possible. The ciliary muscle has no attachments to the ciliary processes, therefore, it is difficult to explain how it can draw the ciliary processes forward as is often stated. The forward movement of the ciliary processes would tighten those fibers which pass backwards to the posterior capsule of the lens and relax the anterior fibers of the zonule. The entire muscle gets thicker with contraction and this increases the cross-sectional diameter and may act as a sphincter to the ciliary ring. (5 figures.) Beulah Cushman.

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Knisely, M. H., Bloch, E. H., Eliot, T. S., and Warner, L. **Sludged blood.** Science 106:431-440, Nov., 1947.

An outline and summary of 16 years of observation and experimentation is presented. The circulation of blood in the vessels of the internal organs of living anesthetized animals—amphibians, reptiles, birds and mammals—and in the bulbar conjunctiva of unanesthetized animals and man was observed. In 600 patients who had a wide variety of diseases the blood was changed from the normal, relatively fluid, state to a circulating sludge. This observation is not offered only as a criterion for the diagnosis of disease. Sludged blood does not traverse the smaller vessels and it is believed that this change in character is one of the fundamental processes of pathologic physiology that produces tissue damage fundamental to many diseases.

The observations on the conjunctiva were made with the corneal microscope familiar to the ophthalmologist. (1 figure, 53 references.) F. H. Haessler.

Mann, Ida. **Induction of an experimental tumor of the lens.** Brit. J. Ophth. 31:676-685, Nov., 1947.

Pathologists state that any tissue capable of cell division is capable of develop-

ing cancer yet neoplasms of the lens are unknown to ophthalmologists. Although mitoses occur in the subcapsular epithelium throughout life. It is not likely that the lens tissue is simply inherently resistant to malignant change or that the capsule inhibits new growth either by the tension it exerts or by its properties as a semipermeable membrane, preventing access of the required stimulus to the lens cells. This is not likely since lenses with ruptured capsules do not become malignant. A third possibility is that the lens owes its immunity to its lack of blood supply.

Pathologic techniques for the induction of experimental cancer include the use of a chemical carcinogenic agent such as methylcholanthrene, and the investigation of inbred laboratory animals. The first experiment consisted of the injection of the chemicals into the lens in situ of rabbits followed by repeated slit lamp examinations. No reactions whatever occurred for 10 months. The second experiment involved the transplantation of the lens to a new position where it could receive an ample blood supply. Mice were used and the chemically treated lenses, with capsule ruptured were implanted in the flank. Thirty-eight experiments were done and 26 tumors resulted; of these, three were cancers of subcapsular epithelium. These were highly malignant, true carcinomas and were reproduced exactly by transplantations. These tumors were chemically identical with lens substance and there was no doubt that they arose from the subcapsular epithelium of the lens. Thus lens epithelium is capable of becoming malignant and its poor blood supply is most probably a factor in its immunity. (9 photographs.)

Morris Kaplan.

Smelser, G. K., and Pfeiffer, R. L. **Influence of grenz rays on cell division and wound healing in the corneal epithelium.** Arch. Ophth. 39:1-8, Jan., 1948.

The eye is subjected to many forms of radiation for the purpose of treatment or diagnosis. Among these are the grenz rays, which have been used extensively for the past fifteen years. They are soft rays of 1 to 4 angstrom units, intermediate between the ultraviolet and the usual roentgen rays, and have some biologic properties in common with both. Grenz rays have been found of value in the treatment of superficial ophthalmic conditions, such as corneal ulcer or episcleritis.

The authors treated normal rats' eyes and eyes that were burned with the thermophore. Single exposure to grenz rays (410r) greatly inhibited cell division in the corneal epithelium for approximately five days. Grenz rays had no effect on the rate of epithelization of thermal burns made within six days of the irradiation. Thermal burns made eight days after a single irradiation healed more slowly than normal in 12 of the 13 animals studied. (2 figures, 11 references.)

Euler, P. **Blindness through wood alcohol and its treatment, particularly with short wave diathermy.** Klin. Monatsbl. f. Augenh. 112:172-182, 1947.

In 20 cases of wood alcohol poisoning hot packs, subconjunctival and retrobulbar salt injections, retrobulbar injection of atropine and shortwave treatment of the eyes were given to produce hyperemia with increase in local metabolism. Short wave treatment proved beneficial in 90 percent of the patients who were subjected to it. (Bibliography.)

Max Hirschfelder.

Feigenbaum, A. and Kornblueth, W. **Human conjunctiva grafted on the chorioallantois of chick embryos.** Arch. Ophth. 39:67-79, Jan., 1948.

The experiments reported here show that it is possible to maintain human conjunctiva in fairly healthy condition outside the body by grafting conjunctival fragments onto the chorioallantoic membrane of developing chick embryos. The chief obstacle to be overcome in these experiments is native infection of the conjunctiva, which can be controlled only to a certain extent with the use of penicillin. The method presented seems to offer possibilities of a systematic study, under conditions excluding somatic factors, of the histogenesis of pathologic changes of the conjunctiva in various diseases, especially those caused by viruses. (7 figures, 3 references.)

R. W. Danielson.

Grignolo, Antonio. **The action of streptomycin on experimental infection of the eye produced by organism sensitive to streptomycin.** Boll. de la Soc. med.-chirurg. di Pavia, nos. 3 and 4, 1947.

Infection of the cornea and anterior chamber were produced in rabbits by the following organisms: Escherichia coli, Proteus vulgaris, Klegsiella pneumoniae (Friedlanderi), Pseudomanas aeruginosa, B. subtilis, Staphylococcus aureus. Identical inoculations were produced in both eyes. In most cases one eye was used as a control and the other was treated. Streptomycin ointments and irrigations were used in the corneal infections and subconjunctival and anterior chamber injections were used in the chamber infections.

Infections of the cornea produced by E. coli, B. proteus, B. Friedlanderi, B. subtilis and S. aureus treated within 12 hours responded to treatment. After 24-48 hours streptomycin was ineffective. Infections with B. pyocyaneous were not altered at any time. Ointments were found to be superior to irrigations. Infections of the anterior chamber by E. Coli and B. pyocyaneous were more resistant to treatment than the corneal infections. Injections of streptomycin into the anterior chamber two hours after inoculation arrested infection with E. coli but were ineffective in the pyocyaneous group. Injections after 12 hours were of little value. Subconjunctival injections produced no changes at all.

Experiments in vivo and in vitro have shown that there is no interference between the action of penicillin and that of streptomycin. The ointment contained 100,000 gamma per gram and was applied every three hours day and night. The solutions contained 100,000 gamma per cc. for irrigations and subconjunctival injections. A total of 50 gamma was injected into the anterior chamber.

Layton, A., Morgan, M. W., Jr., and Olmsted, J. M. D. **Refractive changes pro-**

duced by injection of fluids into the vitreous humor. Am. J. Physiol. 150:568-571, Oct., 1947.

Diets rich in galactose and intravenous injections of galactose have produced cataracts in the rat. The mechanism involved was thought to be an accentuation of the osmotic difference between the lens and aqueous humor resulting from a decreased permeability of the lens capsule.

The high incidence of cataracts and the refractive changes in human diabetics have therefore been attributed to abnormal osmotic pressure relations of the body fluids resulting from a high blood sugar. To ascertain whether local osmotic changes could also cause lens or refractive changes the effects on cats' eyes of intravitreal injections of hypotonic and hypertonic fluids was studied. If more than 0.25 cc. was injected, corneal edema from increased intraocular tension occurred. Similar temporary refractive changes, measured by retinoscopy, resulted after every fluid injection. A change of 1.00 to 3.00 diopters in the direction of hypermetropia was present in each animal injected. No lens clouding was seen. Amyl nitrite inhalations given with the injections inhibited the refractive changes. Adrenalin injections alone produced hypermetropia and the latter was increased when the adrenalin was given at the same time as the vitreous injections.

The cause for the refractive change was considered to be a mechanical one dependent on the blood content of the ciliary body and the consequent increase or decrease in the power of the lens through the action of a relaxed or tonic suspensory ligament. F. M. Crage.

Leopold, I. H., and Steele, W. H. **Penetration of locally applied BAL into the anterior chamber of the rabbit eye.** Arch. Ophth. 38:192-198, Aug., 1947.

Studies were made on rabbits to determine the penetration of BAL (2,3-dimercaptopropanol) into the aqueous when applied to the cornea. BAL essentially neutralizes the arsenic in burns due to lewisite (2-chlorobetachlolorinylarsine).

Aqueous solutions of BAL deteriorate more rapidly than solutions in ethylene glycol and the more dilute the aqueous solutions of BAL the more apparent the loss. Greater penetration into the aqueous humor occurs from the use of a 5-percent solution of BAL in water than from the use of a 5-percent solution of BAL in ethylene glycol. BAL penetrates more readily from a water-containing base, such as K-Y jelly, than it does from a nonaqueous base, such as Friedenwald-Fuqua ointment. John C. Long.

Rosso, Silvio. **A study of purine substances in the aqueous humor.** Ann. di ottal. e clin. ocul. 72:628-536, Oct., 1946.

By experiments on rabbits and man Rosso finds that the purine content of the aqueous varies more or less directly as the purine content of the blood serum. His researches indicate that inflammatory manifestations of the gouty type may occur in ocular tissues as well as elsewhere whenever conditions are favorable for the precipitation of uric salts, since uric acid is always present in the ocular fluids in varying quantities and is increased in hyperuricemia. Harry K. Messenger.

Schmerl, Ernst, and Steinberg, Bernhard. **The role of the diencephalon in regulating ocular tension.** Am. J. Ophth. 31:155-158, Feb., 1948. (6 figures, 12 references.)

Sondermann, R. **The physiology and pathology of intraocular pressure.** Klin. Monatsbl. f. Augenh. 112:113-124, 1947.

Sondermann does not believe that the intraocular pressure is maintained as a result of secretion of aqueous humor. The intraocular pressure is the result of a

damming up of the venous circulation on its way through the sclera and is only modified by the regulatory activities of the ciliary body and the canal of Schlemm. The intraocular pressure is shown to be the difference between the 50 mm. pressure in the vortex veins and the 25-mm. osmotic pressure. The pressure in the veins sinks abruptly after they leave the sclera. With advancing age the sclera becomes still denser, but an increased formation of aqueous and often enlarged Schlemm's canal regulate the intraocular pressure and keep it normal. Only if these emergency mechanisms fail in their regulatory functions because of sclerosis or inflammation will the intraocular pressure establish itself on a level higher than normal. This is the case in chronic simple glaucoma. Acute glaucoma is caused by a sudden exclusion of the regulatory mechanism. It is usually caused through a sudden pushing forward of the iris which blocks the chamber angle and prevents the outflow of aqueous. The pressure in the retinal veins is only about half of that in the vortex veins and is only slightly higher than the intraocular pressure. Almost no outside pressure is exerted on these retinal veins. The ciliary arteries with their thicker walls and more adventitia are also less exposed to outside squeeze and the question of stagnation within their lumen is of less importance. However, a certain amount of choking may exist and may act as an equalizing factor for the variations in the general blood pressure. This is particularly important when there is severe vascular hypertension. The persistence of higher arterial and venous pressures within the scleral channels causes a more even and a more quiet blood circulation within the eyeball. The circulatory stagnation prevents the rapid circulation that is sometimes required in pathologic, especially in inflammatory, conditions. Paracentesis and medication with pilocarpine lessen this stagnation and dilate the vessels which leads to improved circulation.

tice and the consistency of repeated measurements of accommodation and vergence. Am. J. Ophth. 31:191-198, Feb., 1948. (5 tables, 7 references.)

Campos, Raffaele. **Practical notes for cylinder skiascopy.** Ann. di ottal. e clin. ocul. 72:726-748, Dec., 1946.

This succinct and clear exposition of the practice of cylinder retinoscopy is designed to do for Italian ophthalmologists what others have already done for those whose language is English, German, or French. Harry K. Messenger.

Candela, J. R. **Retinal complications in diabetes mellitus.** Arch. Soc. Oftal. hispano-am. 7:851-857, Sept., 1947.

The mechanism by means of which the retinal lesions in diabetes mellitus are produced is still entirely unknown. Formerly it was believed that the fundus picture found in hypertensive retinopathy was the same as diabetic retinopathy but later studies have proved that they are entirely different. A constant fact in diabetic retinitis is the decrease of the resistance of the capillary wall. Electrophoretic tests were made to determine alterations in the plasma proteins. In adequately treated diabetes mellitus one finds slight reduction of the total proteins with reduced level of albumin and an increased amount of B globulin. It has been proved that high protein diabetic diets are valuable in the prevention and treatment of diabetic retinitis. J. Wesley McKinney.

Carlevaro, Gianfranco. **Importance of the diagnosis of asymmetry or decentration in the prescribing of corrective lenses.** Ann. di ottal. e clin. ocul. 72:588-596, Oct., 1946.

A frequent cause of accommodative asthenopia is asymmetry or decentration of the cornea with respect to the pupillary aperture. This lack of coincidence of the optical center of the cornea with the center of the pupil gives rise to astigmatism quite independently of the curvature of the refractive surfaces of the eye. Correction of the corneal astigmatism as determined with the ophthalmometer is not enough; the total resultant astigmatism of the eye must be accurately corrected.

For objective determination of the astigmatism Carlevaro recommends axial or macular retinoscopy with Maggiore's retinoscope, which employs a transparent glass reflector instead of an opaque mirror with a central aperture. The asymmetry or decentration of the cornea may be studied with Gullstrand's square, but keratoscopic examination is neither easy nor rapid, and only the subjective tests can be relied upon for accurate determination of the total astigmatism.

In view of this factor of decentration it can be readily seen why the degree of astigmatism and the direction of the principal meridians may vary with the size of the pupil. Hence sometimes the astigmatic correction for near must differ from that prescribed for distance. A patient may incur accommodative asthenopia by holding his work very close, even though he is not myopic, in order to benefit by the smaller pupillary aperture which reduces the astigmatism due to asymmetry.

Attention is likewise called to the importance of asymmetry in the optics of aphakic eyes, especially where there is a coloboma, and of eyes that have suffered trauma in the anterior segment.

Harry K. Messenger.

Cibis, Paul. **Contribution to the pathology of the adaptation of definite retinal areas.** Arch. f. Ophth. 148:1-92, 1947.

The author studies form and color fields campimetrically. His purpose is to determine the time parameter involved in this test. He uses a Bjerrum screen 130 by 130 cm. in size at a distance of 115 cm. The time is measured which passes by before an object of definite size, color,

and brightness disappears. By help of a stopwatch the disappearance of the object is recorded for one or more meridians at different distances from the point of fixation. Daylight serves as illumination. The objects used are Engelking-Ecksteins pigments that have an area of 10, 20, and 50 square millimeters and are placed on a gray background of the same brightness. Practically the procedure is almost the same as in ordinary campimetry except that usually in perimetry slight movements of the object are preferred whereas in studying the "local adaptation" of the retina the object must be completely at rest. The resulting curves for the normal show a certain range of variation and resemble Wertheim's curve for peripheral visual acuity. Deviations from the normal were found in disturbances of color vision, diseases of the choroid, retina, visual pathways, and cortex, and in cerebral trauma. The studies will be completed by a second contribution.

E. Schmerl.

De Leonibus, Fernando. **Investigations concerning the shape of the conical cornea.** Boll.d'ocul. 26:433-448, July, 1947.

Six conical corneas were meticulously measured. Readings were taken at the center, and 4, 8, 12 and so on to 32 degrees above, below, nasally and temporally from it in the two meridians of greatest dioptric difference. In six tables and diagrams the results concerning radius of curvature and refractive power are demonstrated. These measurements, taken with the Helmholtz-Javal-Schiøtz ophthalmometer, show that there was no approximately spheric zone in the center in any of the eyes and that a decentration of the corneal vertex was present in all of them; the refractive power was unusually high in at least one of these eyes, in which it was reaching 140 diopters maximally. (Bibliography.)

K. W. Ascher.

Goldmann, H. **Contribution to angioscotometry.** Ophthalmologica 114:147-158, Sept., 1947.

The purpose of this study was to investigate the basic mechanism underlying the scotomas which conventionally are designated as angioscotomas. Goldmann has found that the width of a certain angioscotoma (near the upper border of the blind spot) depends characteristically upon the contrast between target and background: The greater the contrast the narrower the scotoma. The increase in width caused by the decreasing contrast occurs in asymmetric fashion, the scotoma gaining in width chiefly in the direction in which the target is carried across the field. The increase in the width of angioscotomas that occurs characteristically after compression of the globe or neck compression also occurs in asymmetric fashion. The point of disappearance of the target remains more or less the same while the place of reappearance is shifted under these experimental manipulations.

Similar observations have been made with a setup that creates an artificial scotoma when a projected target disappears over a bandshaped area because of lack of a reflecting background. The author explains the asymmetric character of the natural angioscotomas and their artificial counterparts as a phenomenon of spatial summation (see Marshall and Talbot, Visual mechanisms, the Jacques Cattell Press, Lancaster, Pa., 1942).

Peter C. Kronfeld.

Hartridge, H. **Some fatigue effects on the human retina produced by using colored lights.** Nature 160:538-539, Oct. 18, 1947.

From his experiments the author concludes that fatiguing the eye to rays from about 65μ to 55μ causes changes in the red, yellow, and green parts of the spectrum but fatiguing the eyes simultaneous-

ly to these rays and to greenish-blue rays, produces little or no effect. The latter rays appear to inhibit the onset of the fatigue effects which rays from 65μ to 55μ would otherwise produce.

F. M. Crage.

Hecht, S., and Hsia, Y. **Colorblind vision. 1. Luminosity losses in the spectrum for dichromats.** J. General Physiol. 31:141-152, Nov. 20, 1947.

The authors feel that there is no completely adequate theory of color vision. The one having the most reasonable basis is that formulated by Young in 1807 which assumes the existence of three receptor systems in the retina for blue, green, and red. Young's supposition that colorblindness was due to the loss of one of these three receptor systems is still held in some form or other.

The author's dark-adapted foveal threshold test values of normal and color blind persons supports this theory of colorblindness but not the notion that these three systems contribute equally to the brightness of the spectrum. Because of this and because the color sensations reported by color blind persons do not support the idea of a lost or inactivated receptor system, they feel that a fresh explanation for colorblindness is necessary.

F. M. Crage.

Jaeger, Alfred. **The changes in the barrel shaped distortion by the eye.** Arch. f. Ophth. 148:152-161, 1947.

The author finds this distortion more pronounced for closer than for more remote objects. Demonstration of the phenomenon by the use of the checkerboard pattern is correct only for a definite distance of the observer from the object.

E. Schmerl.

Lindner, K. **The influence of environment and heredity on the development of school myopia.** Wien. Klin. Wchnschr. 59:867-868, Dec. 31, 1947.

Lindner mentions various theories about school myopia and discusses Steiger's theory which attempted to explain the elongated myopic eye on the basis of growth variation. The author obtained statistics from the Vienna and St. Poelten arch-diocese where he found that 48 percent of the Catholic clergy were myopic. He presents tables showing the amount of myopia, age and occupation of the parents of the priests most of whom did manual labor.

The anlage for both school myopia and for high myopia is similarly and rather evenly distributed in the population, therefor an environmental factor must be assumed. If this factor appears late, then the development of myopia begins late, too. Even though we are sure that so-called school myopia is hereditary, it does not develop without the influence of an environmental factor.

Theodore M. Shapira.

Mihalyhegyi, G. **New experiences with contact lenses.** Ophthalmologica 114:159-167, Sept., 1947.

The author's experiences with plastic contact lenses made from molds of the anterior segment have not been unusual and will therefore hardly be "new" to the American reader. Peter C. Kronfeld.

Obrig, T. E. **Solutions used with contact lenses.** Arch. Ophth. 38:668-676, Nov., 1947.

A research program was conducted throughout the year 1945 to obtain more information concerning the causes and prevention of clouding of the corneal epithelium by solutions used with contact lenses.

To eliminate varying personal equations, Obrig used his own eyes exclusively and employed the same pair of contact lenses in all experiments. The addition of carbon dioxide or oxygen to solutions for use with contact lenses did not

affect the time in which corneal clouding occurs. Solutions with osmotic pressure as high as that of 2.8-percent sodium chloride solution can be worn if the pressure is increased gradually. Correct osmotic pressure is important. The addition of amino acids and methyl cellulose to the solutions increases the time before clouding of the cornea occurs.

R. W. Danielson.

Pace, Mario. **The "invisible spectacles" and their practical use (new contact lenses made of plastic).** Boll. d'ocul. 26:481-504, Aug., 1947.

This is a rather complete review of the pertinent literature with justified criticism of the exaggerations noted. (3 pages of references.) K. W. Ascher.

Rocco, Alfredo. **Color vision.** Arqu. brasil. de oftal. 10:79-91, 1946.

The various grades of perfection or defect in color vision are briefly described, from heptochromia down to monochromia and achromia. The significance of the chromatic sense in relation to aeronautics is discussed. W. H. Crisp.

Ronchi, Vasco. **Recent theoretical developments concerning shape and color perception.** Boll. d'ocul. 26:281-316, May, 1947.

Rayleigh's rule lacks experimental verification. The resolving phenomena of the retina as well as of the photographic film are to be understood energetically rather than in the classic formal way. The photochemical deductions of Hecht will prove more helpful in understanding of the visual and acoustic phenomena, and also of color vision. The trichromatic explanation of color vision will have to be replaced by the assumption of a binary retinal mechanism; this will also explain the Purkinje effect in reduced illumination. (16 figures, 23 references.)

K. W. Ascher.

Santoni, A. **Contribution to the study of the form of the posterior segment of the globe in very high ametropia.** Ann. di ottal. e clin. ocul. 72:577-587, Oct., 1946.

With the aid of leaden casts made from formalin-hardened eyes it was found that the curvature of the posterior segment of both highly myopic and highly hypermetropic eyes is approximately elliptical and that the radius of curvature in each case is noticeably less than in emmetropic eyes. Diagrams with measurements and calculations are given.

Harry K. Messenger.

Schober, Herbert. **Color blindness due to head injury.** Arch. f. Ophth. 148:93-100, 1947.

In 1945 the patient was treated for a gunshot wound in the midline of the occipital bone. The underlying tissue was slightly involved. An examination of the eyes in 1946 revealed homonymous scotomas in the right upper quadrants. Color vision was tested according to Holmgren, Stilling and Nagel. Symptoms of protanopia as well as deuteranopia were found. Purkinje's phenomenon was missing, the adaptation to light was delayed. The findings are discussed in relation to the theories of color vision.

E. Schmerl.

Schober, Herbert. **Night myopia and its causes.** Arch. f. Ophth. 148:171-186, 1947.

Starting from the observation that at night sailors give their telescopes a turn to the minus side the author studied the phenomenon of night myopia in 12 persons. Several hundred tests with telescopes were made and night myopia was found in almost all of the tested persons. The average value amounted to -2.0D, with a standard deviation of ± 1.5D. To some extent the adjustment of the telescopes or the amount of night myopia depended upon the weather and the color of the observed object. With dimness the

composition of the natural light shifted to bluish green and the myopia increased by —0.5D. The myopia increased with the decrease in brightness of the observed object. The night myopia stimulated retinal sensitivity to light and it decreased the visual acuity. As possible factors that might produce night myopia the tendency to increased accommodation in the dark, and the increase in sensitivity to light are considered. This increased sensitivity in night myopia is caused by the formation of larger circles of diffusion on the retina. In emmetropia punctual imagery would have been produced. (References.)

DIAGNOSIS AND THERAPY

Borioni, Domenico. **Metastatic meningococcic ophthalmia favorably treated with penicillin.** Boll. d'ocul., 26:337-339, May, 1947.

Intravenous, intramuscular, and subarachnoid application of penicillin influenced favorably a case of meningococcic meningitis associated with unilateral endophthalmitis in a two-year-old girl.

K. W. Ascher.

Bothman, Louis. **Minor surgery of the eye.** Surg. Cl. North America pp. 46-55, Feb., 1948.

This article is written for the nonophthalmologic practitioner. It is a series of brief descriptions of ocular diseases and injuries with equally brief consideration of the fundamentals of treatment. The author recommends the use of the 2-percent solution of pyribenzamine in cases of allergic conjunctivitis. The McReynolds technique for transplanting pterygia is described briefly. He also describes briefly the principles of closure of lacerations of the lids, emphasizing that through-and-through lacerations should be closed in layers.

The author describes principles of the removal of foreign bodies and warns against the use of anesthetic ointment by the patient in the home because of possible delayed corneal healing and the production of corneal ulceration. The treatment of various types of burns of the globe and of serpentic ulcers is outlined. For the treatment of acid burns irrigation with 3-percent sodium bicarbonate solution is suggested and for alkali burns 10-percent neutrol ammonium tartrate.

Benjamin Milder.

Fox, S. A. **Use of preserved cartilage in plastic surgery of the eye.** Arch. Ophth. 38:182-191, Aug., 1947.

Cartilage obtained at autopsy and preserved in merthiolate solution may be used in plastic surgery. Under proper conditions it may be kept for use as long as

two years. The use of isografts with this "pickled" cartilage is often easier and more satisfactory than the use of fresh autografts. Seventeen cases are reported in which preserved cartilage was used as an isograft. In four cases it was used in reconstruction of the lid to replace a lost tarsal plate. In nine cases preserved cartilage was used inside the orbit to repair depressions of the floor and walls due to fractures. The results were good.

OCULAR MOTILITY

Bartels, Martin, **Nervous factors affecting the ocular movements.** Arch. f. Ophth. 148:107-110, 1947.

Using a schematic drawing the author enumerates a number of factors which in men, mammals, and lower vertebrates cause ocular movements. Stimuli might arise from the vestibulum, the neck, the frontal cortex, the corpora quadrigemina, the nucleus ruber, the cerebellum, the sympathetic, the cutis, the retina, the cochlea, the contents of the orbit, the movement of the limbs or the pelvis and from the urge to fuse the images.

E. Schmerl.

Cushman, B., and Sarro, L. **Vertical anomalies—presentation of vertical anomalies in 100 cases studied.** Quart. Bull. Northwestern Univ.-Med. Sch. 22:17-20, 1948.

Patients with strabismus who get no improvement from lenses or means other than surgical usually have a vertical imbalance. In operative failures a vertical imbalance is almost always found. A bilateral recession gives the most satisfactory result in uncomplicated convergence excess. A conservative recession of one or both external rectus muscles is indicated in uncomplicated divergence excess. If these anomalies are complicated by a vertical imbalance, there may be an undercorrection, but usually a marked overcorrection. In convergence insufficiency with secondary divergence excess or primary divergence excess, if complicated by hypertropia the result may be a definite overcorrection, but more probably an undercorrection. Of 100 patients who had ocular muscle imbalance 71 had vertical anomalies which required surgery. Vertical anomalies should be suspected in every case of imbalance. Irwin E. Gaynon.

Miles, P. W. **Clinic for binocular problems. Three emmetropic patients treated with aniseikonic glasses over 8- to 10-year periods.** Am. J. Ophth. 31:333-336, March 1948. (3 references.)

Ribas Valero, Ramón. **Biastigmatism and bicylinder combinations.** Arch. Soc. oftal. hispano-am. 7:858-889, Sept., 1947.

The subject is extensively reviewed.

J. Wesley McKinney.

Zavalia, A. U. **Divergence paralysis.** Arch. Soc. oftal. hispano-am. 7:890-898, Sept., 1947.

The characteristic findings of divergence paralysis are listed. There is homonymous diplopia for all objects beyond a certain distance, usually 25 to 50 cms. The angle of the deviation remains unchanged or decreased in secondary

positions of gaze. If an object is brought near to the patient, the two images approach each other and finally fuse when the object is 15 to 20 cms. away. When the object is brought still nearer, insufficient convergence causes crossed diplopia. Prisms base out give binocular single vision throughout the entire field of binocular fixation. There is no restriction in the field of fixation in either eye. The angle of the deviation is relatively constant on repeated examinations. The author reports a case of divergence paralysis. A 40-year-old man complained of diplopia of a few days duration. The images are not clear and, in trying to fixate, the images separate more. The eyes seem to be normal and no past history of any illness is given. There is hyperopia of one diopter in each eye. When vision is fixed at distance the eyes seem to be in orthophoria, but the patient sees a double image of light at 5 meters. Fusion of the images begins at 33 cms. and is held when the light is brought to 9 or 10 cms. consequently there is no convergence insufficiency. The diplopia is overcome with a prism of 10 diopters base out. Binocular single vision is conserved in all the fields of vision with this prism. Repeated examinations gave the same findings. Adequate glasses were prescribed and a month later at the patient's last visit all troubles had disappeared.

CONJUNCTIVA, CORNEA, SCLERA

D'Ombrain, Arthur. **The surgical treatment of pterygium.** Brit. J. Ophth. 32:65-71, Feb., 1948.

The author enthusiastically presents a method of surgical removal of pterygium evolved over many years. To the principles of excision of the head and the leaving of a perilimbal strip 4mm. in width, he added complete excision of all submucosal tissue from the limbus to caruncle. No sutures are used. This has yielded uniform success for the past seven years. He also discusses the pathology of the condition and concludes that pterygium is an irritative and secondarily a degenerative disease. (5 figures.)

O. H. Ellis.

Murray, W. B. **Notes on trachoma.** Canad. M. A. J. 58:81-82, Jan., 1948.

In his "notes on trachoma" the author aims to arouse the interest of the general practitioner to the problem of trachoma in western Canada. There the disease exists among Indians, Orientals and Central Europeans, and should be looked for in service men returned from Africa and Italy. Inflamed eyes should be watched with suspicion and prompt, proper treatment started before the serious complications appear. Symptoms, signs, diagnosis, and treatment are briefly discussed.

Francis M. Crage.

Panzardi, Domenico. **Use of fetal membranes for conjunctival plastic, particularly for pterygium.** Boll. d'ocul. 26:332-336, May, 1947.

Amniotic membrane was used in seven cases of severe symblepharon, one case of diffuse papillomatosis, and in 11 cases of pterygium. The results were satisfactory except in eyes with symblepharon. The fetal membranes were obtained from definitely healthy mothers and were kept in Ringer's solution before the implantation.

K. W. Ascher.

Romero, Eduardo. **Keratitis due to vapor of alcohol.** Arch. Soc. oftal. hispano-am. 7:912-914, Sept., 1947.

The author has observed an especial type of keratitis caused by alcohol fumes from shampoo. He does not agree with Valdecasas, who believes that the corneal damage is due to the caustic effect of chirmoya seeds, commonly steeped in al-

cohol and used as a treatment for head lice. J. Wesley McKinney.

Sorsby, Arnold. **The incubation period of ophthalmia neonatorum.** J. Obst. and Gynec. Brit. Emp. 54:842-847, Dec., 1947.

Of 290 consecutive cases of ophthalmia neonatorum, 84.5 percent occur within the first 10 days of life. In the first 5 days of life one sees 70 percent of gonococcal ophthalmia, 50 percent of diphtheroid, 37 percent of staphylococcal and occasional cases of inclusion blennorrhea. Of inclusion blennorrhea 20 to 25 percent begins between the 11th and 15th day of life.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Drell, M. J., Miller, C. P., and Bohnhoff, M. **Gonorrheal iritis.** Arch. Ophth. 38: 221-244, Aug., 1948.

A technique for producing gonorrheal iritis in the rabbit eye is reported. The percentage of eyes yielding cultures containing the gonococcus fell progressively during the first week after inoculation. Thereafter, the infection became chronic in about one third of the eyes. It seemed that injury to the lens was the major factor in making the infection chronic.

The rabbit eyes exhibited many of the gross appearances of human gonorrheal iritis. The histologic picture was initially that of an acute fibrinocellular response and later that of a chronic inflammatory process. The inflammation remained localized to the anterior segment of the eye. The experimental infection lent itself well to in vivo testing of gonococcidal agents.

John C. Long.

Hayden, R. **Questionable sympathetic ophthalmia.** Proc. Ophth. Soc. Vienna p. 13, April 27, 1924.

Seven weeks after perforating injury to the left eye mild iridocyclitis of the right eye started. The exciting left eye was not enucleated because it had comparatively good vision and because, according to Hayden and Lindner, there is still no proof that removing of the exciting eye really can influence the course of established sympathetic inflammation. Vision in both eyes became nearly normal.

F. Nelson.

Lindner, K. **Case of expulsive hemorrhage operated with scleral trephining.** Proc. Ophth. Soc. Vienna p. 12, April 27, 1942.

A man, 63 years of age, with traumatic dislocation of the lens into the vitreous body, was operated upon with a loop after iridectomy. Immediately after removal of the lens a large choroidal detachment developed temporally. The sclera was immediately trephined and blood released through the opening. The bleeding stopped but another choroidal detachment began in the nasal section. Here again the sclera was trephined. The eye became blind. F. Nelson.

Pincus, M. H. **Aniridia congenita: report of five cases; genealogy; possibilities of treatment.** Arch. Ophth. 30:60-66, Jan., 1948.

Five cases of bilateral aniridia, with the genealogic charts and a discussion of the possibilities of treatment, are presented.

Several useful procedures are available to help unfortunate persons with this defect to obtain and to maintain useful vision. In order to be effective, treatment should be started early in life. Tatooing of the outer portions of the cornea, extraction of a cataractous lens and the wearing of an opaque contact lens with a 3 to 4-mm., clear central pupil are the methods of choice. (4 figures, 5 case histories, 12 references.) R. W. Danielson.

Scholz, R. O. **Epivascular choroidal pigment streaks, their pathology and pos-**

sible prognostic significance, additional cases. South. M. J. 41:112-118, Feb., 1948.

Three more cases are added to a previous report, and the literature is reviewed. The generally poor prognosis after the discovery of the fundus picture is discussed. The streaks consist of clumps of pigment deposited serially over partially but not completely sclerosed choroidal vessels. They appear not unlike a chain of black beads, and usually begin one to two disc diameters below the papilla, extend radially, and sometimes are seen far in the periphery. They must be differentiated from angioid streaks, pigment streaks following retinal detachment, and perivascular choroidal pigment atrophy. (8 figures, references.)

GLAUCOMA AND OCULAR TENSION

Brausewetter, G. **Comparison between Elliot trephining and Holth iridencleisis.** Proc. Ophth. Soc. Vienna p. 6, Jan. 19, 1942.

Seventy-five patients with chronic simple glaucoma submitted to Elliot trephining in one eye and Holth iridencleisis in the other. The tension was lowered in 77 percent of all cases. Second operations were necessary after 11 Elliot operations and 19 Holth. Eventual blindness resulted within four years in 13 Elliot operations and 11 Holth. No infections followed the Holth procedure. After the Elliot operations five eyes were infected and three lost. F. Nelson.

Christini, H. **Precapillary and capillary function in glaucoma.** Ann. d'ocul. 180: 530-541, Sept., 1947.

The same vascular degenerations which are at least a factor in practically all glaucomas also exist throughout the body. They are principally arteriolar. Microscopic thinning and atrophy is observed much more frequently in arterioles than venules. Ocular tension is an expression of the hydrostatic pressure in the uveal vessels diminished by the colloidal osmotic force of the plasma proteins, or the balance between intra-ocular secretion and reabsorption.

To coordinate precapillary and capillary function with intra-ocular tension, similar studies were made in 20 persons between the ages of 45 and 65 years with glaucoma and numerous similar persons without glaucoma. These studies included nasal septum oscillograms representing the capillary bed, subungual photoplethymographs representing the precapillary bed and measurements of intra-ocular tension. Coördinated graphs of these data were made before the inhalation of amyl nitrate during the vasodilative phase, and during the vasoconstrictive phase. In the glaucomatous before amyl nitrate inhalation the pulse volume was reduced in the nasal septum but not subungually. During the vasodilative stage changes in the nasal septum were practically nil and during the subsequent vasoconstrictive stage, pulse reduction, especially subungually, was less than in the non-glaucomatous. In the glaucomatous, the capillary and especially the precapillary bed does not react normally to vasodilators. One of the principal and initial causes of ocular hypertension in chronic glaucoma is precapillary arteriolar degeneration occurring also in the posterior uveal vessels. The hydrostatic factors involved in intra-ocular secretion and absorption are altered and vascular permeability is affected. Chas. A. Bahn.

Schorn, Julius. **Glaucomatous attack and weather.** Arch. f. Ophth. 148:121-128, 1947.

Ninety-one patients are studied. In 78 percent of the cases the glaucomatous

attack coincided with atmospheric changes, especially those in temperature.

E. Schmerl.

Wessely, Karl. **Problems of glaucoma.** Arch. f. Ophth. 148:111-120, 1947.

I. Glaucoma in excessive myopia. The author surveys 54 of his cases of glaucoma in myopia of more than −8.0D. He emphasizes the insidious development of the increase in tension, the pale, atrophic appearance and rather shallow excavation of the papilla and the frequent occurrence of glaucoma in surgical aphakia. II. Hemorrhagic glaucoma. A report of cases with thrombosis of the central retinal vein in one eye and chronic glaucoma in the other eye is presented. A common cause of both phenomena is considered.

E. Schmerl.

CRYSTALLINE LENS

Alexander, G. F. **The size of the standard eye and limbal sections.** Tr. Ophth. Soc. U. Kingdom. 65:232-239, 1945.

The author presents a highly mathematical paper with formulas for the type of knife that is best suited for a perfect cataract section. The perfect cataract section must be adjusted to the size of the lens. He found that the one-third section would suffice for ordinary cataracts, the two-fifths section should be reserved for especially large and hard lenses, and the four-ninths sections for the intracapsular removal of the lens. He discusses five characteristics of the perfect cataract section. A Beer pattern knife was accepted as ideal with a blade 26 mm. long, a base of 7 mm., and a point angle of 20° with a stop to prevent the point from moving within the limbus farther than 14 mm. (3 figures.)

Beulah Cushman.

Daily, Louis, Jr., and Daily, Ray K. **A procedure to facilitate intracapsular forceps extraction of intumescent cataracts.** Am. J. Ophth. 31:328-330, March, 1948. (7 references.)

Roper, K. L. **Lancaster's technique of cataract extraction.** Illinois M.J. 93:81-91, Feb., 1948.

The author describes in detail his modification of Lancaster's technique for cataract extraction. This technique is best suited for combating the major postoperative complications:—loss of vitreous, expulsive hemorrhage, delayed reformation of the anterior chamber, hyphema, iris prolapse, retinal detachment, secondary glaucoma and high degrees of astigmatism.

Essential features of the procedure are the use of the O'Brien akinesia with basal anesthesia, topical cocaine, and for prolonged effect, the subconjunctival and retrobulbar injection of a mixture of novocaine-pontocaine-cobephrin. Superior rectus bridle suture is used. The conjunctiva is incised from nine to three o'clock at the limbus and dissected back in the superior quadrant. After making a limbal groove with the Lancaster guarded knife, three appositional corneo-scleral sutures, similar to those used by McLean, are placed but not tied. Section is made with keratome and scissors. The author prefers peripheral button-hole iridectomy and an intracapsular extraction of the lens, where possible. Sutures are tied over the conjunctival flap, drawing the flap over the wound.

Results of 125 consecutive cataract operations, performed by this technique, are summarized. Seventy-four percent of the author's operations were of the intracapsular variety. The incidence of complications is strikingly low in all respects. The average postoperative astigmatism amounted to 0.85 diopters.

Benjamin Milder.

Schiff-Wertheimer, S., and Sedan, J. **Total lens extraction in retinal detachment.** Ann. d'ocul. 180: 513-520, Sept., 1947.

Is retinal detachment more frequent after intra-capsular or extra-capsular lens

extraction? Older statistics say yes, but the authors believe no, because older statistics were inaccurate and incomplete. The 1.3 percent of retinal detachment that statistically follows cataract extraction depends on numerous factors. Complications and failures are as frequent as vascular and other senile degenerative processes. Removal of the lens capsule in intracapsular extraction potentially increases the vitreous vibration and alters retinal tension especially during ocular movement. In the predisposed, retinal detachment is thus facilitated. In the young, intracapsular extraction is contra-indicated and in the middle aged it does not increase the risks of failure. The authors analyze 25 cases of retinal detachment in eyes which were previously operated upon for cataract by the intra-and extracapsular methods. Of these detachments, 60 percent were greatly improved by subsequent operation. In three of them 1½ years elapsed between the injury and the retinal detachment. Generally speaking, the authors believe that the technique and the trauma involved in the operation is more important than the type of operation technique employed. The importance of accurate and complete binocular examination is stressed. Chorioretinal disease and other evidence of constitutional or other degenerations due to injury or disease which may effect the advisability of the cataract extraction as well as the risks of the subsequent retinal detachment are sought. RETINA AND VITREOUS

Bagley, C. H. **Retinal detachment. A survey of the etiology and results of treatments on phakics and aphakics.** Am. J. Ophth. 31:285-289, March, 1948. (26 tables, 14 references.)

Dollfus, M. M. A. **Late results in retinal detachment surgery.** Ann. d'ocul. 180:547-552, Sept., 1947.

This interesting study of approximately 50 eyes successfully operated upon ten or more years previously for primary retinal detachment is most enlightening. In 90 percent, the location of original tears was visible. The operative techniques used included those of Gonin, galvano cauterization with juxtachoroidal tunnelization of Paufique, Coppez, cauterization with the pyrometric electrode, Weeve's with the perforating electrode, Guist's with potassium hydrate pencil, and Hudello's by electrolysis. The first was apparently the most efficient. Only 15 percent developed recurrences, and of these only 10 percent occurred more than six months after operation. The number of recurrences paralleled the number of detachments in the contralateral eye. Recurrences had no relation to the operative technique used. Drawings made at the time of operation showed that little or no progressive damage had been done in either retina or vitreous by the retinal detachment operation. Seventy percent did not have pathologic lens changes of importance. Detachment in the eye that was not operated upon was responsible for more cataracts than were observed in the eye that was. In 35 percent vision was better ten or more years after than at the time of operation. In fifty percent of those studied the ultimate vision in the eye with a successful operation was 0.2 or worse. The other visions ranged rather uniformly up to 0.6.
Chas. A. Bahn.

Eisenberg, I. J. **Congenital retinal fold with vitreous disorganization. A case report.** Am. J. Ophth. 31:337-338, March, 1948.

Foroni, Camillo. **New pathogenetic conception and treatment of retinosis pigmentosa.** Boll. d'ocul. 26:505-524, August, 1947.

Observation of 15 cases during 30 years convinced the author that retinosis pig-

mentosa was caused by an intoxication of the inner membranes of the eye that originated from a hidden chronic infiltration inflammation of the bulbar conjunctiva; heredity and febrille diseases are contributing factors. Without histopathologic evidence this etiologic conjunctivitis was assumed because of the difficulty encountered during retrobulbar or subconjunctival injections. For it, intensive massaging of the bulbar conjunctiva with a glass or metal spoon is suggested. This new procedure, called massoressi, produces extensive hemorrhages which the author considers to be pathognomonic. He even advocates it as a preventive measure to prevent retinal disease and claims secure and permanent arrest of retinal degeneration, rarefaction and eventual disappearance of the retinal pigment spots, and sometimes even an increase of visual acuity and improvement of visual fields and of hemeralopia.

Grafton, E. G., Jr., and Guyton, J. S. **The value of injecting saline into the vitreous as an adjunct to diathermy operations for retinal detachment.** Am. J. Ophth. 31:299-303, March, 1948. (3 tables 5 references.)

Lindner, K. **Two especially interesting cases of shortening of the bulbus.** Proc. Ophth. Soc. Vienna p. 3, Jan. 19, 1942.

A male, 31 years of age, with disseminated choroiditis, dislocated lens and amaurosis in left eye developed a retinal detachment in the right eye one month after cataract operation which improved temporarily under conservative treatment. Deterioration started again 1½ years later and vision was reduced to recognition of hand movements eccentrically. No tear was found. First the upper half of bulbus was shortened by 2 mm., two months later the lower half, and partial reattachment and improvement of the function resulted. Deterioration again set in after several months. Eventually complete reattachment was achieved after a third shortening operation in the temporal section. Corrected vision 6/24 and Jaeger 2 resulted.

The other patient; a man, 47 years of age, who had been operated upon for nuclear cataract in each eye at the age of eight years, developed retinal detachment in the right eye three years later. The eye became blind. The left eye developed chronic glaucoma 22 years after the cataract operation. A "trephining-cyclodialysis" was performed with loss of some vitreous. Subsequently there was retinal detachment of short duration. After reattachment there again was increase of tension. About seven years later retinal detachment was again noted but no tear found. A large radial resection of sclera was done above and temporally without improvement. A second excision in the upper half of the sclera several months later was temporarily successful. During the second postoperative week the scleral wound ruptured and a large staphyloma resulted. This was excised and the sclera sutured with silk. The end result was a partial reattachment and the corrected vision equalled 3/36. F. Nelson.

McKerman, R. L., and Lavery, F. S. **Bilateral retinal detachment.** Tr. Ophth. Soc. U. Kingdom 65:409, 1945.

The history of a patient with bilateral retinal detachment, 49 years of age, is presented. In each eye a "staphylomatous area" of the sclera was found during the operation. The first eye was suspected of having an intraocular tumor during the operation and the eye was enucleated. Ten months later he lost vision in the other eye because of a retinal separation. A staphyloma of the sclera was found and the conjunctiva closed.

Beulah Cushman.

Meyer-Schwickerath, Gerhard. **"Gliomarosettes" and similar formations.** Arch. f. Ophth. 148:139-151, 1947.

Forty-six cases of "gliomas" (retinoblastomas) were studied histologically. Thirteen times rosettes were found. They are described as spherical incompletely closed shells consisting of 60 to 70 tumor cells each. Folding of the retina and retinal rosettes occurred in nine of the 46 eyes. The retinal rosettes consisted of cells of the sensory epithelium. They are said to differ from the gliomo rosettes morphologically as well as ontogenetically. The discussion of the findings refers to Bailey's and Cushing's work. (References.) E. Schmerl.

Michaleson, I. C. **Retinal artery occlusion. A report illustrating the pathogenesis of the fundal appearances and the effect of acetyl-choline.** Brit. J. Ophth. 32:111-117, Feb., 1948.

The author presents an interesting experience of occlusion of the macular branch of the inferior temporal retinal artery of six days duration in a woman, 41 years of age. A retrobulbar injection of acetyl-choline relieved the spasm and restored the circulation; however, there was no notable change in the diameter of the other retinal vessels. The capillary stasis and anoxemia resulting from the diminished arterial inflow had produced a large white opacity of the retina which rapidly disappeared after the injection. (4 figures.) O. H. Ellis.

Loewenstein, Arnold. **Intramural vascular system (vasa vasorum) in retinal vessels.** Arch. Ophth. 39:9-26, Jan., 1948.

Vessels within the wall of retinal vessels have not hitherto been recognized. In general, only the walls of vessels with a caliber greater than 1 mm. are provided with vasa vasorum. The latter arise from adjacent small arteries and form a dense capillary network in the adventitia.

In unstained retinal specimens cleared in glycerin the author found that capillaries are present in many sclerosed vascular walls. Hemorrhage into the diseased wall from these intramural vessels is frequent, especially in cases of vasculitis retinae. He has not yet observed intramural retinal vessels in normal eyes.

New formation of vessels in the diseased retina is a well known fact, but the existence of intramural newly formed retinal vessels was not known. They seem to serve to improve a disturbed nutrition of the walls where new vessels have been described. The intramural vessels may serve to transport blood over an occluded or narrowed part of the lumen. (18 figures, 11 references.) R. W. Danielson.

Pridle, Ronald. **Miliary aneurysms with retinal degeneration.** Bull. Guthrie Clin. 7:128-131, Jan., 1948.

The author presents a white male, 12 years of age, with miliary aneurysms of the right eye. There was an associated extensive macular atrophy with pigmentation. Other atrophic and pigmentary areas were present in the lower temporal quadrant. A grayish connective tissue mass covered the lower half of the disc. The hyaloid artery was large and persistent. The eye had never been injured. The child had had severe pneumonia when he was 1½ years old. This was followed by perineal abscess and bilateral otitis media. He had recurrent croup until he was nine years old and tonsillectomy and adenoidectomy when eleven. The youngster is now healthy, robust, cooperative, and intelligent. All clinical and laboratory investigations were negative.

The author says that it will be interesting to observe whether this is truly a case of miliary aneurysms with retinal degeneration or an early case of angiomatosis or Von Hippel's disease.

Francis M. Crage.

Puntenney, Irving. **Vascular fundus disease with especial reference to the classification of Gifford and MacPherson.** Quart. Bull. Northwestern Univ. Med. Sch. 22:74-79, no. 1, 1948.

A modification of the Gifford and MacPherson classification is suggested to include essential hypertension in Groups 1 and 2 and the collective grouping of pure angiospasm with well developed essential hypertension in groups 3 and 4.

Irwin E. Gaynon.

Shapland, C. D. **Traumatic detachment of the retina.** Tr. Ophth. Soc. U. Kingdom 55:187-211, 1945.

The author reports 16 patients with detachment of the retina while in military service. They averaged 12 years younger than a group of 425 civilian patients that he reported in 1933. The reposition was achieved in 10 of the military men and in less than one-half of the civilians. Eleven of the military men were emmetropic or had hypermetropia and there was no aphakia, whereas myopia was common and of higher degree in the civilians.

Beulah Cushman.

Weekers R., Roussel, F., and Heintz, A. **Visual recovery after successful retinal detachment surgery.** Ann. d'ocul. 180:521-529, Sept., 1947.

Defective central and peripheral vision, light adaptation, and fusion frequently follow successful retinal detachment surgery. After three months no operation can restore visual function completely. Central and peripheral retinal degenerations are frequent, as are central scotomas which may cause twilight amblyopia. The chorioretinitis produced by operation shrinks one or more isopters and often disorganizes fusion. Efficient preoperative examination usually indicates the prognosis, the surgical risks involved, and the most desirable technique.

In the twenty-five retinal detachments successfully operated upon by the authors they used superficial non-perforating coagulating diathermy, perforating diathermy, and the evacuation of subretinal fluid with galvanocautery. Repeated extensive detailed examinations were made before and after operation. The importance of potentially pertinent subjective information is stressed.

The rods and cones and the pigment epithelium depend primarily upon the chorio-capillaris for nutrition. The retinal and subretinal fluid is normally biologically similar to the other body tissue fluids. During detachment it becomes lowered, and oxidation and glycolysis are retarded. Evidences of temporary or permanent retinal ischemia and anoxemia are therefore not surprising. Prompt surgical treatment is urgently indicated in all retinal detachments that are not due to neoplasm or inflammation, and if degenerative changes have not made surgical risks prohibitive. Chas. A. Bahn.

OPTIC NERVE AND CHIASM

Bruetsch, W. L. **Unilateral syphilitic primary atrophy of the optic nerves: an anatomic study of two cases.** Arch. Ophth. 30:80-91, Jan., 1948.

Syphilitic optochiasmatic arachnoiditis, which is frequently present in neurosyphilis, has nothing to do with the causation of the atrophy of the optic nerves. The most efficacious treatment of syphilitic optic nerve atrophy is malarial therapy, aided by concomitant and subsequent courses of penicillin, each course consisting of the administration of at least 5,000,000 units. (3 figures, 2 case histories, 8 references.) R. W. Danielson.

Esposito, A. C. **Tryparsamide optic atrophy.** West Virginia M.J. 44, Feb., 1948.

Tryparsamide exhibits a toxic affinity for the optic nerve and its use in central

nervous system syphilis should be controlled by frequent detailed examination of the visual fields, central vision and fundi. The patient should be cautioned as to the symptoms of toxicity. At the first signs of damage tryparsamide should be immediately and permanently discontinued and other measures should be instituted. F. H. Haessler.

Hess, Leo. **Atrophy of the optic nerve associated with tabes dorsalis and with glaucoma.** Arch. Ophth. 38:199-220, Aug., 1947.

It is suggested that the atrophy of the optic nerve in tabes begins behind the bulbus, somewhere in the optic pathways, producing secondary degeneration along the optic nerve and the optic tract as far as, and including, the lateral geniculate body. A congenital or acquired anomaly of the spinal cord may predispose a patient to the development of tabes. It is fair to assume that an analogous irregularity in the structure of the optic nerve and optic tract may account for the variety of the visual defects associated with tabetic atrophy of the optic nerve. Evidence, including clinical cases, is presented to show that tabes dorsalis is not merely a disease of the spinal cord but may involve the diencephalon. The author also demonstrates that definite characteristics of body build and growth are clinically noticeable in tabetic persons with atrophy of the optic nerve, demonstrating an endogenous alteration of the diencephalic area. The above implies that syphilis is the precipitating, not the causative, agent in tabes and tabetic optic atrophy.

Like the primary atrophy of the optic nerve in certain cases of tabes dorsalis, "glaucomatous" atrophy of the optic nerve may be connected with a congenital anomaly of the diencephalic area. Atrophy of the optic nerve is prone to develop either in persons with asthenia associated with acromegaloid features or in those with a pyknic body build associated with signs of adiposogenital disturbance.

John C. Long.

Kaminskaia-Pavlova, Z. **The role of the premorbid state in the beginning of ocular fundus changes after cranial trauma.** Semana Méd. 15:223-225, Feb. 5, 1948.

The author cites four cases of trifling trauma in which she thinks there might be good reasons to suppose that the injury had stirred up previously existing pathologic conditions so as to produce visual deterioration.

The first patient, a man, aged 42 years, sustained a slight blow on the head, and began to complain of nausea and reduced vision. Examination showed descending atrophy of the optic nerve, and the patient had other evidence of tabes. The second patient, said to have been a sharpshooter, suffered a cerebral contusion, with progressive loss of vision. The third patient was a woman of 45 years who had general vascular hypertension and had struck her head in a fall. She underwent spells of loss of consciousness, showed hemorrhages of the eye-grounds, and then some failing of vision, although the latter had previously been normal. The fourth patient was a man of 30 years who suffered reduction of vision after cranial trauma during a bombardment. He had a descending atrophy.

The author does not offer any analysis as to the validity of the previous histories of the patients as related to spurious claims concerning the causes of loss of vision. W. H. Crisp.

NEURO-OPHTHALMOLOGY

Bender, M. B., and Teuber, H. L. **Spatial organization of visual perception following injury to the brain.** Arch.

Neurol. and Psychiat. 58:721-739, Dec., 1947.

The authors discuss the problem as it hitherto had been studied, and concluded that the approach often was general and uncritical. They describe two of 12 cases, which were characterized by a specific disability to localize objects in a limited portion of the field of vision. They examined for reduced visual function, visual perception of spatial relations, and intellectual functions pertinent to generalized orientation in space. There is a complete report of the case of a 22-year-old Marine officer with a shrapnel wound in the region of the right motor cortex. (References.) Bennett W. Muir.

Cogan, D. G. **Neurologic significance of lateral conjugate deviation of the eyes on forced closure of the lids.** Arch. Ophth. 39:37-42, Jan., 1948.

This paper evaluates a diagnostic sign, a variant of Bell's phenomenon, which consists of a lateral conjugate deviation of the eyes on forced closure of the lids. It occurs in persons with intracranial disease.

Cogan finds that this sign is relatively infrequent in persons with no known neurologic disease. Of the present series of 156 persons, it occurred in only 3. With unilateral cerebral disease, a lateral conjugate deviation of the eyes with closure of the lids does occur in a significantly large percentage of patients. It was present in more than one-half of the present series. The deviation is characteristically to the side opposite the lesion (that is, to the side of the hemiplegia and hemianopsia). It occurs with lesions in the anterior or the posterior part of the hemisphere. However, with presumably unilateral lesions of the cerebellum, brain stem or labyrinth, the deviation of the eyes with closure of the lids was not significantly more frequent to one side than to the other.

As a cognate sign of unilateral cerebral disease, deviation of the eyes on closure of the lids supplements, but does not replace, other signs. It may be present or absent when there is, or is not, gross paresis of conjugate gaze. Similarly, it may be present or absent with or without disturbances of the opticokinetic response, and with or without hemiplegic or hemianopic disturbances. (5 references.)

R. W. Danielson.

Javett, S. N., and Samuel, E. **Tumor of the optic chiasma.** Arch. Dis. Child. 22: 248-250, Dec., 1947.

A five-year-old boy had slight frontal headache for two months preceding the discovery of defective vision of the right eye with retention of only some of the temporal field. He had bilateral atrophy of the disc greater in the right eye. Eight hours after lumbar puncture the patient had a severe pain in the back and the right hip, followed by headache and vomiting. X-ray films showed a characteristic enlargement of the anterior part of the sella turcica with excavation of the under surfaces of both anterior clinoid processes and with increased size of the optic foramina, greater on the right side. A diagnosis of chiasmal glioma was made, and surgery done. After the optic nerve had been stripped, a large tumefaction about the size of a pigeon's egg was encountered. It was continuous with the chiasma and extended backward along the optic tracts. Removal of this lesion would have been technically impossible or nearly so. Chiasmal glioma is essentially a condition of childhood. Growth is slow and may not lead to death for many years. The visual effect is bizarre. In the differential diagnosis one must consider craniopharyngioma, pituitary tumor, aneurysm of the

circle of Willis, suprasellar meningioma, and chiasmal arachnoiditis with cyst formation. (6 figures, references.)

Bennett W. Muir.

Puglisi-Duranti, G. **Treatment of neurolues and particularly of tabetic opticoneuritis and neuro-ophthalmic affections.** Riv. oto-neuro-oftal. 22:179-221, May-June, 1947.

The writer reports 21 cases of neurosyphilis in men from 25 to 43 years of age. There were 2 cases of tabetic optic atrophy, 2 of postneuritic optic atrophy, 2 of retrobulbar neuritis, 5 of optic neuritis, 2 third nerve paralysis and 4 of paralysis of the seventh nerve. Chemiotherapy was associated with the simple rachicentesis or subarachnoid injection of air, phenolsulphonphthalein or even arsenic. In almost all cases the treatment was followed by a rapid improvement of the symptoms, a shortening of the duration of the disease and in some cases by the recovery. The meningeal reaction to the subarachnoid injection was never intense. (Bibliography.)

Matteucci, P. **Congenital nystagmus and spasmus nutans with unusual vertical dissociation in an individual with normal visual and vestibular apparatus.** Boll. d'ocul. 26:317-331, May, 1947.

In an eight-year-old boy an odd posture of the head was noted since early life. The head was tilted forward and exhibited slight rotary movements that were not synchronous with the nystagmus present and continued at all times except during sleep. The eyes, with visual acuity of 9/10, emmetropia, binocular fusion and three diopters of exophoria, presented a horizontal-rotary type of nystagmus with a balance-like vertical component which was characterized by elevation of one eye when the other was depressed. Elevation and depression of the eyes were accompanied by lid elevation and drooping and both were irregular in extent and frequency. The frequency of the vertical movements was less than that of the horizontal-rotary nystagmus which occurred about 50 to 70 times a minute. There was no history of severe infection and the parents and seven siblings were healthy. The discussion of the unique observation is inconclusive. Poetzl and Sittig described similar movements in the Hertwig-Magendie syndrome and related them to a lesion in the posterior longitudinal fasciculus. On the other hand one might assume that the spasmus nutans and nystagmus are congenital and the vertical dissociation of the latter could be ascribed to a more recent process, possibly multiple sclerosis. EYEBALL, ORBIT, SINUSES

De Voe, A. G. **Repair of orbital deformities with glass wool.** Arch. Ophth. 38:245-247, Aug., 1947.

Depressed fractures of the orbital floor are frequently associated with traumatic enophthalmos. A similar type of cosmetic defect in the position of the lids may be seen following some uncomplicated enucleations in which there has been atrophy of the orbital fat. Both types of defect may be remedied by the subperiosteal insertion of inert material in the floor of the orbit so as to restore the orbital volume to its original mass. Many materials have been so used. These include autogenous and preserved cartilage, autogenous and preserved fascia lata, bone, tantalum wool, plates, ribbon and acrylic plates.

Glass wool, known as "fiberglas," has been found to be an excellent material for the subperiosteal insertion. It is nonabsorbent, is not affected by tissue fluids, does not produce toxins, is not susceptible to attack by bacteria and is not considered carcinogenic.

John C. Long.

Diaz Gómez, E., and Marín Amat, M. **Two cases of pseudo-tumors of the orbit, one of the inflammatory type and the other of a hydatid cyst. Treatment.** Arch. Soc. oftal. hispano-am. 7:899-908, Sept., 1947.

Two cases of pseudotumor of the orbit are reported. From the clinical standpoint a diagnosis of neoplasm of the orbit was made in both. A 45-year-old woman had developed an almond-sized painless mass in the right orbit at the superior external angle during the previous year. Exophthalmos. edema and ptosis of the right upper lid were noted. Ocular movements were limited in all directions. Upon exploration, an encapsulated mass of inflammatory tissue was removed from the orbit, which also contained glandular tissue from the lacrimal gland. The second patient, a 16-year-old girl, had had an irreductible, painless exophthalmos of the left eye for three months, with ptosis of the left upper lid and limitation of the ocular movements. Visual acuity was almost nil. Upon exploration, liquid was found in the superior part of the orbit which was enclosed in a hydatid membrane. Recovery was uneventful in both cases. J. Wesley McKinney.

Hughes, W. L. **Integrated implants and artificial eyes for use after enucleation and evisceration.** Am. J. Ophth. 31:303-310, March, 1948. (6 figures, 3 references.)

Naffziger, H. C. **Exophthalmos. Some principles of surgical management from the neurosurgical aspect.** Am. J. Surg. 75:25-41, Jan., 1948.

Unilateral exophthalmos necessitates a diagnosis of the type of lesion and its location. Is it orbital, intracranial, or both? Where the protrusion is bilateral the lesion is not removable and decompression is indicated. With normal bulbar extension of 11 to 20 mm. on the exophalmometer it is not always possible to say that a state of abnormal protrusion is present. By looking down on the cornea from above and comparing the positions relative to the superior orbital margin one can determine a difference in the relative positions of the bulbs. Unilateral protrusion suggests a tumor. With the latter a difference of 5 or 6 mm. on the exophthalmometer is usually seen. Goiter, aneurysm, cavernous sinus thrombosis, and mucocele have caused unilateral exophthalmos. Lesions on one side, confined to the anterior part of the orbit should be treated by the ophthalmic surgeon. The anterior route is the operative approach. Reese, Davis, and Benedict have described suitable procedures the choice of which depends upon the location of the lesion.

As early as 1915 the author produced bilateral decompression by a transcranial but extradural route. Visual improvement resulted where bilateral exophthalmos, from general causes, existed.

The experiences gained by such wide orbital exposure has helped when applied to patients with unilateral tumors, for the technique is the same.

Anterior pituitary injections in animals have shown that the increase in orbital content is dependent upon hormonal and constitutional disturbances. Exophthalmometer readings in those requiring surgery have ranged from 22 to 35 mm. About 16 is the average normal.

In thyrotoxicosis decompression should not be delayed too long; the most important surgical indication in this type of exophthalmos is diminishing vision. When decompression is required, the wider the bone removed the better the result. Krönlein and other restricted procedures are very unsatisfactory.

The surgical procedure employed by the author is described in detail. Frontal bone flaps, smaller than originally, are used and the dura is peeled from the or-

bital plate. Removal of bone from the orbit and incision of the annulus of Zinn, where necessary, complete the important steps in the operation. Postoperative progress is described in detail. Bulbar pulsation is easily seen, protrusion is lessened quickly but returns to some degree temporarily. The choked disc disappears quickly without unroofing the optic foramina. The operation for unilateral intraorbital tumors varies but little from this transcranial extradural operation. Other methods of decompression are referred to in brief. Francis M. Crage.

EYELIDS, LACRIMAL APPARATUS

Agnello, F. **Palpebral ephidrosis in the light of modern theories on pathology of the sympathetic system.** Riv. oto-neuro-oftal. 22:222-228, May-June, 1947.

A boy, 15 years of age, complained of continuous lacrimation of both eyes with burning sensation and itching of the lids. The lids showed hyperchromic spots near the orbitopalpebral fold and looked as though covered by water. Injections of atropine gave only temporary relief. The writer suggests that the lesion is probably a result of a disfunction of sympathetic innervation. Melchiore Lombardo.

Armstrong, C. J., and Garcia, F. A. **The use of a composite graft in reconstructive surgery of the lower eyelid.** Plastic and Reconstructive Surg. 3:79-83, Jan., 1947.

Brown and Cannon have used a composite graft from the helix of the ear for nasal reconstruction, and the authors applied this technic to reconstruction of the lower eyelid in four cases. Under local anesthesia all cicatricial tissue removed, the lid margin is straightened and the complete defect is exposed. A pattern of it is mapped out on the aural crus. Then the composite graft is cut with a no. 11 Bard-Parker blade, which cuts through all layers. Interrupted sutures (6-0 silk) are used along both edges to hold the graft in place. One arm of each suture is left long to tie over a vaseline gauze-cotton stent. The donor area is closed without formation of a defect.

The skin on the orbital side of the graft is tailored or removed so that the conjunctiva is used to its fullest extent. If a normally functioning eyeball is present, the skin on the ocular surface of the grafts should be replaced with an oral mucous membrane graft at a secondary stage. (11 photographs.) Alston Callahan.

Fox, S. A. **Some methods of lid repair and reconstruction. V. Displacement of the canthi.** Am. J. Ophth. 31:317-322, March, 1948. (6 figures, 3 references.)

Mohs, F. E. **Chemosurgical treatment of cancer of the eyelid: a microscopically controlled method of excision.** Arch. Ophth. 39:43-59, Jan., 1948.

In the chemosurgical treatment of cancer of the eyelid, as in the treatment of cancer in other sites, the microscopic control is accomplished by means of a process consisting of the following steps: (1) in situ chemical fixation of the tissues suspected of being cancerous by means of a zinc chloride paste; (2) excision of a layer of the fixed tissue; (3) location of the cancerous areas by systematic microscopic examination of the excised tissues; (4) further chemical treatment of the areas demonstrated to be cancerous, and (5) repetition of the process until the cancer, including all its irregular extensions, has been entirely excised.

The chief advantage of the chemosurgical treatment of cancer of the eyelid is the microscopic control of excision afforded by the method. The reliability of the method is attested by the high rates of cure. (15 figures, 6 tables, 8 references.) R. W. Danielson.

Sugar, H. S., and Forestner, H. J. **Plastic implant for sunken lid.** Illinois M. J. 92:219-224, 1947.

A methyl methacrylate implant (27 to 30 mm. in length and 5 to 8 mm. in width) was inserted beneath the orbicularis muscle in 20 patients. Satisfactory cosmetic results were obtained in all. (6 figures.) Irwin E. Gaynon.

Walser, Erwin. **Nida's ptosis operation.** Arch. f. Ophth. 148:129-138, 1947.

Fifteen operations were performed. The results were very satisfactory. The author describes the procedure quoting from Nida (Bull. Soc. Ophthalm. Paris 1928. No. 9, 566): "A narrow tarso-conjunctival strip is pulled through underneath the tendon of the superior rectus. The strip is taken from the margin of the tarsus. The free end of the strip is stitched to the underlying tissue near the site of its origin." E. Schmerl.

16

TUMORS

François, Jules. **Intraocular Schwanoma.** Ann. d'ocul. 180:542-545, Sept., 1947.

Schwanoma or neurinoma, is a tumor which originates in the sheath of Schwann in the cerebro-spinal nerves. Pathologically, its lesions are identical with those in von Recklinghausen's disease. Cell nuclei are small, elongated or truncated at the ends; the protoplasm is reticular or fibrillar and usually elongated. Although not usually malignant it is potentially so, beginning in meningoblasts or nevus cells. Retinal Schwanoma occurs mostly in the young.

In the case reported, a 44-year-old woman with von Recklinghausen's disease had observed visual failure in one eye one month previously. The eye was totally blind when examined. The retina was detached and a large mass was observed in the periphery. The eye was enucleated, with a tentative diagnosis of melanotic choroidal sarcoma. Sections were characteristic of Schwanoma, the site of which depends upon the location of the ciliary nerves. Chas. A. Bahn.

Miller, D., and Bowling, J. L. **Orbital hydatid.** Brit. J. Surg. 35:211-212, Oct., 1947.

A case of orbital hydatid is presented. The patient, a female white child aged 4½ years, complained of poor vision in the left eye. There was a marked exophthalmos, the cornea was directed downward, the nerve head swollen, and the superior rectus paretic. The vision was reduced to counting fingers.

After raising a frontal osteoplastic flap, the frontal lobe was retracted and the orbital plate removed. Under the orbital fascia and fat a glistening cyst was found. After aspiration of clear fluid it was removed in toto. There was a return to normal but the vision was not mentioned.

The cyst wall revealed a typical hydatid membrane. The literature and five other reported cases are briefly described. Francis M. Crage.

Wolff, Eugene. **The origin of the malignant melanomata.** Brit. J. Ophth. 32:72-82, Feb., 1948.

In a carefully prepared article the author reviews the literature and points out the important contributions that have been made regarding the origin of the malignant melanomata. He believes that these tumors do not arise from a single cell type. Malignant melanomata are known to arise from branched chromatophores, proliferation of surface epithelium and nevus cells (of neurogenic origin, since nevus cells are developed from the end apparatus of the sensory nerves). The nevus should be regarded as a composite of these three types of cells; each may proliferate alone or with the others pro-

ducing a malignant pigmented tumor, the final structure of which depends upon the relative proportions of the three types of cells. (7 photomicrographs.)

INJURIES

Amendola, Francisco. **Ocular manifestations of foliaceous pemphigus.** Arq. brazil. de Oftal. 10:105-119, 1947.

This paper to be published later in the American Journal of Ophthalmology.

W. H. Crisp.

Doppel, H. **Iron splinter, healed in iris, removed after 37 years.** Proc. Ophth. Soc. Vienna p. 10, April 27, 1942.

In a man, 42 years of age, showing signs of endophthalmitis with hypopyon, a foreign body could be demonstrated in the iris near the pupillary margin directly and with X-ray. Uneventful recovery followed removal of the splinter. F. Nelson.

MacRae, Alex. **Injuries to the eyeball excluding intraocular foreign bodies.** Tr. Ophth. Soc. U. Kingdom 65:305-317, 1945.

The author reports 5178 patients with eye injuries who came to the Eye Hospital in Newcastle in 1943, and 113 of them, or 2.2 percent, were serious enough to require admission. The total time lost to industry with these injuries was 17.4 years. Among patients with nonpenetrating injuries were some with hypopyon ulcers, vitreous opacities and dendriform ulcers. Beulah Cushman.

McLaughlin, R. S. **Chemical burns of the human cornea.** Tr. Am. Acad. Ophth. pp. 112-114, Nov.-Dec., 1947.

Employees who are subject to ocular burns should be trained in their emergency treatment. First aid should be with tap water from a faucet, bucket, or a hose. Attempts at chemical neutralization should be postponed until later and when the chemical action is understood. After emergency irrigation the treatment may include the instillation of 0.5 percent pontocaine, irrigation with a siphon of saline, and the removal of foreign matter, preferably with cotton swabs, chemical analysis of the offending substance, staining with fluorescein, a second washing, and restaining. Diseased epithelium is then removed with cotton swabs under the biomicroscope. Final irrigation with stainless merthiolate and instillation of sulfathiazole ointment is followed by closing of the eye with a cover. Patients with local or general evidences of infection are hospitalized. Potentially permanent corneal opacities are treated with 0.5 percent solution of choline chloride instillations, four or five times daily. Sorsby's amniotic membrane grafts are advised in all deep corneal and conjunctival burns. In 800 consecutive cases reported, permanent corneal opacities occurred in less than two percent.

Chas. A. Bahn.

Rudd, Charles. **Injuries to the eyeball excluding intraocular foreign bodies.** Tr. Ophth. Soc. U. Kingdom. 65:318-327, 1945.

One hundred cases of perforating injury were reviewed. Enucleation was necessary in 25 patients. There was one case of sympathetic ophthalmia in which vision of both eyes was lost. Suppuration occurred in seven eyes.

SYSTEMIC DISEASE AND PARASITES

Tassman, I. S. **Ocular changes in the metabolic diseases.** Virginia M. Monthly 75:70-74, Feb., 1948.

The main portion of this article deals with the ocular changes related to dia-

betes. After a brief consideration of the relationship between the autonomic nervous system and the endocrine glands, the author describes the ocular picture produced by sympathetic hyperfunction and hypofunction. The former is characterized by proptosis, widened palpebral fissure, and tearing, with dilated pupil and the latter is manifest as Horner's syndrome. The author discusses briefly the Laurence-Moon-Biedl syndrome, in association with pituitary hypofunction.

In diabetes, there is no correlation between blood sugar level and the appearance of retinal hemorrhages, but there is a correlation between blood sugar level and transient changes in refraction, accommodation, and vision. Oculomotor pareses occur in diabetes. Rubeosis of the iris is described. The retinal changes are predominantly hard yellow exudates, sometimes in circinate arrangement, deep retinal hemorrhage, preretinal hemorrhage and sometimes retinitis proliferans. They depend on the duration of the diabetes rather than its severity. The hemorrhages are probably not on an atheromatous basis. The retinal picture may be altered by coexistent diseases, such as nephritis or hypertension. However, even under these circumstances one may still recognize the underlying characteristic features of diabetic retinosis. The author, with Friedenwald, associates these retinal hemorrhages with increased capillary frigility. Benjamin Milder.

Valdecasas, Pedro. **Ocular myiasis.** Arch. Soc. oft. hispano.-am. 7:909-911, Sept., 1947.

A 15-year-old boy had external ophthalmomyiasis, the larvae of the genus Oestrus ovis were found in the bulbar conjunctiva. J. Wesley McKinney.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Cogan, D. G. **Students' model for demonstration of action of the extraocular muscles.** Arch. Ophth. 39:92-93, Jan., 1948.

The author describes a model eye made from a golf ball. Screws are placed at the muscle insertions and strings are tied to them. By pulling the strings, one can visualize the action of each muscle in any position of the eye. (1 reference, 1 diagram.) R. W. Danielson.

Crisp, W. H. **Early development of the filtration operations for glaucoma.** Am. J. Ophth. 31:277-285, March, 1948. (29 references.)

Fishbein, M. **Medical leadership and education.** Tr. Am. Acad. Ophth. pp. 98-106, Nov.-Dec., 1947.

Medical education, medical leadership and the public health are closely alligned and parallel. They can no more be normally separated than can the marrow and nerves in the bone. The destructions and dislocations of war only temporarily change these relationships. The history of the American Medical Association parallels that of medical education and the public health. Progress in the reduction of infectious diseases is shown by the decreased prominence and second place which typhoid and similiar diseases now

occupy in text-books as compared with only one generation ago.

A recent visit by the author to our Latin neighbors further illustrates these facts. In the United States, tuberculosis is the seventh cause of death with a rate of approximately 42 to 100,000 population; in several South American countries, its death rate is approximately 400 per 100,000. In Chile, 400 of every 1000 babies born die before their first birthday.

In evaluating our medical progress in this, the last bulwark of democratic medicine, comparative methods illustrate the importance especially of preventive medicine. In our medical schools the average class varies between 40 and 100; while in Cuba, one first year class had 1200 students. Adequate medical facilities, equipment, teachers, and discipline are woefully lacking in many Latin American countries. Graded and orderly advancement in training, internships, residencies, as well as the control of specialties, hospitals and nurses are practically nonexistent. The recognition of specialists by boards of certification is unique in this country as are special associations for clinical and study groups. Occasionally, some highly advanced specialist rises above the general sub-standard and accomplishes much, but the general level of medical leadership, education and public health is lamentably low. Disease, like crime, doesn't pay. Death, sickness and deficiency are bed fellows in both.

Of all God's creatures, physicians have the most prolonged infancy. The price of leadership, especially medical, is high and rightly so. The real medical leader of today and especially of tomorrow must first have a deep understanding of the natures of men. He must always and in all ways be steadfast and fair and, just as important, he must be brimful of moral and professional honesty. He must be public-minded and above pettiness, giving without ulterior motives generously of his time and efforts for the good of all.

Investigation has shown that we doctors are not the invariable suckers which we are pictured and generally believed to be. Strange as it seems, ophthalmologists over a period of years have not done badly for themselves economically.

The only free and independent medical profession left in the world is in the United States. To preserve it, bureaucracy and government domination with its stupidities and inefficiencies must be fought every day and in every way by all of us. Now the trend is fortunately away from the governmental domination of medical practice and the medical profession. Your Academy is and has been a material contributor to the quantity and quality of medical leadership, education and the public health. Chas. A. Bahn.

Foster, John. **An oculist in Switzerland.** Brit. J. Ophth. 32:83-111, Feb., 1948.

This is a travelogue of visits to many Swiss ophthalmological centers. It is written so engagingly and refers to such a wealth of interesting work that one is not only moved to admiration of Swiss ophthalmology but is tempted to go see for oneself. O. H. Ellis.

Fiedenwald, J. S. **Standardization of tonometers.** South. M. J. 41:44-47, Jan., 1948.

The data and recordings from instruments made according to the specifications of Schiøtz have been generally accepted as reliable. However, due to differences in manufacturing, many instruments vary widely from the desirable standards. This led to the establishment by the American Academy of Ophthalmology and Otolaryngology of a committee on standardization of tonometers. Three checking stations are now in operation, the charge for each instrument checked is $5.00. All American manufacturers have now agreed to produce

instruments which conform to the standards that are considered essential. All instruments are independently tested by the Electrical Testing Laboratories, Inc., New York, and those passing are certified. (References.) Bennett W. Muir.

McCoy, D. A. **Experiences in industrial eye problems.** Tr. Am. Acad. Ophth. pp. 107-114, Nov.-Dec., 1947.

The 45 million industrial employees in the United States all potentially need industrial ophthalmic service. This should include pre-placement examination for the job, as well as periodic and diagnostic examinations and treatment for all eye injuries and diseases. Twenty percent of all employees are visually handicapped for their specific jobs. The approximately one thousand eye injuries which occur daily cost in medical care and compensation alone over one billion dollars yearly. The importance of preventive and industrial ophthalmology is illustrated in the epidemic of industrial keratoconjunctivitis which occurred in 1942. Soon after efficient treatment was instituted and transmission through unsanitary practices was reduced, the disease practically ceased to exist.

In industrial ophthalmology, the most difficult problems involve the inability or unwillingness of individuals to use reasonable precautions. The magnitude of industrial ophthalmology necessitates optometric assistance but the primary responsibility for screening and other examinations as well as leadership should be in ophthalmic hands. Greater standardization of eye examinations is needed as is greater efficiency in first aid treatment. United and concerted policy and action of management, labor, and insurance companies are badly needed. Even slight differences are harmful to all concerned. Ophthalmology and ophthalmologists have unfortunately drawn away from industrial ophthalmology in the past, apparently because of its slightly different techniques and standards. Industrial medicine and surgery, including ophthalmic, should be taught in all undergraduate medical schools. Chas. A. Bahn.

Minton, Joseph. **Vision and the selection of personnel in industry.** Tr. Ophth. Soc. U. Kingdom. 65:211-218, 1945.

The author recommends that all individuals whose vision is less than 6/12 in each eye be referred for an ophthalmological examination and that the standards of vision should not be rigid, but vary according to the analysis of the job.

He suggests that five visual groups are possible among the workers and describes the visual acuity and the characteristics of the work in each. Special visual problems are presented in the selection and allocation of jobs to juveniles, those with myopia, and for fine, close work.

Beulah Cushman.

Payne, B. F. **Aviation Ophthalmology.** Jour. Aviation Med. 18:367-378, Aug., 1947.

Aviation ophthalmology is concerned with the visual standards for personnel engaged in flying and maintaining aircraft. The examination is concerned with visual acuity, depth perception, color testing, extraocular muscle balance, and the discovery and elimination of disease in the external or internal portions of the eye. An outline of the course in ophthalmology at the AAF School of Aviation Medicine is given.

Irwin E. Gaynon.

Rennie, T. A. D. **General aspects.** Harrington, D. O. **Ophthalmology. Psychosomatic manifestations.** Tr. Am. Acad. Ophth. pp. 65-74, pp. 78-89, Nov.-Dec., 1947.

This symposium should be read by every ophthalmologist. Its parts are so closely alligned that a composite abstract is advisable.

Only psychosomatic ophthalmology is good ophthalmology because it, alone, is comprehensive ophthalmology. Among the general diseases with important psychosomatic ophthalmic manifestations are diabetes, hypertension and hyperthyroidism. The sensory stimuli which begin in the retina play an especially important part in physical and mental activities and inactivities, both quantitatively and qualitatively. Therefore, the mental processes of sight are vitally involved in psychosomatic sickness, in which anxiety is always involved. There is nothing to which one will not resort to escape the discomforts of prolonged anxiety when it becomes intolerable. The most frequent escape mechanisms include numerous patterns of mental conversions and/or vegetative psychoneuroses. The former includes blepharospasm, convergence spasm, asthenopia, photophobia, hysterical amblyopias, and amauroses; the latter ciliary spasm, transient amblyopias, angiospastic retinopathies, migraine and glaucoma.

Limited space precludes even a brief discussion of the many important concepts presented. My paraphrasing of a few of its more provocative ideas will, I hope, stimulate the readers' interest. The first function of all physicians is to honestly and intelligently care for the human beings who have sickness. Psychosomatic ophthalmology is not veterinary ophthalmology, because only human beings can express in the spoken and written word the link that connects symptoms with their complete causation. The eyes have been closely associated with both sight and understanding since the beginning of history in all phases of human activity. All psychosomatic sickness is an expression of anxiety and its effects. Their manifestations are expressed positively and not negatively to those who can and will see. The proponents of psychosomatic ophthalmology have been damned with faint praise. Those who have professed to cure symptoms of psychosomatic sickness both within and without our profession have probably aggravated more neuroses than they have cured. There would be fewer unsuccessful operations or blind and unhappy patients, if more ophthalmologists would practice more psychosomatic ophthalmology. Words are to the practitioner of psychosmatic ophthalmology what ophthalmoscopes are to physical opthalmologists. Chas. A. Bahn.

PAN-AMERICAN NOTES

Edited by M. URIBE TRONCOSO, M.D.
500 West End Avenue, New York
Communications should reach the editor by the 12th of the month

III PAN-AMERICAN CONGRESS

This Congress convened at Havana, Cuba, from January 3 to 10, 1948, with great success and a larger attendance than at any of the previous meetings in Cleveland, Ohio, and in Montevideo, Uruguay. Although Dr. Vail has already reported in the editorial section on the principal features, excellent organization of the meetings, and on the scientific and commercial exhibitions, it may be pertinent to emphasize some other results obtained by the Congress.

Although a greater number of ophthalmologists were present from the United States, nearly one half of the total came from the Latin-American countries. Not only the big nations on the continent sent delegates, but even the smaller countries in Central America had several representatives. I met colleagues from Guatemala down to Costa Rica. Mexico had a big delegation with about 12 members; Brazil had nearly 20 members, with Argentina and Chile following in numbers. Three ophthalmologists came from Uruguay. Paraguay, Peru, and Bolivia were also well represented. Cuba, the host of the Congress, had numerous official members who vied with each other in helping the colleagues who had difficulties with lodgings, language, or with traveling after the Congress was finished.

Latin-American members showed a great spirit of comradeship between themselves and made friends with physicians of other Spanish- or Portuguese-speaking countries. The English-speaking ophthalmologists also made numerous acquaintances with Latin physicians and a true international atmosphere prevailed.

The many courses of instruction were a new departure greatly appreciated by all members. Some courses were given in Spanish, although the majority were in English. All had many attentive listeners.

The entertainments provided by the Congress were all splendid and enthusiastically attended. The last one, in the Cathedral Square, the final day of the Congress, was particularly brilliant. The mild climate allowed the ladies and members to remain outdoors in evening attire and dance until the early hours of morning. There were many couples in costumes from different countries and Cuban performers gave special exhibitions.

The next Congress should convene in 1950, but is delayed until 1952 because of the meeting in London that year of the 15th International Congress of Ophthalmology. The next Pan-American reunion will be held in Mexico City in 1952.

Dr. Harry S. Gradle was honored in absentia with the first Pan-American Medal of the National Society for the Prevention of Blindness for his services in establishing friendly relations with the Latin-American countries.

New officers elected for the Pan-American Ophthalmological Society were Dr. C. Berens, president; Dr. W. L. Benedict, vice-president; Dr. Thomas D. Allen, secretary; and Dr. Derrick Vail, secretary for instructional courses.

SOCIETIES

MEXICAN OPHTHALMOLOGICAL SOCIETY

The board of directors of the society for 1948-1949 has been changed as follows: president, Dr. Lino Vergara Espino; vice-president, Dr. F. Martinez Hinojosa; secretary, Dr. Raul A. Chavira; annual secretary, Dr. J. Antonio Quiroz; treasurer, Dr. F. Palomino Dena.

NATIONAL CONGRESS IN MEXICO

The Mexican Society of Ophthalmology has initiated and will organize the meeting of the National Congress to be held in Mexico City in the second week of January, 1949.

SOCIETY OF SÃO PAULO, BRAZIL

This society elected new members for the board of directors for the period 1947-1948 as follows: president, Dr. Benedito Paula Santos Filho; vice-president, Dr. Plinio Toledo Piza; executive secretary, Dr. Paulo Braga Bagalhães; secretary, Dr. Rubens Belfort Mattos; archives, Dr. Alcides Del Ciello; treasurer, Dr. Aureliano Fonseca.

SOCIETY OF GUADALAJARA, MEXICO

Guadalajara is the second city in population in Mexico. The ophthalmologists practicing there have formed a new Society of Ophthalmology with the following board of directors: Dr. Elias Mendoza Gonzalez, president; Dr. Manuel Romo, vice-president; Dr. L. Nunez Leal, secretary; Dr. Antonio Diaz Guerrero, treasurer. Dr. Enrique Avalos, Sr., was appointed honorary president.

PERSONALS

Dr. H. Arruga, the well-known surgeon from Barcelona, Spain, after attending the Pan-American Congress of Ophthalmology in Havana, came to New York to renew old acquaintances in the city and to supervise the translation into English of his book on ocular surgery which has received so many laudatory comments.

Dr. Karl Lindner and Dr. Adalbert Fuchs of Vienna, Austria, came to the United States after attending the congress in Havana. Dr. Lindner gave lectures at the New York Academy of Medicine and

at the St. Louis Ophthalmic Society and Dr. Fuchs lectured at Gill Memorial Eye, Ear and Throat Hospital in Roanoke, Virginia.

Dr. Algernon B. Reese has just returned from Mexico where he gave a series of lectures on "Tumors of the Eye."

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2
News items should reach the editor by the 12th of the month

DEATHS

Dr. Willis Orville Nance, Chicago, Illinois, died January 16, 1947, aged 76 years.

Dr. Elias Selinger, Chicago, Illinois, died December 21, 1947, aged 49 years.

ANNOUNCEMENTS

ACADEMY HOME STUDY COURSE

The home study courses, sponsored by the American Academy of Ophthalmology and Otolaryngology, in the basic sciences related to these two specialties, will be given again, beginning September 1, 1948. Registrations must be completed before August 15. Detailed information may be obtained from Dr. William L. Benedict, executive secretary, 100 First Avenue Building, Rochester, Minnesota.

JACKSON'S "SKIASCOPY"

About 25 copies of Dr. Edward Jackson's 120-page volume on "Skiascopy" are still available for distribution, and a copy will be sent without charge to each of those ophthalmologists first addressing a request to receive one to Dr. William H. Crisp, 1276 Emerson Street, Denver 3, Colorado.

There will probably be several months delay in complying with these requests, since Dr. Crisp will be out of the United States from a little after the middle of May until the latter part of September, and will not be represented by an office secretary during his absence.

MISCELLANEOUS

ITALIAN JOURNAL CHANGE

The Italian *Rivista di Oftalmologia,* beginning in January, 1947, under the editorship of Prof. B. Alajmo and published by L. Salpietra is being continued by Dr. B. Alajmo and the same group of collaborators as the *Giornale Italiano di Oftalmologia* under the management of the Clinica Oculistica of the Universitaria of Florence, Italy. The journal will be published every two months. Volume 1, number 1, January-February, 1948, has already been received in this country.

UNIVERSITY OF MICHIGAN CONFERENCE

On May 6th to 8th, an ophthalmology conference was held at the University of Michigan. The first day's program included: "Applied Physiologic Optics," Charles Sheard, Ph.D.; "Toxoplasmosis," Dr. Raymond L. Pfeiffer; "Anomalies and Diseases of the Optic Nerve," Dr. Winsor S. Davies; a fundus clinic at the Wayne County General Hospital; and a joint meeting with the Detroit Ophthalmological Society and Club and the Michigan Triological Society.

The program for the second day was: "Applied Physiologic Optics," Charles Sheard, Ph.D.; "The Roentgenographic Diagnosis of Retinoblastoma," and "Roentgenography of Exophthalmos," Dr. Raymond L. Pfeiffer; "Modern Trends in Ophthalmic Surgery," and "The Management of Common Ocular Injuries," Dr. William B. Clark; "Vascular Lesions of the Ocular Adnexa," and "Vascular Lesions of the Globe," Dr. Banks Anderson.

On the concluding day, the following program was presented: "Recent Advances in Ocular Therapeutics," Dr. Harold F. Falls; "Applied Physiologic Optics," Charles Sheard, Ph.D.; "The Familial Corneal Dystrophies," Dr. William B. Clark; "Ocular Manifestations of Dermatological Disease," Dr. Banks Anderson; "Clinical Manifestations of Involvement of the Visual Pathway," Dr. John W. Henderson; and "Surgical Anatomy of Operations for Glaucoma," (movies) Dr. F. Bruce Fralick.

REFRESHER SYMPOSIUM

During the four-week period, April 26th through May 22nd, a full-time refresher symposium in ophthalmology is being given to eight qualified ophthalmologists by the ophthalmologic and medical staffs of the Mount Sinai Hospital in affiliation with Columbia University. This symposium is designed to be an intensive review of modern concepts in the field and consists of clinical, laboratory, and didactic instruction in pathology, embryology, bacteriology, optics, surgery, ophthalmoscopy, and so forth.

SOCIETIES

WINS ADVERTISING AWARD

At the first quarterly meeting of the Better Vision Institute, Inc., Pres. M. J. Julian displayed the medal won by the Institute in the annual advertising awards for 1947. This was the highest honor given in the classification of association advertising.

BROOKLYN PROGRAM

The 104th regular meeting of the Brooklyn Ophthalmological Society was held at the Brooklyn

Eye and Ear Hospital on April 15th. Case presentations on the scientific program included: "Stevens-Johnsons Disease," Dr. Julius M. Dan; "Coloboma Iris, Choroid, and Optic Nerve," Dr. A. B. Rizzuti; "Boeck's Sarcoid of the Orbit," Dr. Martin Bodian; "Spontaneous Dislocation of the Lens," Dr. Charles Stern, *(By Invitation);* "Ciliary Staphyloma," Dr. Jerome Samuel, *(By Invitation);* "Subchoroidal Hemorrhage Complicating Intraocular Surgery," Dr. Leo Esbin, *(By Invitation);* "Herpes Zoster Ophthalmicus," Dr. Mortimer Cholst, *(By Invitation);* "Aniridia In Three Generations," Dr. Israel Gerberg.

University of Glasgow Meetings

During the month of May a series of meetings will be held in the Department of Ophthalmology, University of Glasgow, on Wednesdays at 8 p.m. The general arrangements will be similar to the series held last year. Tea will be served after the paper and a discussion will follow. The meetings will be open to all medical practitioners and senior students interested in ophthalmology. On May 5, Dr. I. C. Michaelson will present "The Growth of Ocular Vessels;" May 12, Dr. James Hill, "Disturbances of Lacrimal Apparatus;" May 17, Dr. W. O. G. Taylor, "Wounds of the Cornea;" May 26, Mr. O. M. Duthie, "Cataract Extraction."

Oxford Congress

The next meeting of the Oxford Ophthalmological Congress had been arranged for Thursday, Friday, and Saturday, July 8th, 9th, and 10th, at the School of Geography, Mansfield Road, Oxford.

The congress will be opened by a discussion on "The Use and Abuse of Topical Ocular Therapy," and will be led by Mr. Frederick Ridley, Dr. J. R. Robson (pharmacology), and Dr. F. E. Preston.

The Doyne Memorial Lecture will be delivered by Sir Stewart Duke-Elder and will be entitled "The Blood Aqueous Barrier."

Round-table conference

The annual round-table conference of the New York Society for Clinical Ophthalmology was held on April 5th. The subject for discussion was "Nonsurgical Therapy in Ophthalmology." On the panel of discussors were: Dr. Irving H. Leopold, Philadelphia; Dr. Parker Heath, Boston; Dr. Ludwig von Sallmann, New York; and Dr. Derrick Vail, Chicago. Dr. Daniel Kravitz, president of the society, acted as moderator.

Milwaukee society

The regular meeting of the Milwaukee Otoophthalmic Society was held on March 23rd. "Tumors of Ciliary Body: A Case Report," was presented by Dr. M. Kadin, as a membership thesis.

Los Angeles officers

The Los Angeles Society of Ophthalmology and Otolaryngology has elected the following officers for 1948: president, Dr. Colby Hall; secretary-treasurer, Dr. Warren A. Wilson; chairman of section on ophthalmology, Dr. John A. Bullis; secretary of section on ophthalmology, Dr. Rodman Irvine; chairman of section on otolaryngology, Dr. Leland G. Hunnicutt; secretary of section on otolaryngology, Dr. Alden H. Miller.

The Los Angeles County Medical Association Building, 1925 Wilshire Boulevard, Los Angeles, is the place of meeting, and the time is 6 P.M. the fourth Monday of each month from September to May, inclusive.

N.S.P.B. appoints nursing consultant

The National Society for the Prevention of Blindness announces the appointment of Helen E. Weaver, R.N., as consultant in nursing activities. Miss Weaver comes to her position from the New York State Department of Health where she was consultant public health nurse of the Division of Venereal Disease Control.

United Kingdom society meets

The annual congress of the Ophthalmological Society of the United Kingdom was held on April 8th, 9th, and 10th at the Royal Society of Medicine, London. Dr. A. J. Ballantyne, president, gave the welcoming address. Others participating in the program were: Prof. H. Cohen, Dr. Denis Williams, and Mr. J. H. Doggart, who presented "Subjective Disorders of Vision;" Dr. Helen Dimsdale and Mr. D. G. Phillips, "Ocular Palsies Due to Infection of the Nasal Sinuses;" Mr. J. P. F. Lloyd, "A Preliminary Survey of 45 Consecutive Cases of Congestive Glaucoma;" Mr. Eugene Wolff, "The Conjunctival Nevus and the Neurogenic Theory of Melanomas;" Dr. H. M. Traquair, "Pictorial Demonstrations;" Prof. Marc Amsler, "New Clinical Aspects of the Vegetative Eye" (The Bowman Lecture); Dr. T. L. Thomassen, "The Venous Pressure in Glaucomatous Eyes;" Dr. G. I. Scott, "Some Observations on Clinical Perimetry;" Mr. G. T. W. Cashell, "Two Case Presentations—Subconjunctival Rupture of the Globe with Extensive Migration of Uveal Pigment, and an Aneurysmal Varix of the Retina;" Mr. A. G. Cross, "Papilledema in Association with Toxic Hydrocephalus;" Mr. T. Keith Lyle, "Latent Nystagmus;" Prof. Arnold Sorsby, "The Classification of the Unassociated Dystrophies of the Fundus;" Dr. J. Ellison, "Pictorial Demonstrations;" Mr. C. Dee Shapland, "Prognosis in Detachment of the Retina;" Dr. I. C. Michaelson, "The Mode of Development of the Vascular System of the Retina, with Some Observations on Its Significance for Certain Retinal Diseases;" Prof. W. H. Melanowski, "Atropin in the Treatment of Glaucomatous Iridocyclitis;" Dr. W. C. Souter, "Auto-Eversion of Upper Lid, Voluntary, Unaided."

New York society officers

Newly elected officers of New York Society for Clinical Ophthalmology for the year 1948-1949, are:

president, Dr. Benjamin Esterman; vice-president, Dr. Sidney A. Fox; recording secretary, Dr. Bernard Kronenberg; corresponding secretary, Dr. Leon H. Ehrlich; treasurer, Dr. Edward Saskin; historian, Dr. Howard J. Agatston. Committee chairmen are: program, Dr. Adolph Posner; instruction hour, Dr. Frederick H. Theodore; legislative, Dr. Max Chamlin; membership, Dr. Bernard Fread; industrial, Dr. David A. Newman. Dr. Daniel Kravitz, the retiring president, was elected to the advisory council.

Journal club organized

A meeting was held at the home of Dr. Samuel V. Abraham, 610 North Linden Drive, Beverly Hills, California on April 15, for the purpose of organizing the Ophthalmological Journal Club.

The primary interest of the club is to abstract current literature on ophthalmology and related subjects for the purpose of presenting it to the members for discussion.

The meetings will be held the first Thursday of each month at 8 P.M., at 416 Bedford Drive, Beverly Hills. Dr. Samuel V. Abraham is chairman of the club.

Personals

Retires because of ill health

Dr. Frank R. Slopanskey, Salt Lake City, Utah, has recently retired because of ill health after 42 years of active medical and surgical practice.

Will tour European area

Dr. Harold Scheie, associate professor of ophthalmology at the University of Pennsylvania and chief of the eye service at the University of Pennsylvania Hospital, will visit the United States Army hospitals in the European area under the program whereby a team of civilian medical consultants spend several days at each hospital advising the theater surgeon and hospital staffs in the treatment of their patients.

To conduct clinics

Dr. Albert D. Ruedemann, professor of ophthalmology, Wayne University College of Medicine, Detroit, is conducting clinics on beta irradiation in ophthalmology at the City of Detroit Receiving Hospital from 10 a.m. to noon every other Wednesday until June.

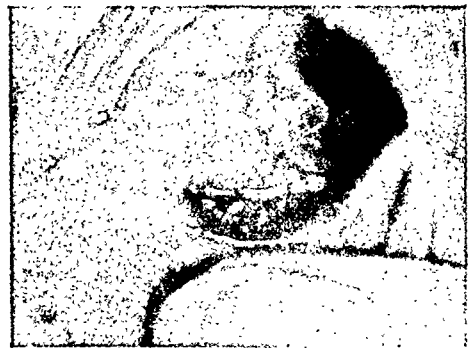
Gives lectures

On February 13, 1948, Dr. Joseph I. Pascal gave a lecture to the graduate class in ophthalmology of the Harvard Medical School on "A Graphic Study of Ocular Muscles." The same subject was presented by Dr. Pascal at the March 4th meeting of the Eastern New York Eye, Ear, Nose, and Throat Association in Albany, New York, and at the March 8th meeting of the Passaic-Bergen Ophthalmological Club.

Awarded medal

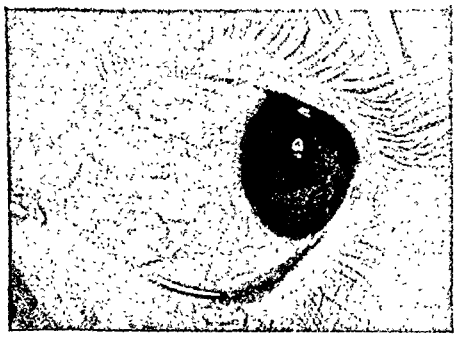
The Richard Pearson Strong medal for distinguished and outstanding work in tropical medicine has been presented to Dr. Neil P. Macphail, medical superintendent, East Coast Division, United Fruit Company, Quirigua, Guatemala, for a lifetime of service devoted to tropical medicine in Central America.

Resigns hospital appointment



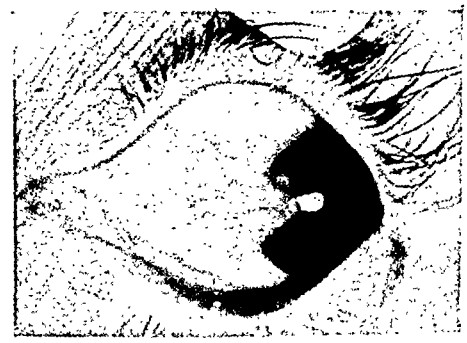
On April 1, 1948, Dr. John N. Evans resigned as Ophthalmologist-in-Chief of Long Island College Hospital, and has been appointed Consultant to the Department of Ophthalmology.

Colorado consulting ophthalmologist



Dr. John C. Long has been appointed as consulting ophthalmologist to the State of Colorado under the Aid to the Blind law, in place of Dr. William H. Crisp (resigned).

Announcement



The 20th semiannual conference in "Neuromuscular Anomalies of the Eyes," will be held at The Children's Memorial Hospital, Chicago, Illinois, by Dr. George P. Guibor on June 13 to 18. The class will be limited and no applications will be accepted after June 8. Lectures and Demonstrations will be at the Hospital, Entrance 700 Fullerton Avenue. The tuition is $50.00; $25.00 payable on enrollment, balance payable on registration. All correspondence and checks should be addressed to The Children's Memorial Hospital.

SURGICAL TREATMENT OF PTERYGIA FOLLOWED BY X-RAY THERAPY TO PREVENT RECURRENCE*

HENRY L. HILGARTNER, M.D., R. T. WILSON, M.D., AND J. D. WILSON, M.D.
Austin, Texas

One of the most common conditions seen in the southwest section of this country is that of a pterygium encroaching on the cornea of one or both eyes. As everyone knows, this is usually a painless, slow-growing, disfiguring growth composed of fibrillar connective tissue and epithelium of the conjunctiva. It may or may not be vascular. It is most commonly seen growing from the nasal side, but it may also grow from the temporal side at the same time, and, in some rare cases, the pterygium will descend from above, or ascend from below. This latter condition is, however, infrequent.

STRUCTURE OF PTERYGIUM

Doherty has divided the pterygium into four parts: (1) the cap, which is the flat grayish section which precedes the head as it encroaches on the cornea, (2) the head, (3) the neck, and (4) the body. The head consists of loose connective tissue which advances between Bowman's membrane and the epithelium, the latter becoming detached. Bowman's membrane is partly or completely destroyed. The neck and body consist of blood vessels, connective tissues, and conjunctival epithelium.

It is not our purpose to give a long dissertation on the pathology, incidence, and surgical technique for the removal of pterygia, but it is necessary to review briefly the facts. In conclusion we wish to present our technique for the prevention of the recurrence of the growth.

TYPES OF PTERYGIA

We feel that there are two distinct types of pterygia: (1) The small, slow growing, rather avascular pterygium with a flat, more or less whitish-gray head, and practically no cap. (2) The highly vascular, thick, somewhat inflamed growth, with elevated head and a very definite cap which extends some distance beyond the head onto the cornea. The second type is fast growing and invades the deeper structures of the cornea. If allowed to stay on the cornea for any length of time, a definite grayish scar may form beneath it, which is disfiguring after removal of the pterygium from the cornea.

It is this second type of pterygia with which we are really concerned and which usually recurs following surgery. The usual story is that the growth recurred soon after surgery was performed, sometimes within a few days after the operation, and that the growth developed more rapidly than it formerly had.

A true pterygium develops and grows without previous corneal ulceration or injury. A false pterygium is one in which there has been a corneal ulcer or injury and the healing process has pulled the conjunctiva up on the cornea.

In our opinion, a pterygium seldom stops growing; the growth may be very, very

* Presented at the meeting of the Texas Ophthalmological and Otolaryngological Society, Houston, Texas, December 5, 1947.

slow, but if measured and observed over a period of years, it will be seen that it has progressed.

Surgical treatment

Various procedures have been described for the removal of pterygia. Des Marres was the first to transplant the pterygium after dissecting it from the cornea. McReynolds later modified the Des Marres operation, and his is the procedure most commonly used. We will not go into detail regarding the surgical technique, but we wish to stress several points that seem important to us.

In the first place, the head and cap of the pterygium should be dissected free from the cornea, removing all of the strands and trabeculae on the initial dissection. We generally incise the conjunctiva just adjacent to the body of the pterygium above and below, and then (this is important) see whether the pterygium fits with the least distortion with the head pulled upward or downward, bringing normal conjunctiva over the former site of the growth and adjacent to the limbus. No tension should be exerted.

All the surgical textbooks emphasize that the pterygium should be buried beneath the lower bulbar conjunctiva, but this is not obligatory. It is better surgical judgment to adapt the transplant to its new position in the most normal and natural way, with no tension and no bulging of the body under the conjunctiva.

The head of the growth is anchored beneath the bulbar conjunctiva, either above or below, with a double-armed, black-silk, 6-0 suture. Then the bulbar conjunctival flap is picked up and brought down over the transplanted pterygium and anchored into the body of the pterygium with a single black-silk suture.

Indication for X-ray treatments

During the last two years one of us (H. L. H.) has operated on 36 cases of pterygia. Nine of these had bilateral growths, and both eyes were operated on at the same time. One of the first cases which was operated on soon after resumption of private practice showed a recurrence following the first operation. This patient was operated on a second time, and there was a recurrence within a short time. Since the nasal side of the eye was quite vascular and the pterygium again commenced to extend onto the cornea, the patient was referred for X-ray treatments. Following the first X-ray treatment, the vascularity subsided, and the pterygium stopped growing.

X-ray treatments following surgery are not indicated in every case; in fact, they are contraindicated in the avascular, small, flat type of pterygium. Only the vascular, raised, large type requires X-ray treatment, but these cases need it badly. Of the 36 cases operated on, 10 required X-ray treatment. Our usual procedure is to advise the patients that on the fifth day following surgery, when the stitches are removed, they will be referred to the roentgenologist for one or more X-ray treatments. Our results from the combined procedures have been excellent.

X-ray treatment of pterygium

X rays have been useful in the treatment of various lesions about the eyes. Of these pterygium has been one that has received some attention in the literature. Bucky reported the use of soft X rays in this condition in 1927. Other workers, notably Burnham and Neill, have used Beta rays of radium in the form of radon applied by a special applicator in the treatment of superficial lesions of the eye. Estrada brings out the value of postoperative X-ray therapy in cases prone to recurrence. It has been in these cases that we have used radiation therapy. Choice of the patients to be treated is made by the ophthalmologist after consideration of the patient's history and study of the type of pterygium.

The purpose of X-ray treatment is to help prevent recurrence and growth of the

pterygia. The vascular type, being the kind most likely to recur, is also the type most sensitive to radiation. The effect is produced by the inhibiting action of X rays upon young connective tissue, the epithelial cells, and the blood vessels. This means that the younger the cells of the tissues and the faster the growth, the more pronounced are the effects of radiation. Therefore, we have chosen to treat these pterygia only after surgery, and soon after the operation, while the tissues are in the active reparative phase. In this manner, the maximum effect is produced on the pterygium and also on the scar of the cornea. We begin treatment on about the fifth postoperative day.

Technique of X-ray therapy

The size and shape of the pterygium is measured accurately and a portal is cut out of lead foil which will closely fit the lesion. Then the eye is anesthetized with 1-percent pontocaine, and the lids are held open with a speculum. The lead-foil shield is put in place over the eye and the X-ray beam is directed through the portal (fig. 2). Its direction is angulated to the side of the lesion being treated so that the center of the beam does not go through the center of the orbit.

Unfiltered X rays produced at a voltage of 70 K.V. (H.V.L. 1.0 mm. al.) are used at a distance of 22.5 cm. (9 inches). This gives the longer wave-length, less penetrating rays. The output is 130r per minute so that the exposure time is short and rarely runs over two minutes. Each pterygium is treated in this manner at each treatment, and the treatments are repeated at intervals of 3 to 5 days. It is important to give the treatments in a period of 2 to 3 weeks to take advantage of the altered pathologic processes which follow the operation.

Comment

In this series of cases, 10 patients were given postoperative radiation. Of these two were women. Six of the patients had bilateral lesions and one of these had three pterygia. There was a history of multiple operations and recurrences up to a total of six in one patient.

No statistical analysis of this small series of cases will be attempted. The patients received an average of six treatments, with

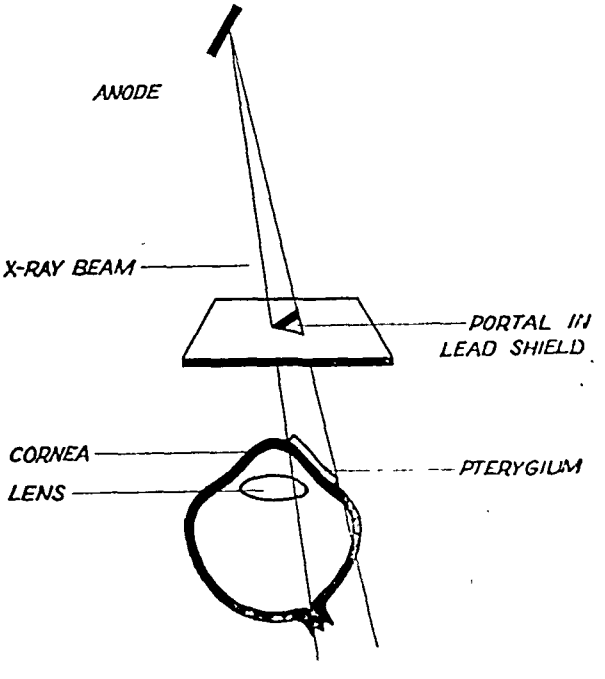

Fig. 2 (Hilgartner, Wilson, and Wilson). Diagram illustrating the angled X-ray beam striking the pterygium.

an average total dosage of 1,100r. Very gratifying results have been obtained. In some of the earlier cases, which have been followed for almost two years, the lesions show no evidence of growth. No complications of any kind have been noticed. We might stress that the tolerance of the cornea to irradiation is much higher than is generally thought so that no adverse effects from this or even higher dosage are to be expected.

We are presenting this combined method of treatment of pterygium because of its simplicity, availability, and its effectiveness in stopping the growth and preventing the recurrence of these lesions.

CAPILLARY FRAGILITY AND CUTANEOUS LYMPHATIC FLOW IN RELATION TO SYSTEMIC AND RETINAL VASCULAR MANIFESTATIONS: RUTIN THERAPY*

JUSTIN M. DONEGAN, M.D., AND WILLIAM A. THOMAS, M.D.
Chicago, Illinois

With increasing frequency it is recognized that vascular accidents, particularly of arterioles and capillaries, are not solely the result of simple elevation of blood pressure with mechanical rupture, or of degenerative atheromatous changes, such as may lead in larger vessels to massive hemorrhage or dissection of the wall, but are due to some defect in the architecture of the vessel, similar to but not identical with the disorders seen in scurvy, occurring in many persons with normal blood pressures, and bearing no relationship to the actual level of pressure in hypertensives.

Thus, we have long pondered over the cause of the ecchymoses and bruises so frequently seen in a certain type of woman—usually blonde, well nourished or obese, with skin of fine texture, good complexion —whose arms and legs are covered with numerous black and blue spots which result from the slightest pressure or injury. These bruises are not due to scurvy, are not relieved by enormous quantities of ascorbic acid, and appear in patients without other ascertainable cause.

Working in Europe in 1936,[1] Szent-Györgi isolated from the rinds of citrus fruits a substance which corrected or prevented artificially produced capillary fragility in experimental animals and for which he proposed the name citrin, briefly referred to as vitamin P (for permeability). Since it is not a vitamin, none of the effects that it remedies having been observed in dietary restrictions, and since its action is more concerned with capillary fragility, the designation of vitamin P is obviously inappropriate.

Citrin is composed of at least two distinct glucosides, hesperidin and eriodictyol, the former of which varies greatly in physiologic activity while the latter is inert. Presumably much of the activity of this impure mixture is due to rutin,† derived at present from the flowering leaves of immature buckwheat. Rutin is a flavonal glucoside, and is now available in an accurate and stable form.

The pioneer work on capillary fragility and its control has been done in this country by Griffith, Lindhauer, Couch, and Shanno,[2-6] and we have drawn freely from their results, especially as exhibited at the Scientific Assembly of the American Medical Association, July, 1946, to supplement the work which we are reporting. Fragility is measured by one of various techniques, all of which depend on the number of petechiae produced in a measured area following application of a tourniquet, commonly a blood pressure cuff, for a definite time and pressure. Griffith and his associates prefer the Göthlin technique (see references), while we have used a modification of the Wright and Lilienfeld method, performed in the following manner.

A circle 2.5 cm. in diameter is outlined in the antecubital fossa, the upper edge lying 4-cm. below the crease of the elbow, and all confusing blemishes in this area are marked off. The cuff of the blood-pressure manometer is then applied in the usual position, the pressure set at a point midway between the previously determined systolic and diastolic pressure. After five minutes the pressure is released, and one-half hour later the petechiae in the circle are counted. On the average, normal subjects of varying

* Presented in part before the Chicago Ophthalmological Society December 16, 1946. From the Presbyterian Hospital, Chicago.

† Supplied for this work by Abbott & Co., Chicago.

ages will exhibit not more than 10 petechiae after this procedure.

Our reason for selecting this method rather than that of Göthlin (which elevates the pressure to 35 mm. Hg for 15 minutes, followed in an hour by pressure of 50 mm. Hg for 15 minutes) is that with the great variations encountered in both systolic and diastolic pressures, determination of the number of petechiae in a given individual with a certain blood pressure will more nearly represent the state of capillary fragility than a more arbitrary procedure. We have as yet found no reason to modify this technique, but the matter is open to debate and correction. However, it is clear that any such procedure, if carefully standardized, will give accurate and reliable results in the hands of those employing it.

The first comprehensive work of Griffith and Lindauer[2] may be summarized as follows. Increased capillary fragility, occurring in approximately 20 percent of 1,600 hypertensives, irrespective of the blood-pressure level, is accompanied by an incidence of cerebral or retinal hemorrhages and death, varying from 6 to 10 times that found in hypertensives of comparable levels showing normal fragility. This abnormal fragility can be restored to normal by rutin therapy in 75 percent of cases, becomes borderline in 15 percent, becomes normal but relapses in 4 percent, and remains abnormal despite large dosage in 6 percent.

Furthermore, restoration of normal fragility is followed by a decrease of vascular complications to the approximate frequency encountered in hypertensives with normal fragility, only to be followed by a return of greater incidence in relapse due to discontinuance of therapy or failure of treatment.

Finally, thiocyanate therapy, extensively used for control of hypertension, produces in a significantly large number of cases an increased fragility, thus predisposing the patient to the hazard of vascular complications that are frequently more serious than uncomplicated hypertension, which tendency is fortunately controlled by rutin.

These findings of Griffith and Lindauer are in complete accord with our findings in a smaller series of hypertensives and are in marked contrast to the results obtained in diabetics, to be discussed later.

The determination of the rate or expectancy of vascular complications in normal and increased fragility is obviously difficult, since one cannot select two groups of 100 cases each, with 20 exhibiting normal fragility, proceed to treat one group with rutin, and conclude either that, in the treated group, this or that specific individual would or would not have met with some hemorrhagic phenomenon; or that, in the untreated cases, any specific complication would have been prevented by therapy.

Consequently, it is necessary to adopt a post-hoc method, whereby a comparison of the incidence of accidents is made after they have occurred, and then related to the state of fragility. To complicate the situation further, we cannot withhold treatment, or withdraw it, in order to obtain additional data on human beings, thus exposing them to the danger of disaster.

Rutin, available in 20-mg. and 60-mg tablets, has conventionally been administered in doses of 80 to 100 mg. daily. However, in resistant cases, or where rapidity of action is desirable, 240, 300, or even 500 mg. daily may be given for long periods without any evidence of untoward or toxic effects. When apparently adequate dosage has been established, the tourniquet test should be done every 4 to 6 weeks to forestall relapses due to possible increase of rutin requirement, bearing in mind that the result is not valid if done within three weeks of a previous test on the same arm.

During an acute shortage of rutin while these studies were in progress, we fortified our meager dosage with large amounts of ascorbic acid, such as 1,000 mg. intravenously once or twice daily, or 200 to 300 mg. orally if tolerated. Although the struc-

tural formula of rutin, a flavonal glucoside, in no way resembles that of ascorbic acid, their action in capillary bleeding is similar, and we found that this addition so enhanced the action of rutin, that administration of 40 to 60 mg., by itself ineffective, resulted in satisfactory and prolonged control of increased fragility. Recent work demonstrating control by Tocopherol of hemorrhage in dogs produced by large doses of Stilbestrol, led to a trial of this substance in a similar manner, but in dosage of 300 to 400 mg., daily. Tocopherol* failed to modify or enhance the action of rutin.

Cutaneous lymphatic flow (C.L.F.),[5] when increased, indicates in many instances increased permeability of vessel walls and was found to accompany increased fragility in about one third of the cases.

Apart from increased permeability, increased C.L.F. occurs in increased capillary pressure due to renal or pituitary disease, is decreased in congestive heart failure, lymphatic block (such as in phlebitis accompanied by peri-venous inflammation), and in edema of nephritis and nephrosis. Work in progress indicates marked reduction or absence of flow in edematous lower extremities of nephrotic patients, while remaining normal in the noninvolved areas of the arms, increasing to normal values in the legs as edema subsides.

As one example, a girl with pure nephrosis or nephrotic syndrome (total serum proteins 2.63, albumin 1.01, globulin 1.62), persistently four-plus albumin, and massive edema of all tissues below the diaphragm, had normal capillary fragility in both antecubital and popliteal spaces, with C.L.F. normal in arms and absent in her legs. During five days she lost 40 pounds as the result of strict electrolyte management, administration of two units of plasma daily for the preceding seven days (this was discontinued at the onset of diuresis), and maximum doses of vitamin K. C.L.F. became normal in the legs (1 to 6 cm. in 14 minutes) in spite of the fact that there was no decrease in the quantitative 24-hour output of protein.

This indicated either that (1) a return to normal C.L.F. was not paralleled by improved capillary permeability, at least in so far as the kidneys were concerned; (2) the decreased C.L.F. in the edematous portions was due to mechanical forces rather than derangement of permeability, which in this instance would have been decreased; or (3) proteinuria in such cases may be due to faulty protein metabolism rather than changes in permeability.

On the other hand, macular edema, as described in subsequent case reports, responded in some instances with amazing rapidity, paralleling improvement in capillary fragility induced by rutin therapy. Unfortunately, determination of C.L.F. was not available at the time but was presumably increased before therapy. C.L.F. studies are now to be made routinely on such cases. On patients exhibiting increased C.L.F., cyanate therapy is ineffective and may actually be harmful, but, following response to rutin, cyanate may be administered with satisfactory results in those in whom it is ordinarily effective.

In striking contrast to the retinal picture and generally satisfactory response to rutin in the hypertensive and sclerotic patient, is that condition encountered in the diabetic, and more frequently in the patient carrying a moderate degree of hyperglycemia without frank glycosuria.

Briefly, the retinal lesions are small, round rather than flame shaped, are situated deep in the retina, are relatively permanent in size and shape, appearing unchanged in character and location over long periods, and respond little or not at all to therapy.

Moreover, these individuals display a much higher average petechial index than hypertensives and are extremely resistant to rutin, in some cases showing no improvement and in 45 cases, as reported herein,

* Supplied by Hoffman-La Roche Co.

responding with a final average of 29 petechiae following maximum treatment.

In his discussion of edema and hemorrhages of the retina, Duke-Elder[7] states "in most cases the escape of fluid from the circulation is through the capillary walls, and since it is probable that these preserve their permeablity to a great extent so long as the endothelial cells are healthy, the appearance of edema is usually an indication of capillary or tissue damage."

He considers as an essential factor in this process, "an increased transference of fluid to the tissues when the capillary permeability is increased, as in toxic and inflammatory conditions, a process which, when accentuated, leads to the escape of albumin and fibrinogen which coagulate in the form of exudates, and eventually to the escape of the formed elements of the blood as actual hemorrhages."

"It would seem," he further states, "that the essence of retinal hemorrhage is probably capillary dysfunction rather than high blood pressure itself."

Of the many instances of exudation and hemorrhage in the retina, which the ophthalmologist constantly observes, none is more troublesome than that which occurs, in apparently ever-increasing frequency, in diabetes mellitus. Despite almost a century of investigation, the cause and cure of this type of retinopathy still eludes us. Opinion is still divided as to whether the retinal changes observed are specific or are merely the findings which are generally accepted as characteristic of arteriosclerotic or renal retinopathy. Recently the latter view has been challenged by Ballantyne,[8] who found that 50 percent of diabetics with retinopathy exhibited no evidence of arteriosclerosis or hypertension. He contends that the condition is primarily venous in origin and begins with fatty infiltration and swelling of the endothelium of the smaller vessels and proceeds to capillary and venous stasis.

Elwyn[9] also feels that the small retinal hemorrhages observed in diabetes have no relation to the vascular changes of aging, sclerosis, hypertension, and obstruction of veins, but rather are dependent on a prestatic condition in the capillaries of the retina which is in some way related to continuous moderate hyperglycemia.

"This," he states, "is as far as anyone can go unless one would rather assume as a cause of the hemorrhage the presence of toxic substances which cannot be found, or a deficiency of unknown vitamins, which so far have not been discovered."

During the course of the Gifford Lecture before the Chicago Ophthalmological Society in 1946, Friedenwald[10] related that he had observed an increase in the general capillary fragility, as determined by the arm-band test, in patients with diabetes mellitus. Recently Wagener[11] referred to some as-yet-unpublished observations of Foxworthy of the Mayo Clinic. In a group of 85 nondiabetic patients of varying ages and in whom, too, there was no evidence of hypertension, she found an average of 14 petechiae after application of the blood-pressure manometer cuff for 10 minutes; 69 diabetics without retinopathy presented an average of 41 petechiae, and in 44 diabetics with retinopathy, the petechial average was 101.

This paper is a preliminary report of some studies which are being continued and expanded. Until recently rutin was not generally available, and the number of patients treated and the size of the dosage were consequently limited.

In addition to the determination of the capillary fragility other related data were obtained. These include the age, general medical studies, urinalyses, complete blood counts, the bleeding time, platelet count, blood sugar level, blood cholesterol, plasma vitamin-C level, and prothrombin time. The capillary fragility was determined by the positive pressure method described above.

Of the 81 patients studied, 45 had diabetes mellitus, and these diabetics revealed the following pertinent data: their average

age was 55 years, varying from 24 to 73 years; 33 were females and 12 males. General studies revealed complicating mild nephritis in 8, and arterial hypertension in 15. Evidence of arteriosclerosis was present in 13 instances. Incipient or immature cataract was found in 11 patients, and retinopathy was present in 25 of the 45. The average systolic blood pressure was 154 mm. Hg, ranging from 96 to 270 mm., and the average diastolic was 85 mm. Hg, varying from 60 to 130 mm. Glycosuria was present in 11 instances, and blood studies revealed mild anemia in 3, and leukocytosis in the same number. A prolonged bleeding time was found in only one patient and a lowered platelet count in two. The fasting blood sugar ranged between 84 mg. percent and 289 mg. percent and averaged 141. Blood cholesterol was also generally elevated, averaging 320.6 mg. percent. In more than one third of these patients the fasting plasma vitamin-C level was subnormal, averaging 0.74 mg. percent and varying between 0.15 and 1.35. Prothrombin was reduced to 60 percent and 80 percent, respectively, in two instances. Nineteen of these patients took insulin daily.

Capillary fragility averaged 53 petechiae for the whole group and 60 for those with retinopathy. In the 20 diabetic patients without retinopathy the average capillary fragility was 16. Except for three instances the capillary fragility decreased, usually within 12 to 18 days, after the administration of an average daily dosage of 160 mgm. of rutin by mouth, to an average level of 29 petechiae.

Despite the reduction in the general capillary fragility, there was no significant objective improvement in vision or in the appearance of the retinopathy in these 25 patients over periods of 3- to 12-months' observation. However, it may be of great significance that in 18 instances of retinopathy on rutin therapy from 10 to 12 months, there has been no decrease in vision and little or no change in the retinopathy. No effect on the blood pressure, bleeding time, platelet count, and so forth, was observed.

Report of cases

The fundus photos (figs. 1 and 2) will best illustrate the type of lesion with which we were generally dealing.

Case 1. J. D., a white woman, aged 54 years had been a known diabetic for 18 years. Small doses of insulin were employed for the last six months only.

At the time of her original eye examination in December, 1943, a mild degree of retinal angiosclerosis and a fairly marked retinopathy were noted. The fundus picture has remained essentially unchanged and corrected vision, which was recorded as: O.D., 0.1; O.S., 0.3, in 1943, was noted to be: O.D., 0.1; O.S., 0.2−1 in November, 1946.

On May 9, 1946, the blood pressure was 154/84 mm. Hg, and the capillary fragility was 101. A daily dose of 120 mg. of rutin was prescribed. On June 3, 1946, capillary fragility measured 32. Only 10 petechiae were present on testing the capillary fragility on July 23, 1946. After employing no rutin for 10 days the fragility was found to be 44 on September 12, 1946. The last test, on November 7, 1946, after the resumption of rutin therapy, revealed 32 petechiae.

Case 2. A. E., a white woman, aged 54 years, was the private patient of Dr. E. V. L. Brown. She had been a known diabetic for 10 years, under insulin therapy. When first examined in July, 1946, the right fundus presented the picture of an old occlusion of the central retinal artery. There was marked retinopathy of the left eye. Vision was: O.D., perception of light; O.S., 0.2−1, with correction. The blood pressure was 138/74 mm. Hg, and the capillary fragility 18. She was given 120 mg. of rutin daily and on reëxamination on August 19, 1946, the capillary fragility had dropped to zero. When the patient returned on October 17, 1946, she related that she had exhausted

her supply of rutin one month previously. A determination of the capillary fragility revealed 25 petechiae. Rutin was resumed and on November 14, 1946, the fragility was 8 petechiae. At this time vision was: O.D., none; O.S., 0.2, with correction.

In addition to these patients with diabetes mellitus, 36 individuals with a wide variety of ocular and general disturbances have been studied.

Three young men who had experienced recurring hemorrhages into the vitreous, so-called Eales's disease, presented no abnormalities on general physical examination and laboratory studies were negative in two. In these two, capillary fragility was increased to 26 and 32 respectively and, after rutin, has fallen to 16 in each. In the third instance, the prothrombin time was reduced to 60 percent but responded promptly to vitamin K. The capillary fragility of this third patient measured 6 in June, 1946, when he was given rutin, which he has continued, and was reduced to zero when tested three months later. This patient has experienced no recurrence of vitreous hemorrhage during the last six months; whereas during the previous two years bleeding recurred once in six weeks on the average. The period of observation of the other two patients has been limited but one of them has recently experienced a recurrence despite daily doses of rutin of 160 mg.

Of interest are two adults found to have

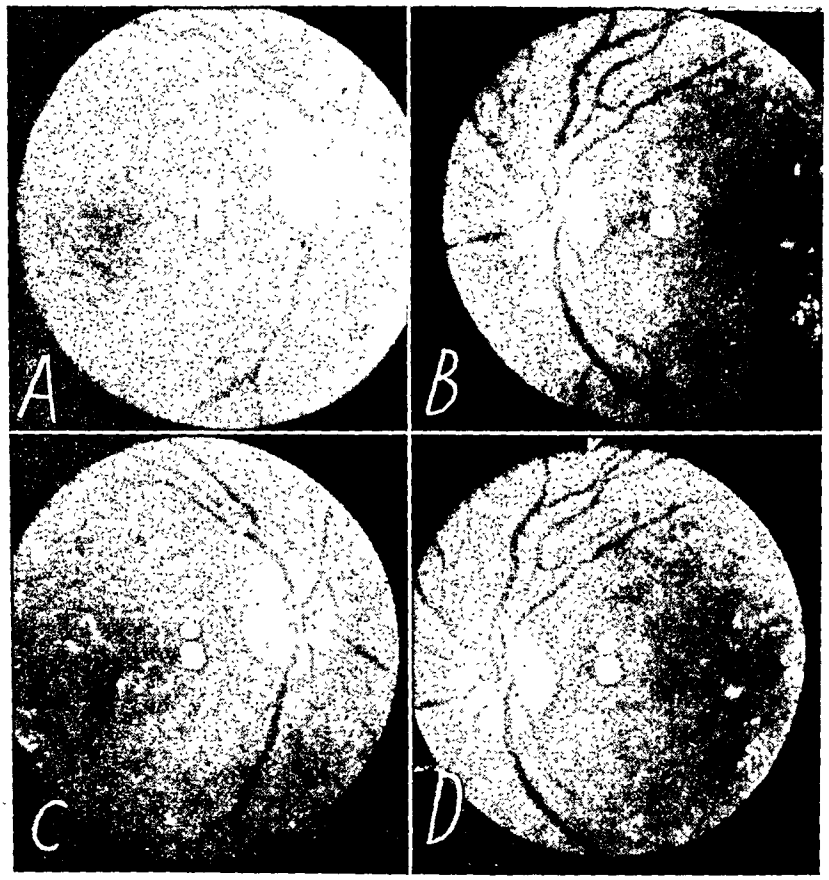

Fig. 1 (Donegan and Thomas). *Case 1.* A white woman, aged 54 years, had been a known diabetic for 18 years. On May 9, 1946, before beginning treatment with rutin (A) fundus of the right eye with capillary fragility equaling 101 and vision, 0.1. (B) Fundus of the left eye at the same time, with capillary fragility equaling 101 and vision, 0.2—1. (C) Fundus of the right eye and (D) fundus of the left eye six months after beginning treatment with rutin. Capillary fragility is 32; vision: right eye, 0.1; left eye, 0.2—1.

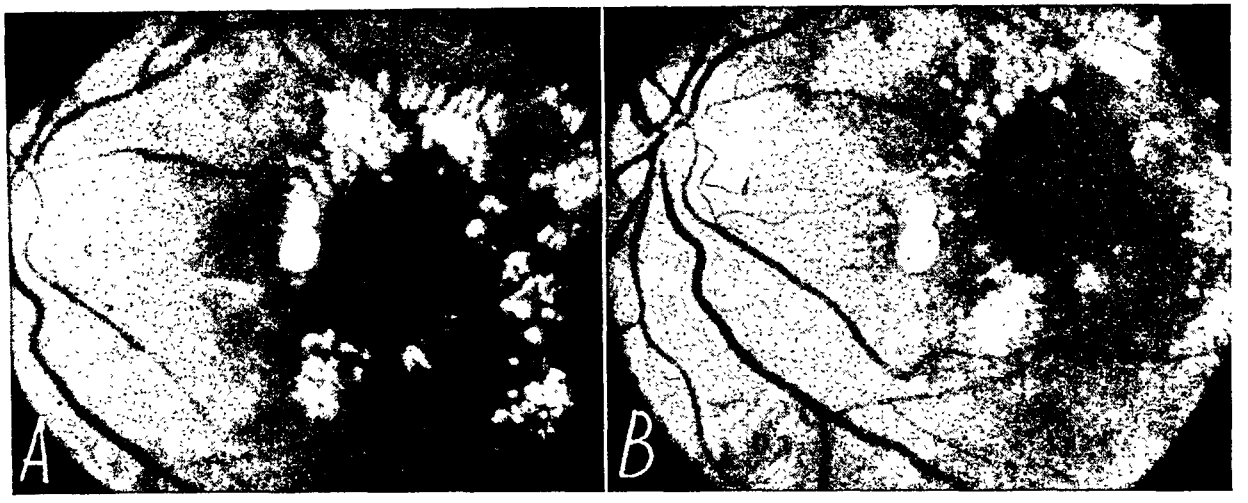

Fig. 2 (Donegan and Thomas). *Case 2.* A white woman, aged 54 years, had been a known diabetic for 10 years. (A) The fundus of the left eye before rutin therapy was begun; capillary fragility is 18; vision is 0.2—1. (B) Fundus of the left eye five months after beginning of treatment with rutin. The capillary fragility is 4; the vision is 0.2.

unilateral macular edema, with corresponding slight reduction in vision and relative central scotomas. The first, a white woman, aged 39 years, with mild vascular hypertension had noted slight blurring of right central vision for six weeks prior to examination. Except for the circumscribed area of edema in the right macula, the fundi and retinal vessels were normal. Her blood pressure was 150/90 mm. Hg, and the capillary fragility measured 81 on May 9, 1946. Rutin (160 mg.) daily was prescribed and seven days later she reported that the vision had cleared completely. Examination revealed only a few minute, yellow dots in the right macular region. No central scotoma could be elicited and the petechial index was 16.

In the second case, that of a 38-year-old white man, the history was similar and examination revealed a circumscribed area of edema in the left macula, with a corresponding relative central scotoma. General physical examination was essentially negative and the blood pressure was 112/72 mm. Hg. Only two petechiae were found on testing the fragility but 160 mg. of rutin were prescribed. Two weeks later he reported that vision in the left eye had returned to normal, and reëxamination revealed no central scotoma. The left macula appeared normal except for three tiny yellow dots. At this time the capillary fragility was zero.

Two of three patients with high myopia and macular hemorrhages had normal capillary fragility, while one presented 63 petechiae after application of the cuff pressure. The fragility decreased to 16 after rutin therapy but no significant improvement in vision or the fundus picture was noted in this patient nor in the other two.

No improvement in vision nor in the ap-

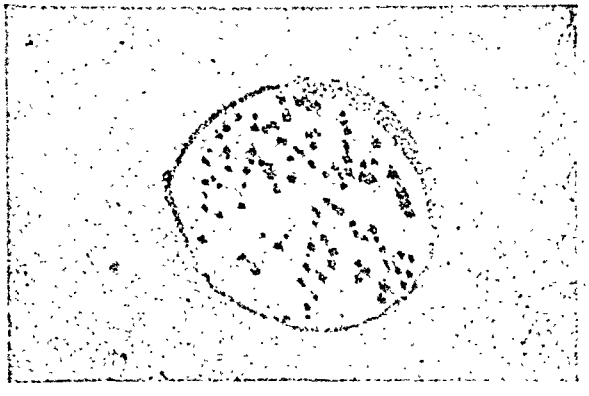

Fig. 3 (Donegan and Thomas). Demonstrating an abnormal number of petechiae in a 2.5-cm. circle in the antecubital fossa after application of the blood-pressure cuff for five minutes at a pressure midway between the previously determined systolic and diastolic pressure.

pearance of the retina was found after rutin therapy in two cases of occlusion of branches of the central retinal vein.

However, one patient, a 72-year-old white woman, suffering from mild generalized arteriosclerosis and hypertension experienced a sudden loss of left vision which was attributed to occlusion of one of the disc vessels. A remarkable recovery of vision and coincident clearing of the edema and petechial hemorrhages took place under rutin therapy, while the capillary fragility dropped from 46 to zero.

No increase in general capillary fragility was demonstrable in three individuals with central choroiditis or in two patients with disciform degeneration of the macula, and no improvement in vision occurred after administration of rutin.

The remaining 20 patients studied were hypertensive and arteriosclerotic individuals with a heterogenous collection of retinal complications. Capillary fragility was abnormally increased in all of these and was generally reduced after the administration of rutin. In numerous instances favorable changes in the retinal complications were observed after institution of rutin therapy.

In summary, it would seem that our findings are similar to those of Friedenwald and Foxworthy, who recently found the capillary fragility generally increased in diabetes mellitus, and even more markedly increased in diabetic patients with retinopathies. An increased capillary fragility in vascular hypertension, as reported by Griffith and Lindauer and by Shanno, was also demonstrated in our small series. The general capillary fragility was almost universally reduced by the ingestion of rutin in 51 patients.

Although no significant improvement in vision or decrease in the extent of retinopathy was observed in 25 patients with diabetes mellitus, we feel that the subject warrants further study. The retinal lesions in diabetes mellitus are noted for their chronicity and inertness, and in the patients included in this study the retinopathy was marked and undoubtedly irreversible.

Conclusions

1. Capillary fragility was found to be abnormally increased in arteriosclerosis and hypertension, to a greater extent in diabetes mellitus, and most markedly in diabetics with retinopathies.

2. Rutin has been found to decrease capillary fragility, but not to normal levels in diabetics with retinopathies.

3. Although no significant improvement in vision or decrease in retinopathy was observed in diabetes after rutin therapy, it may be significant that no loss of vision or increase in retinopathy occurred during a period of 10 to 12 months' treatment.

4. Rutin appears to be of benefit in the treatment of Eales's disease and central serous retinopathy.

MILD GLAUCOMA*

ADOLPH POSNER, M.D., AND ABRAHAM SCHLOSSMAN, M.D.
New York

The classification of glaucoma into acute, chronic congestive, and chronic simple forms is based on the clinical course of average typical cases. It does not take into account, however, the degree of severity of the disease. The division of the cases into narrow- and wide-angle types suffers from a similar inadequacy.

To the patient and his family, it is more important to know the prognosis of his disease than to receive an accurate diagnosis. In a series of 373 cases of primary glaucoma,† we observed 40 patients in whom the disease remained unusually mild throughout the entire course. Several of these patients were observed for many years. Some of the cases were discovered accidentally on routine examination, others were diagnosed because of the presence of glaucoma in other members of the family, while still others complained of mild symptoms of glaucoma.

In these patients the ocular hypertension is not very high, and generally is well tolerated. A good response to miotic therapy is the rule. The fields show no deterioration during the entire period of observation, and the fundi and vision remain normal.

Those cases in which the elevation of tension was the only sign of glaucoma were included if a provocative test or pupillography, or both, gave a positive result. Brief histories of 16 of these cases are reported in this paper. In addition to these, there are several patients in our series who showed mild glaucoma in one eye, and a severe or moderately severe form in the other. One such case (Case 17) is included in this paper.

CASE REPORTS

Case 1. Lottie C., aged 60 years, was told 25 years ago by an eminent ophthalmologist that she had glaucoma. She has had recurring episodes of ocular discomfort and blurring of vision. Tonometric readings have varied between 20 mm.‡ and 35 mm. in both eyes. The Knapp adrenalin test was positive in 1922 but homatropine failed to elevate the tension. Her anterior chambers and angles are intermediate in depth. She is a moderate hyperope. Her visual acuity has remained 20/20 in the right eye and 20/25 in the left eye over the past 18 years of observation. Visual fields and fundi are normal. The pupillographic curve is similar to that found in primary glaucoma. Pilocarpine (½ to 1 percent) relieves symptoms. Her brother and father suffered from glaucoma.

Case 2. Samuel D., a 64-year-old lawyer, was first seen in 1927 when he complained of intermittent pain in his eyeballs. Tension was normal at that time. In 1934, he saw colored halos around lights on three different occasions. The tension was still normal in both eyes. These symptoms continued at intervals. In addition, there was blurring of vision especially after near work and card playing. The attacks occurred at varying intervals, more commonly in the left eye, and were relieved by 1-percent pilocarpine. The tension was measured frequently over a period of 18 years and was found to be below 30 mm. except on three occasions. In 1939, the tension in the left eye was 33 mm. In 1943 the tension was 36 mm. in the right and 45 mm. in the left. Similar tonometric readings were obtained in 1945. His vision has remained 20/20 in each eye. The left eye is emmetropic while the right

* Presented before the New York Academy of Medicine, Section of Ophthalmology, October 20, 1947.

† Many of these cases were originally patients of the late Dr. Mark J. Schoenberg.

‡ All tonometric measurements were made with the Schiøtz tonometer and readings refer to the 1924 graph according to which 30 mm. Hg represents the upper limit of normal.

eye takes a −0.50D. cyl. ax. 180°. Fundi and fields are normal. His anterior chambers are deep and angles are wide. Pupillography showed a curve similar to that found in primary glaucoma. Thus it was not until 16 years after the onset of symptoms that a significant elevation of tension was discovered.

Case 3. Samuel F., a 55-year-old physician, began to complain of tearing, blurring of vision, and halos in 1931, three months after a golf-ball injury to the left orbit. The symptoms recurred intermittently for 10 years; yet at no time was the tension found to be elevated even though he made frequent visits to an ophthalmologist. If he used pilocarpine before a movie, he could prevent the subsequent appearance of halos. Between March, 1942, and October, 1943, the tension of his left eye was found to be 36 mm. on four different occasions. His right eye showed an elevation to 33 mm. on only one occasion. The symptoms were readily controlled by pilocarpine in dilutions as low as ½ percent. He has been suffering from left-sided familial migraine since 1913. The chamber angles are narrow. Vision of the right eye is 20/20 with a +4.0D. sph. ⊂ +2.5D. cyl. ax. 100°; and that of the left eye is 20/20 with a +3.5D. sph. ⊂ +2.75D. cyl. ax. 70°. Fundi and fields have remained normal. Pupillography shows curves similar to that found in primary glaucoma.

Case 4. Sarah A., aged 63 years, was first seen in 1937 when she complained of occasional blurring of vision. Examination revealed bilateral incipient cataracts. The fundi were normal and the tension was 26 mm. in each eye. The vision of the right eye was 20/20 with a +0.50D. sph.; and of the left eye, 20/30 with a +0.25D. sph. ⊂ +0.25D. cyl. ax. 180°. She was advised to use scopolamine (1/5 percent) three times a week in each eye. For nine months, while using the scopolamine, she was seen on several occasions and her tension was always below 26 mm. Hg (Schiøtz). She stopped medication and had no subjective symptoms, except occasional blurring of vision, for the next eight years. In May, 1945, in the course of a routine examination, her tension was 33 mm. in the right and 31 mm. in the left eye. One month later, it was 49 mm. in each eye, but dropped to 28 mm. one hour after the instillation of 2-percent pilocarpine. At this time, the patient was going through emotional stress. Pilocarpine (1 percent), used twice daily, has controlled the tension to date. Chamber angles are wide. Fundi and fields have remained normal. This patient has nerve deafness and obesity. She is one of six siblings of a consanguinous marriage (first cousins). There are no other cases of glaucoma in the family. However, one brother, her mother, maternal grandmother, and several other members of her mother's family had defective hearing. Her mother also had diabetes.

Case 5. Carrie K., a 62-year-old musician, was first seen in 1929 on routine examination. Her vision was 20/20 in each eye with +0.50D. sph. Tension and fundi were normal. She was seen at regular intervals, and it was not until August, 1944, that the tension in her left eye was found to be elevated to 33 mm. She was not given any medication. At the next visit, one month later, the tension was 40 mm. in the left eye and 28 mm. in the right. She was placed on 1-percent pilocarpine, two times a day. Her tension has been below 30 mm. up to the present time. Vision, fundi, and fields have remained normal up to the present. Pupillography shows a curve similar to that found in primary glaucoma. The patient does not complain of any ocular symptoms, except for tearing of the right eye which is due to partial obstruction of the lacrimal duct. She is a highly sensitive and a high-strung individual.

Case 6. Fay L., a 55-year-old housewife, was first seen in September, 1942. For two years previously, she suffered from eye-strain and sensitivity to light. She would fatigue easily and could not do her work.

A diagnosis of glaucoma was made at a hospital clinic in February, 1942. When she first saw Dr. Schoenberg, she was using miotics three times a day in each eye. She was also being treated for early menopausal symptoms and obesity. Vision was 20/20 in each eye with +0.25D. cyl. ax. 180°. Tension was maintained below 30 mm. in both eyes with 1-percent pilocarpine, three times a day. On one occasion (November, 1943) the tension in the left eye was 41 mm. and in the right 35 mm. Vision, fundi, and fields have remained normal. Pupillography, in 1942, showed a curve which contained elements similar to those found in glaucoma in addition to features suggestive of other neurologic disturbance.

Case 7. Suzanne M., a 66-year-old housewife, has been under observation since 1925. She has never had any ocular complaints. In June, 1945, routine tonometry gave a reading of 39 mm. in each eye. No treatment was started because she was advised to have a pupillographic examination. The patient left town and reported again in December when the tension was found to be R.E., 35 mm. and L.E., 41 mm. She went south and on her return visit in March, 1946, the tension was 36 mm. in each eye. Pupillography at this time revealed a curve which combined the usual pupillographic findings in cases of glaucoma with those of essential hypertension. She was then placed on 1-percent pilocarpine, twice a day. Her tension now fluctuates between 26 mm. and 33 mm. No symptoms referable to glaucoma have been experienced. Fundi and visual fields have remained normal up to the present. Vision is 20/20 in each eye with +0.50D. cyl. ax. 180° for the right eye; and +0.50D. sph. for the left. Gonioscopy shows wide angles. She developed diabetes in 1944 and also suffers from mild essential hypertension.

Case 8. Lillian R., a school teacher, aged 60 years, has been followed since 1931. She had no ocular symptoms until 1941 when she complained of eye fatigue after reading. Routine tonometry revealed tension of 28 mm. in each eye. In 1943, the tension was 36 mm. in each eye. Pilocarpine (½ percent) was prescribed but patient used it very irregularly. In 1945, the tension was again 36 mm. in the right eye and 34 mm. in the left and has remained at about 30 mm. Fundi show shallow cupping. Vision has remained 20/20 with +2.50D. sph. on each eye. Fields have remained normal. The patient also suffers from essential hypertension, diabetes, and obesity. Her mother, four sisters, and two brothers have diabetes. She also suffers from nerve deafness of the left ear.

Case 9. Carrie N. was first seen in 1921 at the age of 35 years. In 1924, she had occasional blurring of vision and ocular discomfort in the left eye, especially in bad weather. The tension was normal at this time. The Knapp adrenalin test resulted in mydriasis, generalized vasoconstriction, and hysterical crying. The jugular compression test was positive in the left eye but failed to raise the tension in the right eye. Homatropine failed to raise the tension; however, pilocarpine lowered tension from 26 mm. down to 14 mm. Elevation of tension was first noted in the left eye in 1928. Although the tension was normalized by pilocarpine, the symptoms persisted. Iridencleisis on the left eye, in 1941, controlled both symptoms and tension. The right eye remained normal until 1944 when the ten sion was 36 mm. Vision has remained 20/15, O.U. She has a moderate degree of hyperopia. Anterior chambers are shallow. Fundi and visual fields have remained normal. She suffers from asthma and essential hypertension. The pupillographic curve was similar to that found in primary glaucoma. Her mother, sister, and several other members of the family suffer from glaucoma.

Case 10. Rosa L., a sister of Carrie N. (Case 9), was first seen in 1921 at the age of 45 years. Because of her symptoms of recurrent blurring of vision of the right eye and a history of glaucoma in her mother,

she was carefully watched for glaucoma. Except for a positive reaction to the Knapp adrenalin test, there was no clinical evidence of glaucoma until 1927 when an elevation of tension to 42 mm. was noted in the right eye and to 36 mm. in the left. Miotics controlled the tension. Homatropine and ephedrine used as provocatives failed to raise tension significantly. Vision has remained 20/20 in each eye with −3.0D. sph., O.U. The fundi and fields were still normal when last examined in October, 1946.

Case 11. Gussie F., a 64-year-old woman, had an attack of acute glaucoma in 1932 at the age of 49 years. The attack subsided under miotics, but eight months later she suffered from another episode of congestion in the left eye. In 1933, she had another attack. This one responded to miotics, but she continued to have frequent elevations of tension with mild congestive symptoms until 1942 when a severe congestive attack necessitated iridencleisis. Tension in the right eye remained normal until 1945 when it was found to be 36 mm. on two separate occasions. She had no symptoms in this eye. Vision has remained 20/20 with +1.5D. cyl. ax. 90°, O.U. Fields and fundi have remained normal. Her sister has glaucoma.

Case 12. Norma P., aged 49 years, began to see colored halos in 1940. In 1941 she was refracted by another ophthalmologist who told her that her eyes were normal. She came under the observation of Dr. Schoenberg, in 1943. In view of the symptoms and the fact that her sister (Gussie F., Case 11) suffered from mild glaucoma, the patient was kept under careful observation. Nevertheless, a rise of tension was not observed until five months later. At this time the tonometric reading of the left eye was 43 mm. Under pilocarpine the tension dropped to 25 mm. on the following day. Pupillography showed a curve in both eyes similar to that found in glaucoma. The right eye has remained normal. Vision is: R.E., 20/25 with a +2.0D. sph. ⊂ +1.0D. cyl. ax. 160°; L.E., 20/20 with a +1.25D. sph. ⊂ +1.5D. cyl. ax. 180°. Fields and fundi have remained unchanged.

Case 13. Celia H., a 64-year-old housewife, began to complain, in 1937, of intermittent colored halos and pain around her right eye, especially after emotional excitement. A diagnosis of glaucoma was made by another ophthalmologist. Since the symptoms were not controlled by miotics, this physician advised surgery. She consulted a second ophthalmologist, but did not tell him her history. He found the tension to be normal and instilled homatropine in her right eye. This was followed by an acute congestive attack in the right eye. She responded to miotic therapy. The left eye has remained normal. Vision is 20/30 in the right eye with a +7.0D. sph. ⊂ +1.0D. cyl. ax. 140°, and 20/30 in the left eye with a +5.5D. sph. ⊂ +0.75D. cyl. ax. 170°. The anterior chambers are shallow and both angles are narrow. Fundi and fields have remained normal.

Case 14. Regina B., a 67-year-old journalist, first noted a heaviness and blurred vision in her right eye, in 1934. The symptoms followed closely upon news of the revolution in Vienna where her family was living. She made her own diagnosis of glaucoma because her cousin suffered from the disease. Tension in her right eye fluctuated between 18 mm. and 33 mm., while that in the left eye measured constantly below 25 mm. Vision has remained 20/20 in her right eye with +4.5D. sph., and 20/70 (amblyopia ex anopsia) in the left eye with +5.0D. sph. Fields and fundi are normal. The course of the glaucoma in this case is very similar to that of her cousin, Celia H. (Case 13).

Case 15. Rachel G., aged 72 years, has been followed since 1934. Aside from mild retinal arteriosclerosis and incipient cataracts, her eyes were found to be normal. In January, 1947, she complained of frontal headaches of one month's duration and occa-

sional blurring of vision. She has slight anisocoria, the right pupil being 4 mm. and the left 3½ mm. Slight cupping of the lower border of the right optic disc was noted, but both discs were normal in color. Vision in the right eye was 20/40 with a +3.5D. sph.; that of the left eye was 20/30 with the same correction. Peripheral fields and blind spots were normal. Tension was R.E., 35 mm.; L.E., 28 mm. Gonioscopy showed wide chamber angles. A lability test showed an increase in the intraocular pressure from 26 mm. to 36 mm. in each eye. Pilocarpine (1 percent) relieved the symptoms and lowered the tension to 22 mm. This case is an example of *early* glaucoma. It is too soon to prognosticate the course which the disease will follow.

Case 16. Ada F., a 65-year-old housewife, had an Elliot trephining operation performed on her left eye in 1926 for an advanced chronic simple glaucoma. At that time, the vision and field had already been greatly reduced. Her right eye remained symptom-free until 1937, when she was seen soon after an attack of cloudy vision which had subsided upon the installation of a miotic. While under continuous miotic therapy for the right eye, tension fluctuated between 16 mm. and 30 mm. until 1944, when a tonometric reading of 36 mm. was noted on one occasion. This patient also has diabetes and thyrotoxicosis. Fundus and field of the right eye have remained normal. Vision in the right eye, when last seen in 1945, was 20/20 with +3.0D. sph. ⊂ +2.0D. cyl. ax. 20°. This case illustrates that the course may be radically different in the two eyes.

Case 17. Osias M., a 70-year-old business man, suffered from a spontaneous retinal detachment of the right eye, in 1920. When first seen, vision in the right eye was 20/30 with +1.5D. sph., and that of the left eye, 20/20 with −1.0D. sph. ⊂ −1.50D. cyl. ax. 45°. Ultimately, he developed a total detachment and complicated cataract in the right eye. He was examined at frequent intervals and the ocular tension was always within normal limits. In 1935, the patient complained of discomfort and ocular fatigability in his left eye after close work. Even on this occasion the tension was R.E., 23 mm., L.E., 28 mm. However, one hour after the instillation of one drop of 1-percent homatropine, the tension of the left eye rose to 39 mm. He used ½-percent pilocarpine two times daily and the tension of the left eye fluctuated between 22 mm. and 33 mm. On another occasion, in 1942, 1-percent homatropine raised the tension of the left eye from 28 mm. to 39 mm. He developed lens opacities and index myopia. His corrected vision in 1945 was 20/70, and his fundus showed shallow cupping. Although no pallor of the disc was noted, a slight degree might have been masked by the presence of nuclear sclerosis. The peripheral field remained normal and the central field showed a small Bjerrum scotoma in 1945, 10 years after the diagnosis of glaucoma was made.

Comments

Mild and atypical forms of glaucoma offer a challenge in diagnosis. Many ophthalmologists have, at various times, emphasized the importance of recognizing the disease when signs and symptoms are absent or minimal. Several terms have thus found their way into the nomenclature. Among these are "preglaucoma"[1] and "prodromal glaucoma."[2] These terms are generally used to describe not the course of the disease but a specific stage in its life cycle. The choice of the terms is unfortunate since they imply that glaucoma has not yet become clinically manifest. It is an established fact that any disease may occur in a mild form and remain mild throughout its entire course. Jacobson[3] mentions a case of "prodromal glaucoma" of 28 years' duration. It is obvious that these terms refer, in reality, to clinical glaucoma which is either early or mild, or both.

An example of true preclinical glaucoma

is the normal eye in a monocular case. Five cases in our series showed a time difference of 8 to 15 years in the onset of glaucoma in the two eyes. In some instances provocative tests such as the Schoenberg[4] jugular compression test were negative in the normal eye. However, in all monocular cases pupillography showed a similar curve for both eyes.[5]

Another example of preclinical glaucoma is the glaucoma-free interval in the acute and chronic congestive forms. In several cases there was a time interval of more than five years between congestive attacks in the same eye. In one case, the left eye remained apparently free from glaucoma following an Elliot trephining operation until 18 years later, when a congestive attack occurred in the same eye.[6] Provocative tests may be negative during this interval. The glaucoma-free intervals should not be confused with the stage which follows a congestive attack, when the tension is often lower than in the other eye. One of our patients who complained of recurring attacks was considered a hypochondriac for one year by several ophthalmologists, because they always found the tension to be low normal. The subsequent course proved that he had chronic congestive glaucoma. If due credence is given to the patient's subjective symptoms, a diagnosis of glaucoma will be made earlier.

The best way to study the preclinical phase of glaucoma is to utilize normal individuals. Since the incidence of the disease in glaucoma families is greater than in the general population, a study of the preclinical stage of glaucoma may be facilitated by limiting one's self to the unaffected members of these families.

In a study of 30 such families from a genetic point of view, it was found that certain individuals, while themselves clinically normal, transmit the disease to their offspring. Since the inheritance is of the dominant type, one of the normal parents must of necessity carry the gene for glaucoma and may therefore be considered to have "genetic glaucoma." Thus genetic glaucoma is one type of preclinical glaucoma.

Pupillographic studies are now being carried out to discover whether pupillography may be an aid in the recognition of such preclinical cases. Three out of 14 children of glaucoma parents showed a curve similar to that found in primary glaucoma. In the general population, the finding of such a curve is extremely rare.

It is obvious that the terms "preglaucoma" or "prodromal glaucoma" should not be used in referring to the clinically established disease. The terms "early glaucoma" and "mild glaucoma," however, are descriptive of the clinical behavior of the disease. It is true that, in the early stage, it is not always possible to predict the future course which the disease may take. The case may be regarded as an early glaucoma until the physician is relatively certain that it is going to continue as a mild case. Of course, a certain number of these cases may later become more severe.

The term "mild glaucoma" was deliberately chosen because in trying to classify these cases in the conventional manner, we found it impossible to evaluate the symptomatology. If patients have symptoms of occasional bluring of vision, slight ocular discomfort, tearing, occasional halos, and difficulty in reading, are we justified in labelling them as chronic congestive glaucoma, even though congestion of the eye is never observed either by the patient or by the physician? There are other cases which have no symptoms nor loss of field and yet show fluctuations in tension. They cannot be unqualifiedly placed in the same category as a typical case of chronic simple glaucoma. In mild glaucoma conventional classifications break down and one has to identify the case according to its clinical behavior.

The diagnosis of glaucoma in such cases is often extremely difficult. Tonometric measurements form part of the routine examination in this office in all patients over

40 years of age. Tensions of 30 mm. or over are considered suspicious and warrant further investigations by means of provocative tests and pupillography. Of course, the reliability of the tonometric readings depends on the proper technique, care of the instrument, and accurate calibration. More important, however, than the numerical reading, is a difference of tension in the two eyes. We agree with Downey[7] that a difference of 4 mm. between the two eyes is significant; wide fluctuations in tension over a period of time are very suggestive even if the tension never exceeds 30 mm.

Among the provocative tests, we consider the lability test[8] and the water-drinking test[9] as the most reliable ones. A history of glaucoma in the family should make one less ready to dismiss the patient's symptoms even in the absence of objective signs. Such patients form excellent material for the study of the earliest phases of the disease. Pupillography has proved a useful adjunct in the diagnosis of a doubtful case.

If a case appears to have a mild form of glaucoma, it is not necessary to rush in with miotic therapy. It may be of benefit to the patient, and it certainly is to the advantage of the physician, to observe the case without masking its course by treatment. Placebos may be useful for psychologic reasons. Many patients are labelled as glaucomatous on the basis of one abnormal tension reading and are told that they must use drops for the rest of their lives.

Even if a patient is known to have mild glaucoma, it may be advisable for him to abstain from miotics as long as the symptoms are minimal and the fields show no signs of deterioration. It is worth mentioning that in some patients, the symptoms are even aggravated by the use of pilocarpine or other miotics. Since the earliest changes in the field occur in relation to the angioscotomas, it goes without saying that the fields should be carefully plotted on a tangent screen or stereocampimeter with small test objects and under standard conditions. We are using a tangent screen without markings from which the field is transferred by means of a pantograph.[10] (See this issue of the JOURNAL page 728.)

As in all forms of glaucoma, one can learn a great deal about these mild cases through long observation. The cases presented have been chosen with this in mind. For example, some patients tolerate moderately elevated tension for relatively long periods of time without showing any symptoms, ophthalmoscopic signs, or loss of field. We have observed such instances even among the more severe forms of glaucoma. Can ocular hypertension within certain limits be regarded as a compensatory mechanism which serves a useful purpose in maintaining the normal function of the eye? This point has been considered at greater length elsewhere.

It is obvious that surgery has no place in the treatment of a disease which runs such a mild course that none of the visual functions are impaired. Some of the cases, indeed, serve as controlled experiments. Several patients who suffered from glaucoma of equal severity in both eyes had an operation on one eye only; yet the disease followed a similiar course in both eyes. In general, it may be said that any statistical study aimed at evaluating the role of surgery in glaucoma should take into consideration the degree of severity of the disease prior to surgery.

A form of mild glaucoma which was not included in this paper is the syndrome of recurrent glaucomato-cyclitic crises.[11] This is a form of recurring attacks of unilateral glaucoma with mild cyclitic signs. It is probably a clinical entity and may be regarded as intermediate between primary and secondary glaucoma.

We have already referred to the fact that in many instances one eye ran a severe course while the other eye followed a mild course. Even among glaucoma patients in general, the two eyes may occasionally vary in the type as well as the severity of the disease.

Our experience with mild glaucoma is not unique. These cases are a part of the everyday practice of ophthalmology. The physician's and patient's attitude toward glaucoma is naturally colored by the dramatic experiences with severe cases. It is well to think of mild glaucoma. It may, at times, prove of great psychologic value for the patient to know that the diagnosis of glaucoma is not incompatible with a good prognosis.

Summary

1. In some cases of glaucoma, the disease is so mild that the fundus, fields, and central vision remain unaltered for many years.

2. Of 373 cases of glaucoma, 40 had the mild form. Seventeen case histories are reported in this paper.

3. Diagnosis is made by prolonged observation, provocative tests, and pupillography. Special attention should be given to the patient's symptoms and hereditary history.

4. Patients suspected of glaucoma should be very carefully studied before a definite diagnosis is made. An attempt should be made, whenever possible, to determine the degree of severity of the disease before instituting miotic therapy.

A COMPARISON OF ANISEIKONIC TEST INSTRUMENTS AND PROLONGED INDUCTION OF ARTIFICIAL ANISEIKONIA*

PAUL W. MILES, M.D.
St. Louis, Missouri

Aniseikonia can be produced artificially in any normal individual by the wearing of afocal glasses which by different lens thicknesses and base curves will magnify the image seen by one eye more than the other. The unequal images produced will interfere with fusion, cause subjective distortion of objects in space when perspective and rectilinear shapes are absent, and if the difference in size is more than approximately 5 percent, fusion and stereopsis are prevented altogether. Lesser differences will cause eyestrain in certain individuals who are unable to maintain suppression under all circumstances. Suppression of parts of an image helps to eliminate the false stereoscopic clues in favor of the more accurate monocular clues in such individuals. Many who have anisometropia or unequal or oblique astigmatic refractive corrections, or have different-sized eyes, have such unequal, yet highly acute, ocular images. Some of these persons will never have comfortable vision until the images are made equal, or one eye is occluded sufficiently to allow continuous suppression.

EXPERIMENTAL PROCEDURE

These experiments involved wearing afocal glasses which magnify in the vertical meridian (axis 180°) of one eye for periods of 25, 37, and 23 days. The final experiment involved oblique aniseikonia, and the lenses were worn for 28 days. Glasses in each instance were worn continuously every waking moment, and measurements were taken twice a day on the test instruments.† The experiments provide evidence about the following questions:

1. How does an individual react subjectively and functionally when suddenly and persistently forced to cope with binocular images which do not match?

2. What is the nature of the subjective and measured adaptation to artificially induced aniseikonia? Will the binocular organization change to promote fusion?

3. How does the space eikonometer[2] correlate with the ophthalmo-eikonometer[3] in measuring artificial aniseikonia? Why is the simple frontal plane alignment[4] unsuitable as a diagnostic test?

4. How sensitive and precise are the two standard instruments? Do they over- or under-estimate the error?

5. What is the effect of homatropine and eserine on the measurement of artificial aniseikonia?

THE AXIS-180° EXPERIMENT

Figure 1 summarizes the first experiment. The subject is the writer, whose eyes are normal except for slight myopia (O.D., —0.75D. sph. ⌒ +0.25D. cyl. ax. 90°; O.S., —0.50D. sph. ⌒ + 0.25D. cyl. ax. 90°) for which he had not been wearing glasses. Aniseikonia, measured without glasses many times before and after the experiment, is: Axis 90°, O.S., 0.4 percent; axis 180°, O.S., 0.8 percent. This means that to equalize the images of the two eyes, the whole left image must be magnified 0.4 percent, and the axis 180°, an additional 0.4 percent. The lines on

* From the Department of Ophthalmology and the Oscar Johnson Institute of the Washington University School of Medicine.

† The writer acknowledges the aid and direction of Kenneth N. Ogle, M.D., and Robert E. Bannon, B.S., of the Dartmouth Eye Institute in these experiments, performed between February 4, 1946, and July 25, 1946. He also thanks Ethel Jean Babbitt, O.D., who was the subject in the experiment of Figure 4. This work differs from that of Herman Burian, M.D., in 1943,[1] in that the size lenses in his experiments were worn at axis 90° instead of axis 180°, and were worn a maximum of 14 days.

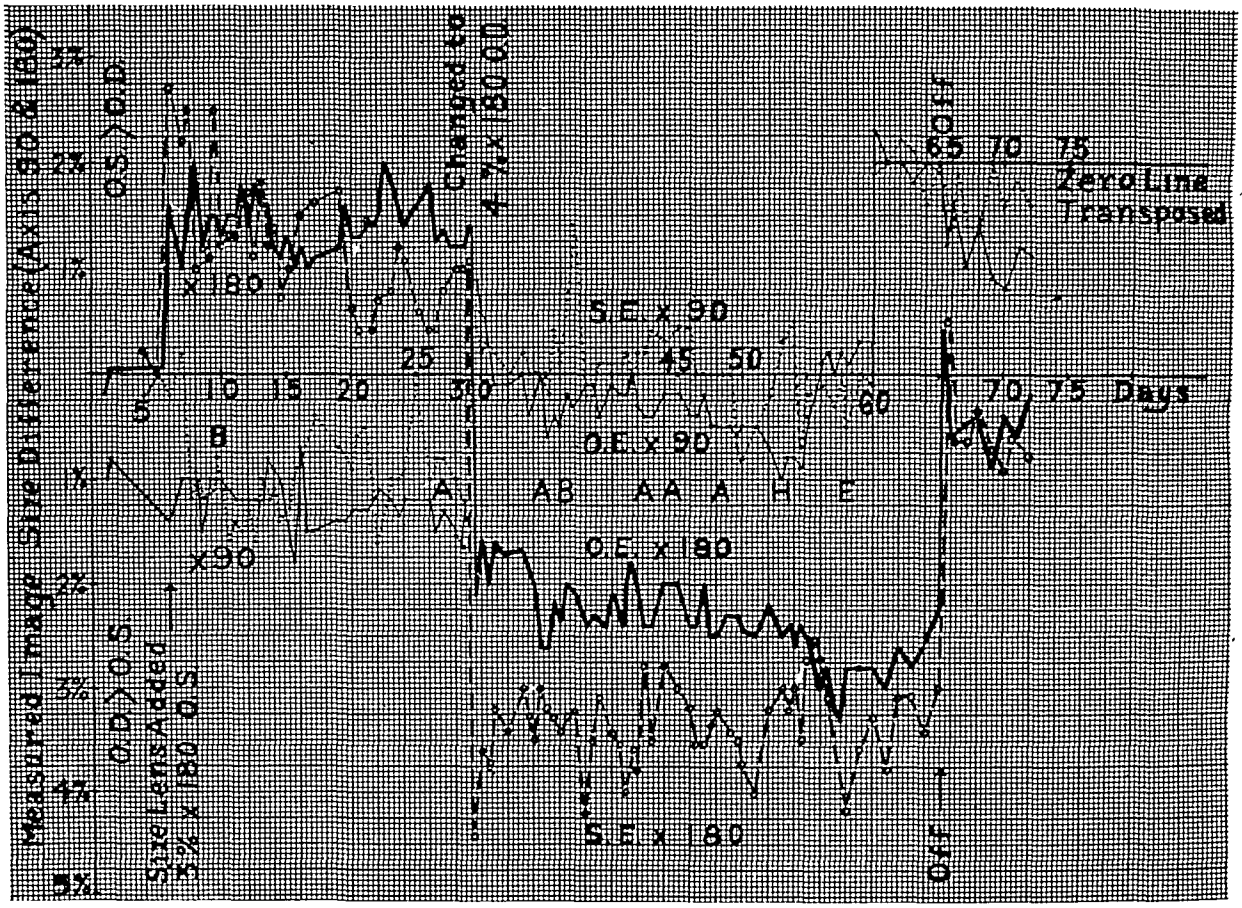

Fig. 1 (Miles). The differences in the size of the images of the two eyes as determined by the ophthalmo-eikonometer (O.E.) at 20 feet and the space eikonometer (S.E.) at 10 feet with the subject (P. W. M.) wearing a meridional size lens of 3.0 percent at axis 180° before the left eye for 25 days, then 4.0 percent at axis 180° before the right eye for 37 days. (A) indicates headache. (B) indicates subjective adaptation to distortion. The heavy lines indicate axis 180° measured, the fine lines, axis 90°.

the graph record this figure: the magnification required over the other eye to equalize the images. The O.S. > O.D. means that under the test conditions, the left image has been found larger than the right in the two meridians the amount specified on the graph.

The graphs may be better understood by referring in Figure 2 to the four diagrams, "P" to "S." "P" shows diagrammatically a stereoscopic card where a tall right image is presented for fusion with a square left image. Obviously, magnification of the left image, axis 180°, is required to equalize the images. Below the abscissa, right images are too large, and above the abscissa left images are too large.

In Figure 1, the abrupt change in the two heavy lines indicates the changes in axis-180° aniseikonia according to the space eikonometer (S.E.) and the ophthalmo-eikonometer (O.E.) when aniseikonic glasses were put on, the fifth day. These glasses were afocal, but the left lens was three times thicker than the right, and was "bent" on the 180° axis so that the upper and lower edges approached the face. This magnified the image seen by the left eye 3.0 percent in the vertical meridian. Neither lens worn blurred the vision perceptibly. Visual acuity at 20 feet was: O.D., 20/25; O.S., 20/20.

Subjective findings with axis-180° aniseikonia

Immediately, there was distortion of surrounding objects, but no particular discomfort. The desk top tipped down toward the right. At dinner the first evening, I dis-

covered an inability to pass a plate of peas. The plate was held 15 degrees off the horizontal. On walking, there was some tendency to try to adjust to the slope visualized, when the feet could much better take care of themselves. A level lawn seemed to slope level. Worse yet, it was impossible to fit a trial frame on a patient's face without a monocular side view. Minor surgery was done without difficulty.

After about five days, "B" in Figure 1, the distortion was no longer annoying in

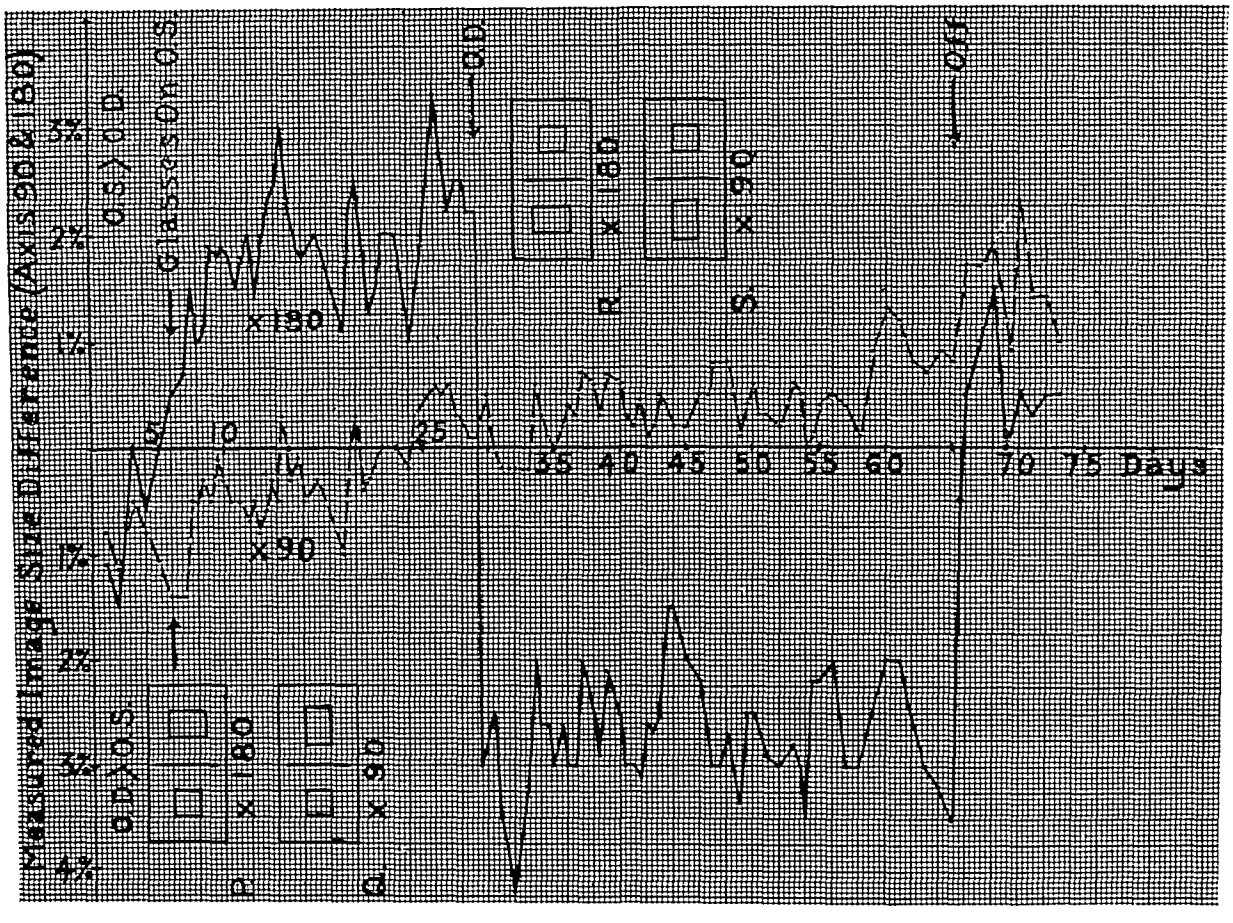

Fig. 2 (Miles). Measurement of axis-90° and axis-180° aniseikonia in the same experiment as in Figure 1, by means of the frontal-plane apparatus (fig. 4). In the axis 180° in subject P. W. M., the test was relatively stable. Axis 90° should remain near the zero line throughout, however. This is the broken line near the abscissa.

up to the left and down to the right for a radius of about 40 feet. More distant lawn was flat, but tipped as it was approached. The left foot appeared smaller than the right and was on a shorter leg. Objects on the right seemed larger and more distant than they were known to be. A wall actually in a frontal plane appeared more distant on the right. Any rectangular object such as a sheet of paper or a magazine appeared trapezoid, larger on the right.

I found it impossible to fix a lampshade ordinary surroundings, but there were occasional mild headaches, points "A." However, when the surroundings contained no perspective or rectilinear detail to increase the probability of mental choice of monocular clues for depth judgments, the distortion returned. For instance, on looking down on a grassy slope, or walking through underbrush, one is forced to depend on binocular clues. A slope was perceived in error as much as 20 degrees. There was a fearful helpless feeling while following a

path through dense underbrush. Branches on the right seemed feet away, but without provocation would approach and strike.

INSTRUMENTS UNDERESTIMATE THE ERROR

In Figure 1, the solid line, axis-180° aniseikonia starts out nearly at zero, but on putting on the glasses on the fifth day, 3-percent axis-180°, left, the image O.S. becomes larger in this meridian than the image O.D. However, the heavy solid line and the heavy dash line (space eikonometer) do not approach a measurement of 3 percent, but fall considerably short. The error was known with certainty, because the glasses worn were tested on the diopto-eikonometer for an eye-wire distance of 9 mm. both at the factory and at the Dartmouth Eye Institute.

The space eikonometer measured correctly the known error at first, but began a progressive undercorrection. The measurement fell in a 25-day period from 2.75 percent to about 0.4 percent, which requires explanation. The space-eikonometer (S.E.) test is based on subjective adjustment of a string target to appear on a frontal plane before the eyes. It is supposedly free of monocular clues, so that judgment is entirely based on stereopsis. Apparently, in this experiment, the adaptation shown was due to some obscure monocular clues which gradually became sure enough to affect final judgment. Stereopsis was given progressively less weight due to memory of its failure in ordinary surroundings.

When the 3-percent lens was removed from the left eye and a 4-percent lens placed axis 180° before the right eye, the adaptation or progressive undercorrection on the S.E. did not take place. In Burian's experiment[1] it was noticed that "the effect of a size lens of 3 percent worn by the two observers H. M. B. and R. E. B. in front of the right eye (10 to 14 days) was reduced by about 50 percent at the end of the experiment, whereas when the lens was worn in front of the left eye, the decrease in effectiveness was only about 20 percent." Burian did not state whether this "adaptation" was limited to readings on the S.E. as in the experiments reported here.

For many years, patients at the Dartmouth Eye Institute have been tested in the "leaf room."[5] This is a box with an open end 6 by 6 feet with a head rest in the center. The box is 7 feet deep, set exactly level with true right angles. The interior is covered with several layers of artificial leaves. Lacking perspective detail and monocular clues, one's judgment of the leaf room depends on stereopsis. One with aniseikonia will state that it is distorted. On placing aniseikonic lenses before the eyes, the end and sides and floor and ceiling all change position. Now, some patients see this distortion with a very weak magnifier before one eye who do not see it when the magnifier is placed before the other. It has been assumed that this is due to dominance. Theoretically, suppression of stereoscopic clues is easier in the recessive eye. These experiments do not confirm this theory. H. M. B. and R. E. B. got adaptation with the lens over the dominant eye; E. J. B. got no adaptation with the lens over the dominant eye. P. W. M. got adaptation with the lens over the recessive but not over the dominant eye.

Moreover, there is no evidence at all of adaptation on the O.E. instrument (solid line fig. 1). This test measures aniseikonia by a comparison of visual angles of about four degrees and requires no use of stereopsis. The adaptation is, therefore, not real. It is due to a change in choice of conflicting monocular and binocular clues in the cerebral centers. Incidentally, monocular clues are more numerous and are given more weight in space judgments than is commonly believed. They include in order of decreasing importance: perspective, overlay, parallax, known size, illumination contrast, position above or below, color, atmospheric haze, and convergence proprioception. Perspective can, under laboratory conditions,

actually predominate over free binocular vision with parallax.

The time factor in aniseikonic tests

In these experiments, perhaps five minutes were spent on the S.E. test, 10 minutes on the O.E., and 25 minutes on the frontal plane apparatus about twice a day. It requires about 10 minutes to get all of the head rest adjustments just right on the O.E., but, once done, the settings can be recorded and duplicated quickly. Adjustment on the S.E. is somewhat simpler. Prof. R. E. Bannon criticized my experiment on the basis that not enough time was taken to measure the full amount of aniseikonia present. He has reiterated for years that one should not be satisfied with the first end point, but should repeat and repeat the test up to an hour or more. Dr. Herman Burian said,[1] "The longer an observer watches a field which is relatively free from perspective factors, the more he frees himself of the memory values of the previous experiences and the more he is apt to give weight to the disparity factors."

The adaptation found in Figure 1 measured on the space eikonometer should not lead to doubts of the instrument's value. The axis-180° adaptation would undoubtedly have disappeared with prolonged testing. Many patients need prolonged testing on this instrument for a different reason. Some, because of aniseikonia or faulty development, have poor sensitivity on the S.E. They do not habitually use stereopsis, and give it no weight in space judgment. Such a patient improves markedly with repeated tests. It is excellent orthoptic training.

Professor Bannon proved his point in the E. J. B. experiment (fig. 3). On the 28th day the measurement had been running along for a week at: O.S., 2.0 percent plus or minus 0.2 percent on the O.E. instrument, when it suddenly went down to 1.6 percent. Her remark that it was adaptation elicited doubt in Professor Bannon. Upon measuring her for an hour, the aniseikonia became 2.6 percent axis 180°, which was more than the 2 percent worn.

Effect of homatropine and eserine

In Figure 1, "H" indicates the use of 2-percent homatropine (3 times daily) in each eye for four days. Plus-2-diopter clip-ons were used for the daily work, but not for measurements. On the O.E., this caused an immediate change in both axis-90° and axis-180° readings, a measurement more nearly the known aniseikonic error by 1 percent in each meridian. Surely homatropine has nothing to do with a memory factor. Immobilization of the lens mechanism or change in the accommodation-convergence ratio may affect the O.E. test. No change was evident in the S.E. test. On the fifth day, eserine ointment was applied, and a myopia of more than 6D. induced. This resulted in a spike not shown on the graph. On the O.E., but not on the S.E., there was more axis 90°, O.D., by 1 percent and less axis 180°, O.S., by 0.75 percent.

Subject E. J. B. found that homatropine for 24 hours did not affect the measurements. She was not undercorrected without it, nor did she show any tendency to adaptation. Her eyes are normal except for myopia: O.D., −2.5D. sph., 20/15; O.S., −2.5D. sph., 20/15. Axis 90° is not recorded in Figure 3, but it ran throughout the experiment (O.S., 0.2 percent plus or minus 0.6 percent on both S.E. and O.E.).

In Figure 1, it can be seen that, while P. W. M. was wearing O.S. axis-180° magnification, the axis-90° reading remained about 1.2 percent, O.D. When the magnification was worn O.D., the axis 90° became about 0.2 percent O.D. This difference is a bit more than experimental error, and is attributed to the induced size effect.[6]

Frontal-plane measurements

Figure 2 shows the aniseikonia as measured on the frontal-plane apparatus. As in Figure 1, the axis-90° line wanders upward, but in a more purposeful way. In

this case, axis 180° is measured quite accurately. The error in axis 90° is evidently due to an increasing amplitude of fusion during the prolonged test, repeated daily for weeks. This can easily be explained by a description of the apparatus and the technique. The accuracy of the method depends on the amplitude of fusion, which is so weak in many patients that the graphic determination of aniseikonia is impossible.

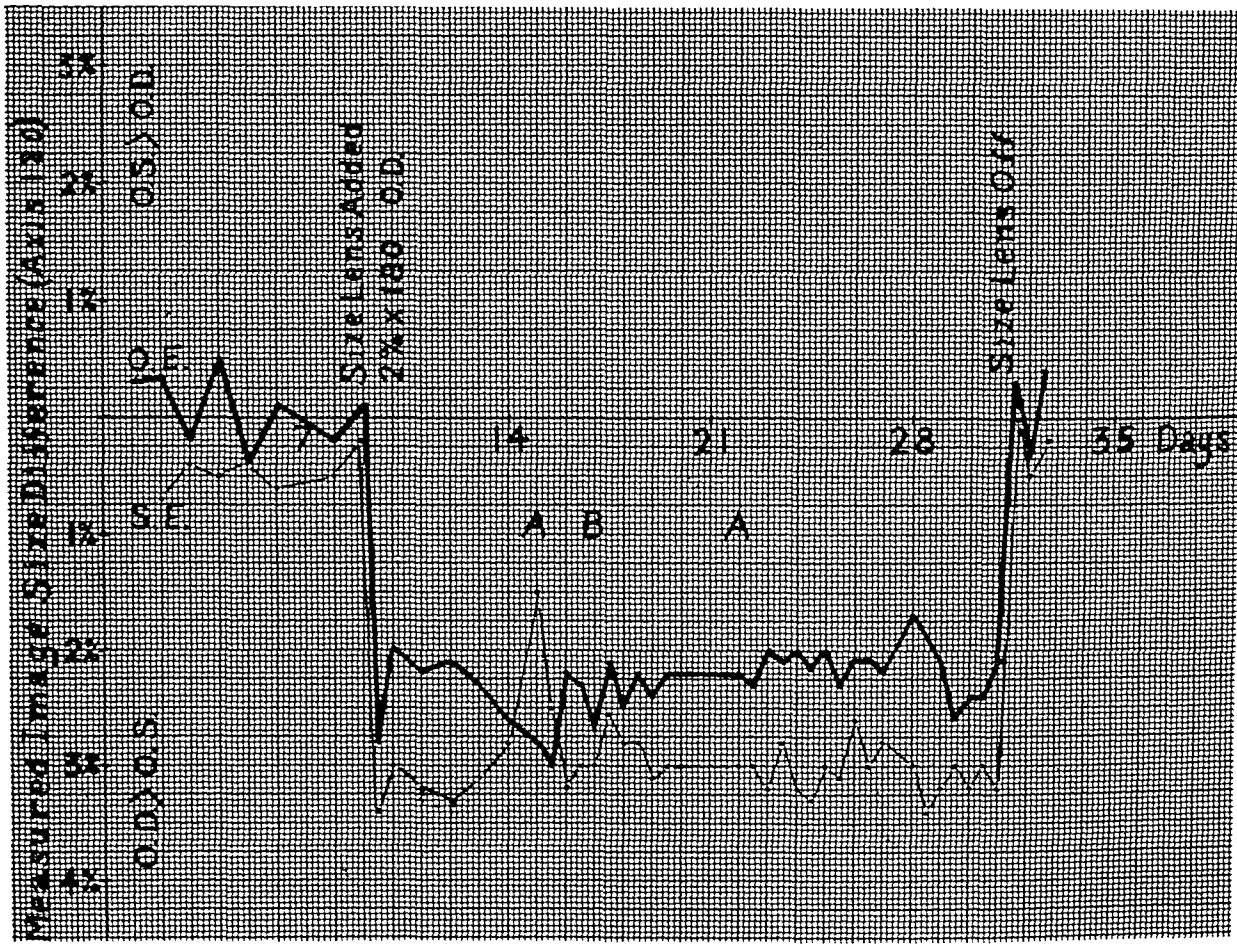

Fig. 3 (Miles). The differences in the size of the images of the two eyes as determined by the ophthalmo-eikonometer (O.E.) at 20 feet and the space eikonometer (S.E.) at 10 feet with the subject, E. J. B., wearing a meridional size lens of 2.0 percent at axis 180° before the right eye. (A) indicates headache. (B) indicates subjective adaptation to distortion.

Figure 4 shows the apparatus to consist of a head holder, dissimilar apertures (to prevent their fusion), a target on glass consisting of irregularly shaped and sized spots arranged along a horizontal line level with the two eyes, with a few irregular spots above and below, seen in peripheral vision, which increase the amplitude of fusion. This target is placed before a white background, so that no outside details exist to affect the judgment as to its position. When axis-90° size is placed before one eye, the dots on that side appear larger and are perceived further away. This axis-90° depth change is geometrical and has been explained frequently in the past.[1] The plane is moved by the subject on a vertical central axis until the two sides of the target appear equidistant. The total absence of perspective clues and minimum of monocular clues makes the setting depend chiefly on stereopsis. The number of degrees the plane is rotated proportional to the percentage magnification in the axis-90° direction up to the limit, about 20 percent.

When axis-180° size is placed before one eye, it has exactly the opposite effect as axis 90°, with equal but opposite rotation of the target plane up to about 6 to 8 percent. This is the induced size effect of Ogle.[6] Stronger magnifications produce less rotation, so that the information—magnification over either eye axis 180° and the rotation of the target plane in degrees plotted graphically—becomes an S-curve. From the center of the S-curve and the slope of the line determined by target rotation due to 2 percent, axis 90° over either eye, aniseikonia is determined.[6]

THE OBLIQUE ANISEIKONIA EXPERIMENT

An analogous experiment was performed on subject P. W. M. with oblique meridional size lenses and is summarized in Figure 5. Tests were made twice daily on the space eikonometer. Only the "delta," the amount of oblique aniseikonia, is recorded here. Axis 90° and axis 180° remained; 0.0 percent plus or minus 0.4 percent, and O.S., 0.8 percent plus or minus 0.7 percent respectively. Oblique aniseikonia is of clin-

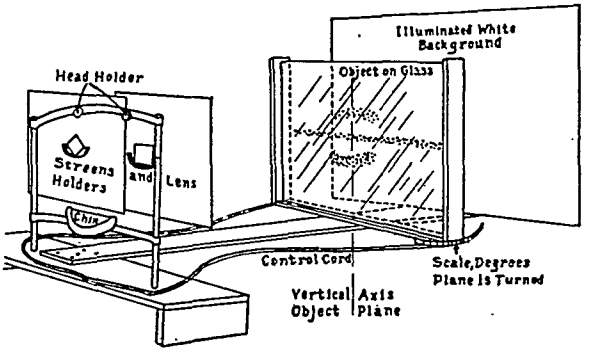

Fig. 4 (Miles). Schematic drawing of the frontal-plane apparatus used for measuring aniseikonia. Size lenses are placed at axis 180° before one eye magnifying from 1.0 to 14 percent, and the object plane is adjusted to appear perpendicular to the median plane of the head.

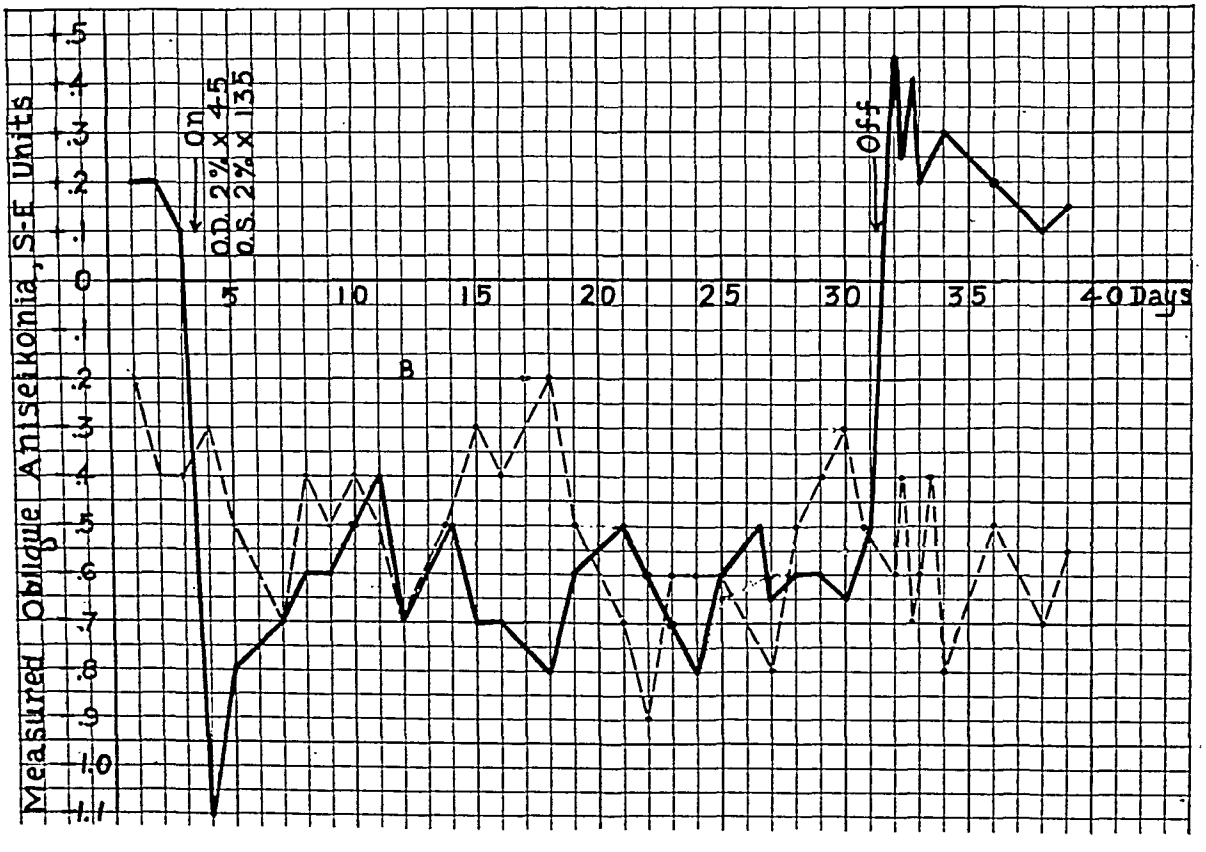

Fig. 5 (Miles). The solid line indicates the amount of oblique aniseikonia in subject P. W. M. when wearing oblique meridional size lenses as measured on the space eikonometer. The broken lines indicate simultaneous cyclophoria in the same units, apparently unaffected by the glasses. (B) indicates when partial subjective adaptation occurred.

ical importance in patents with oblique astigmatism.

In this experiment, the oblique lenses caused much more discomfort than did the axis 180°. The prescription was O.D., 2 percent, axis 45°; and O.S., 2 percent, axis 135°. This is equivalent in its effect on cyclophoria and spacial distortion to a dioptric strength of 2.5D over each eye at the same axes, placed at an eyewire distance of 9 mm. It is well known that patients wearing glasses for such astigmatism are seldom comfortable. The glasses worn in this experiment were afocal, and did not blur the vision.

In Figure 5, the solid line is the oblique aniseikonia as measured on the space eikonometer with actual strings at 10 feet. The broken line is cyclophoria measured in the same units under the same target conditions by means of a half-silvered mirror and additional test targets thereby projected into the scene.[7] It is seen that cyclophoria at the beginning was recorded at −0.2 and −0.4 (degrees total excyclophoria) but increased to about −0.6 percent plus or minus 0.3 percent during the experiment at the same time that adaptation to oblique aniseikonia as expressed by the solid line occurred. The persistence of cyclophoria after removal of the glasses is not understood.

Subjective symptoms

Such glasses, like plus cylinders with axes converging above, put strain on the superior oblique muscles. Each of the 28 days the glasses were worn, there was eye strain with a constant almost overwhelming desire to remove them. The pull on the superior obliques would have been decreased by adjusting the axes nearer either the vertical or horizontal. Adjusting the axes to diverge above would shift the pull to the inferior obliques which are normally much stronger and more efficient. The eyestrain from the experiment was never sufficient to prevent daily work, although concentration and study were difficult.

There was distortion, extreme at first, which was not much improved after a week. Even after 28 days, there was little subjective adaptation. The distortion, like that with axis-180° magnification, was limited to objects within about 40 feet. Geometrically, the distortion (for instance the rotation of a frontal plane in degrees) should increase approximately with the square of the distance.[8] Practically, this increase is not important because beyond about 40 feet monocular clues to depth perception begin to predominate. The question has been raised in the use of the space eikonometer whether the front vertical strings can be made equidistant to the observer without making the rear vertical strings unequal, and vice versa. In practice with the target at 10 feet, the difference is imperceptible. Due to the relatively small interpupillary distance, steropsis itself is limited to from 100 to 600 yards.[9]

At first, buildings and walls looked too tall, and seemed to lean toward me. Persons nearby seemed tall and overbearing with long spindly legs. On looking down at a grassy lawn, I seemed to be standing in a depressed area or trough extending laterally. On standing in a field of barley, this trough was deeper, and on changing the visual direction, the trough rotated causing everything to wave like the surface of the ocean. Walks through the woods were very unpleasant due to a feeling of unreality and even fear. The brush seemed to close in about the head. Persons with claustrophobia should be tested for this type of aniseikonia!

At badminton, I missed the shuttlecock by a foot or more at first. After some practice, I did fairly well.

I did not try to drive the car with these glasses on, but it has been done. A. Ames, Jr., reports,[8] "In driving an automobile . . . there is only the very slightest or no apparent tipping of the road. However, with the glasses one feels elevated, almost as if sailing along 10 or 15 feet above the road." With the meridional size lenses each rotated

90 degrees, "The glasses have the opposite effect, as if one were driving in a child's cart with his feet almost dragging on the road. Contrary to what might be expected, movement of the car enhances these effects."

Additional remarks

These subjective findings are rarely described by patients suffering from aniseikonia until glasses correcting the aniseikonia are worn. Patients then complain of distortion for a day or so. Clinical experience shows that when the full amount of aniseikonia measured on either the ophthalmo-eikonometer or space eikonometer is prescribed, the correction measured again at any later date remains consistent. One need not overcorrect or undercorrect aniseikonia.

Prof. R. E. Bannon told me of an instance "in the old days" when every patient so unfortunate as to have measurable aniseikonia was forthwith corrected by glasses. By some fluke, the size lens was placed over the wrong eye. The patient was I. C. F., Ph.D., who wore about 1.5-percent magnification on the wrong eye, thereby increasing what error she had by 1.5 percent. On reëxamination three years later, she was still wearing the glasses daily, and still showed the 1.5-percent error measured originally.

However, not all healthy individuals can wear experimental size lenses. A young physicist wore my O.S., 3-percent, axis-180° glasses for one-half hour, and went home with a splitting headache that lasted several hours.

Summary and Conclusions

This paper describes experiments in which meridional magnifying lenses were worn for prolonged periods of time. Subject P. W. M. wore 3-percent, axis-180° lens over the left eye for 25 days, changing immediately to 4-percent, axis-180° lens over the right eye for 37 days. Later, he wore O.D., 2-percent, axis 45°, and O.S., 2-percent, axis 135°, for 28 days. Subject E. J. B. wore 2-percent, axis 180°, O.D., for 23 days. With the axis-180° glasses, there was slight discomfort, occasional mild headaches, and marked distortion of objects in space. The distortion disappeared in about five days, except in surroundings devoid of perspective or rectilinear detail.

With the oblique aniseikonic glasses, there there was constant eyestrain and distortion of objects in space which was reduced in ordinary surroundings, but never did completely disappear. Excyclophoria produced during the experiment was measured and was found to increase an amount approximately equal to the amount which measured oblique aniseikonia decreased during the first two days. In other words, the compensation process which decreased subjective distortion involved increase in the cyclophoria.

The adaptation process otherwise is thought to involve a suppression of the objectionable parts of the image of the recessive eye. The parts suppressed are those slightly disparate due to the interpupillary distance. Since this disparity is necessary to stereopsis, this function becomes defective in aniseikonia, and monocular clues are given greater weight.

There is no real adaptation to aniseikonia. When an individual is forced to rely on stereopsis as in the space eikonometer, or when aniseikonia is measured by comparing actual visual angles as in the ophthalmo-eikonometer, aniseikonia is found to remain the same indefinitely.

There is apparently a time factor involved in measuring aniseikonia, which may explain some of the variability and "adaptation" shown in these experiments. In order to measure the total amount of aniseikonia present on either the space eikonometer or the ophthalmo-eikonometer, determinations must be repeated until, finally, memory factors, and habitual favoring of monocular clues over stereoscopic have been overcome.

Use of the space eikonometer is good training to develop stereopsis, since monocular clues are almost entirely eliminated.

In these experiments, the space eikonometer measured a larger portion of the artificial aniseikonia known to be present than did the ophthalmo-eikonometer. In one instance, the use of homatropine cycloplegia made the ophthalmo-eikonometer more accurate. Neither of these findings apply to clinical tests where more time is taken.

Historical Miniature

The word "phoria" is associated with a multitude of concepts of binocular coördination. It was introduced by von Graefe to designate potential strabismus. He had observed that, with many pairs of eyes which were obviously free from strabismus, the double images induced by a vertical prism were also displaced laterally.

SIZE OF LINE IN THE MADDOX-ROD TEST*

RICHARD G. SCOBEE, M.D.†
Saint Louis, Missouri

AND

EARL L. GREEN, PH.D.‡
Columbus, Ohio

This study is one of several (Scobee and Green[1]) concerned with the effect of variables in testing technique on the measurement of heterophoria with the Maddox-rod test. The particular variable studied in this report was that of the size of the line of light as seen through the Maddox rod in measuring heterophoria at a testing distance of 13 inches. It is a well-known fact that different examiners using the same test of heterophoria on the same individual may get different results. In a search for possible explanations of this variation, several possible variables have already been studied. These include: examiner variation, test used and its correlation with the cover test, amount of illumination in the testing room, color of the Maddox rod used, the eye before which the Maddox rod is placed—that is, dominant or nondominant—in performing the test, and individual subject variation from day to day.

METHODS FOR MEASURING

TEST LIGHTS USED

It was believed that since different examiners may use different sized muscle lights at the 13-inch testing distance and produce varying sized lines as seen through the Maddox rod, any possible effect of this size difference should be determined. In the beginning, three test lights were used. One was an ophthalmoscope with a May-type head removed; a second was a flashlight fitted with a solid diaphragm in which a hole 1.0 mm. in diameter had been bored; a third was a Welch-Allen ophthalmoscope with the head removed. The May-type ophthalmoscope gave a broad line image when viewed through a white Maddox rod. The 1.0 mm. light gave a narrow, sharply delimited line. The Welch-Allen ophthalmoscope light had such a comparatively large filament and resulted in so many lines of varying brightness when viewed through the Maddox rod that it had to be discarded because it was too confusing to the subjects.

TESTING DISTANCE

All measurements were made at a testing distance of 13 inches with the testing technique previously described (Scobee and Green[1]). In brief, both lateral and vertical heterophoria were measured at 13 inches with a white Maddox rod placed before the right eye of all subjects. For lateral hetrophoria, a Risley rotary prism mounted on a phorometer (American Optical Company) was placed before the same eye as the Maddox rod; the rotary prism had a total strength of 30 prism diopters and was calibrated in units of 1 prism diopter. For vertical heterophoria, the Maddox rod was used in conjunction with a Stevens phorometer mounted on the same instrument; the prisms were split before the two eyes and had a total strength of 2 prism diopters, being calibrated in 0.2 diopter units. Thirty-two subjects were tested.

* This study was done under a contract with the Office of Naval Research as Project N6onr-202, Task Order I.

Results of measurements

Lateral heterophoria

The average heterophoria was −4.89 prism diopters (exophoria) when the source of the light was large (*ophthalmoscope*) and −4.87 prism diopters when the source of light was small (flashlight). The difference of 0.02 prism diopters is not statistically significant, the standard error of the difference being 0.398 prism diopters ($t = 0.05$, $df = 31$, $P > 0.90$).

Two tests were made of the justification for using the statistical method of comparing a mean difference with its standard error. The first of these was to see if the frequency distributions of heterophoria under the two conditions of large and small sources of light were approximately normal in form. The distributions were shown to be sufficiently symmetrical and bell-shaped to justify the assumption of normality. The second test was to see if the variances of the two distributions were the same within sampling limits. These variances were found to be 25.67 square prism diopters for the large light source and 25.72 square prism diopters for the small light source. The ratio of these two variances, $F = 1.002$, indicates they are not significantly different as judged by the method of Morgan[2] for comparing variances of correlated series.

The heterophoria determinations under the two conditions of large and small light sources are highly correlated, $r = +0.90$. This is sufficiently high to indicate that knowledge of a heterophoria reading made under one condition will be equivalent for most practical circumstances to a heterophoria reading made under the other condition. Of the 32 subjects examined, only one had as much as 6 diopters difference, a shift from −14 prism diopters with the large light to −8 prism diopters with the small light. Two subjects had shifts of 4 prism diopters, one from +4 to +8, the other from −6 to −10. The remaining 29 subjects gave readings with differences of 3 prism diopters or less.

Vertical heterophoria

The average heterophoria was −0.03 prism diopters with a large light source and +0.03 prism diopters with a small light source.

The difference of 0.06 prism diopters is not significant when compared with its standard error of 0.12 prism diopters, ($t = 0.48$, $df = 31$, $P = 0.70 - 0.60$). The correlation coefficient was +0.85 and this is high enough to permit substitution of the large light for the small light reading or vice versa.

The same two tests for the justification of using the above test of significance were made. The distributions were approximately normal in form and the variances, 0.664 and 0.660, were homogeneous.

TABLE 1

Average heterophorias for 32 subjects for two sources of light*

Source of Light	Lateral Heterophoria (in prism diopters)	Vertical Heterophoria (in prism diopters)
Ophthalmoscope (large)	−4.89	−0.03
Flashlight (small)	−4.87	+0.03
Difference	0.02	0.06
Standard error of difference	±0.39	±0.12
Coefficient of correlation	±0.90	±0.85

* Note: − =exophoria; + =esophoria.
− =left hyperphoria; + =right hyperphoria.

Conclusions

There is no significant difference in the measurement of lateral and vertical heterophoria with the white Maddox rod at a testing distance of 13 inches when the size of the line as seen through the Maddox rod is either large or small. This means that any variation in heterophoria measurements in the same individual by different examiners using the Maddox-rod test at 13 inches cannot be considered due to any variation in the size of the line produced by varying sized muscle lights. Such a conclusion seems justified as long as the size of the muscle light used is within the limits of those included in this study.

REGENERATION OF THE CORNEAL STROMAL CELLS*

I. Technique for destruction of corneal corpuscles by application of solidified (frozen) carbon dioxide

Alfred E. Maumenee, M.D., and Walter Kornblueth,† M.D.
Baltimore, Maryland

Regeneration of the cornea has been extensively studied in the past. The origin and mode of replacement of the epithelium, endothelium, and Descemet's membrane is clearly understood.[1,2] There is still, however, a difference of opinion about the origin of the corneal stromal cells. A detailed review of the literature on this subject will be published at a later date. The purpose of this paper is to report the technique of a method for studying the regeneration of stromal cells which appears to be superior to the methods previously used by other investigators in this field.

Previous experimental methods

The essence of the previous methods is as follows. Salzer[3] made incisions into the

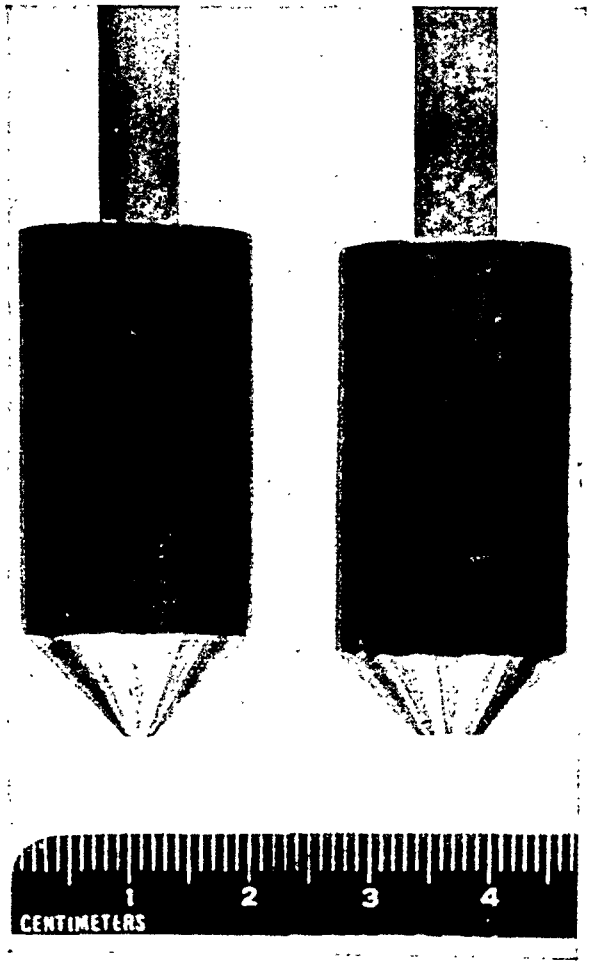

Fig. 1 (Maumenee and Kornblueth). Solid brass applicators.

* From the Wilmer Ophthalmological Institute of The Johns Hopkins Hospital and University.
† Fellow of the Eye-Bank for Sight Restoration, Inc., New York.

cornea with a trephine and concluded that the new stromal cells were derived from the epithelial cells. Hanke[4] made perforating and nonperforating incisions into the cornea with a trephine. Wolfrum and Boehmig[5] used a knife to make nonperforating incisions into the stroma from the posterior surface of the cornea and perforating wounds from the external surface of the cornea. Hanke and also Wolfrum and Boehmig were of the opinion that the newly formed cells were a product of the division of the uninjured corneal corpuscles. Pullinger and Mann[6] destroyed the stromal cells in the center of the cornea by applying a small drop of liquid dichlorodiethylsulphide (mustard gas) to the cornea. The authors could not obtain definite proof, but they thought that the new stromal cells probably were derived from wandering macrophages. While these methods of attack are useful in the studies of the regeneration of the corneal stromal cells, they entail certain disadvantages in studying the regeneration of the corneal corpuscles in clear corneas. External and internal incision into the stroma disrupt the corneal lamellae, allow the ingrowth of epithelium or endothelium, open a portal for the entrance of secondary infection, and destroy only a few stromal

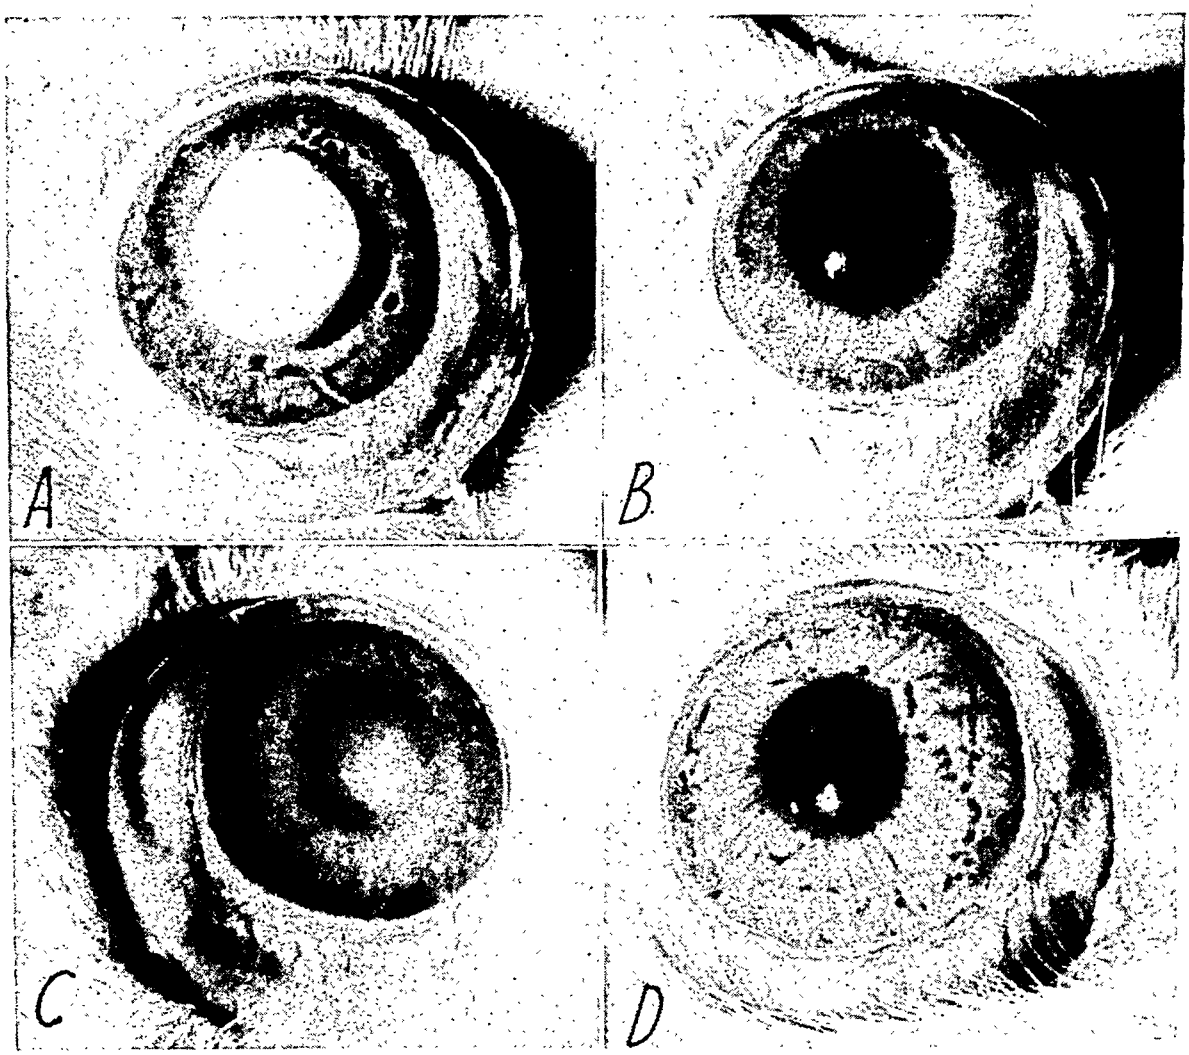

Fig. 2 (Maumenee and Kornblueth). (A) Rabbit cornea immediately after application of brass rod (—78°C.) for 5 seconds. (B) Same cornea 30 seconds later. (C) Same cornea 12 hours later. (D) Same cornea 7 days later.

cells. Lesions produced by liquid "mustard" eliminate these complications, but they also have some disadvantages. Liquid "mustard" is hard to obtain in some laboratories, it produces considerable inflammatory reaction, and the dosage is difficult to control.

Method used in this study

The method here reported consists in destroying the corneal stromal cells without disrupting the corneal lamellae or producing a severe inflammatory reaction.

Materials. The materials used are solidified (frozen) carbon dioxide (dry ice), absolute alcohol, and a solid metal rod. The solid metal rods are used because they are good temperature conductors, they will maintain the desired degree of coldness for a sufficient period of time to allow completion of the experiment, and they will produce a standard area of freezing. In our experiments solid brass rods, 19 mm. in diameter and 45 mm. long, were used. The end of the rod which was applied to the cornea was shaved down so that the area of contact was a circle 2 mm. in diameter on one applicator, and 6 mm. on the other (fig. 1).

The applicators are cooled to −78°C. by immersing them for a short while in a beaker of absolute alcohol containing "dry ice." The alcohol is removed from the applicators with a dry towel before placing them in contact with the cornea.

The animals are given a general anesthesia and the eyes are proptosed from the socket or fixed with forceps so that an accurate application of the rod to the cornea can be made. The lesions may be produced in the center or the periphery of the cornea. The area of the lesions can be varied from a circle, 2 mm. in diameter, to the entire cornea.

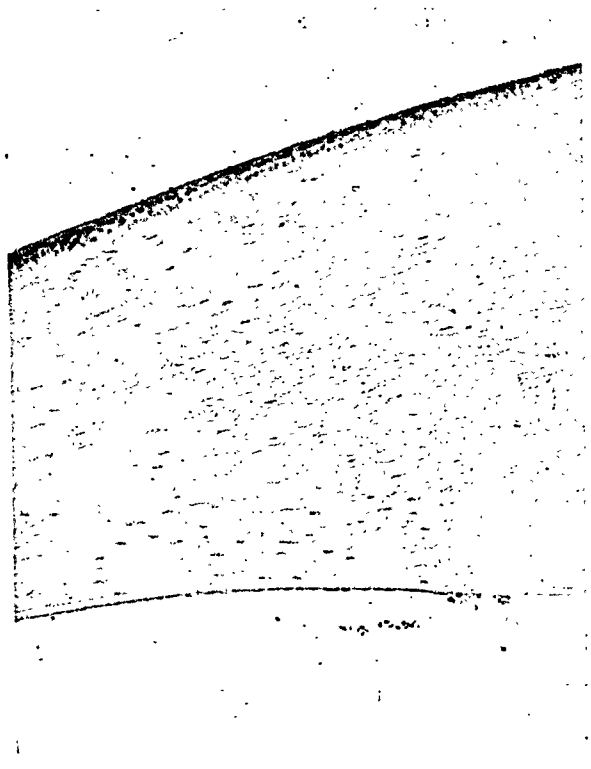

Fig. 3 (Maumenee and Kornblueth). Rabbit cornea 12 hours after application of 6-mm. brass rod (−78°C.) for 5 seconds. This view shows the margin of the lesion. (Histologic section. Hematoxylin-eosin stain. Magnification ×200.)

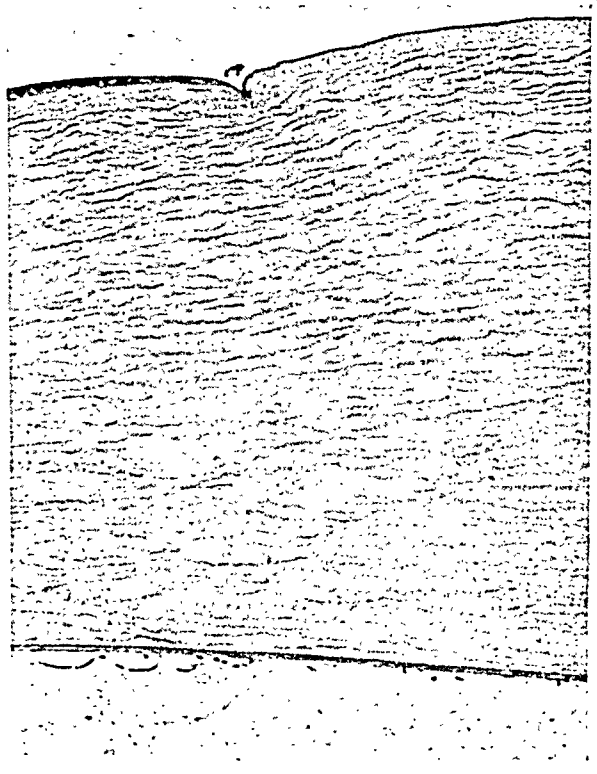

Fig. 4 (Maumenee and Kornblueth). This shows a slightly more central area of the same lesion as in Figure 3.

Application of the brass rod to a rabbit's cornea for 3 to 5 seconds freezes the full thickness of the cornea for 15 to 25 seconds (fig. 2A).

Appearance of cornea. After the cornea thaws it appears clear, although a very slight haze is present (fig. 2B). Two to three hours later the cornea becomes hazy due to edema of the stroma (fig. 2C). This edema persists for a varying length of time depending on the duration and area of the freezing. When the edema subsides, the cornea resumes its normal clarity and appearance on gross and slitlamp examination (fig. 2D). Blood vessels do not invade the cornea following central or peripheral lesions but they do invade the stroma following freezing of the entire cornea. Secondary infection does not occur except in some lesions of the entire cornea where there is persistent edema and eventual sloughing of areas of the stroma.

Histologic study. On histologic examination, all of the cells of the cornea including the epithelial, stromal, and endothelial cells are destroyed in the area that has been frozen. The corneal lamellae, however, do not appear to be damaged by this procedure. Twelve hours after freezing the cornea is edematous, and all remnants of the stromal cells have disappeared in the area of the lesion (figs. 3 and 4). It is remarkable that so few polymorphonuclear cells invade the cornea in spite of the extensive destruction of the stromal cells. After 72 hours most of the polymorphonuclear cells have disappeared from the cornea, and stromal cells show definite replacement in the periphery of the lesion. During the next few days, the stroma assumes an entirely normal appearance on histologic examination.

Summary

It has been found that freezing various sized areas of the cornea to −78°C. for 3 to 5 seconds produces a very convenient lesion for the study of the regeneration of the corneal stromal cells. These lesions do not disrupt the corneal lamellae, are not prone to secondary infection, and cause very little inflammatory reaction. After the lesions have healed the cornea is clear.

TREATMENT OF PHORIAS IN ADULTS*

ELECTRA HEALY
Chicago, Illinois

Treatment of phorias in adults is highly important, extremely gratifying in the results obtained, and, due to the wide variety of problems presented, is the most interesting procedure in orthoptic work.

SYMPTOMS OF PHORIAS

The importance of treatment cannot be too highly stressed since the patients in this group suffer the greatest amount of discomfort of any persons having an "ocular muscle imbalance." Frequently the patient so afflicted is the one who goes from "doctor to doctor" with the hope of getting a pair of glasses that will be just right and will relieve the strain, fatigue, or particular discomfort to which he is subject. A thorough case history should be taken and the patient encouraged to talk about his eyes. This will not only make possible a better diagnosis but give the patient confidence and the feeling of being understood which psychologically will aid in relieving his symptoms.

Burning, itching, difficulty in focusing or in altering the focus quickly may be some of the symptoms of heterophoria; while severe headache, especially after close work, even the "one-sided" headache with nausea typical of migraine, may be experienced. Other symptoms can be blurring of vision approximating diplopia or actual diplopia. Some patients complain of nothing but inability to read longer than five minutes.

PROBLEMS IN TREATMENT

The first step in treating phorias is to do a careful refraction under cycloplegic, to be followed at a later visit by a Maddox-rod test on a phorometer and, if possible, a major amblyoscope.

Livingston suggests that heterophoria should be divided into two primary groups: (a) inherent, and (b) acquired; and that it is necessary to speak of that which is (a) symptom free, and (b) symptom producing.

He also states that ocular imbalances and their sequelae follow no happy and consistent pathway. Certainly this is true. A cover test for near may show a deviation of approximately 26-degrees exophoria, yet it will measure only 12 degrees on a Maddox-rod scale, and a patient whose measurements are orthophoric may be found to have several degrees of deviation when the cover test is applied. Measurements may vary in morning and late-afternoon readings and on subsequent days, while three consecutive tests may reveal three widely variant responses. These results, rather than being confusing, should lead to a more comprehensive understanding of this patient's problems, as will be shown later.

After the muscle-balance and fusional-reserve tests, including the near point of convergence have been taken, a decision must be made as to the patient's need for treatment. It is a very simple decision. Phorias are important not because of their degree, but because of the symptoms which may arise from this condition. Therefore, the patient who is "symptom free," regardless of how large the degree of heterophoria, is best left alone. To attempt treatment with the hope of achieving orthophoria, or of preventing future symptoms might well prove disastrous both physically and psychologically by giving him an "awareness" of his condition. However, these same tests

* Presented at the sixth annual meeting of the American Association of Orthoptic Technicians, Chicago, October 12, 1947.

should prove determining factors in the prescribing of glasses.

Prescription of glasses

A hypermetrope with esophoria may, or may not, be fully corrected; whereas, one with exophoria should be undercorrected. A myope with exophoria is more comfortable, as a rule, with full correction although occasionally one is found with a high degree of myopia who will not tolerate this, thus necessitating the sacrifice of vision for comfort. A myopic patient with esophoria will almost invariably experience discomfort for near work which may usually be relieved by the use of bifocals or reading glasses although he is not presbyopic. To disregard the importance of phoria measurements when prescribing glasses may cause one who is orthophoric to become esophoric or exophoric, as the case may be, and may explain the complaint of the patient who later returns saying that although he can "see just fine with the new glasses he cannot stand to wear them." Therefore, it cannot be too strongly emphasized that a careful refraction is the first step in the treatment of heterophoria. Indeed, in some cases it is the only treatment that is required.

Importance of general health

Next in importance is attention to the general health. There is no doubt that the physical condition of a patient may be the dividing line between "symptom free" and "symptom producing" heterophoria. One whose condition has previously not caused symptoms may do so following an illness or peroid of over fatigue. Lack of sleep, toxicity, foci of infection, and especially anemia are all debilitating factors and should have careful attention. Not to be overlooked as a cause for eye discomfort is the habitual use of intoxicants. The prognosis in such cases is good with appropriate treatment, and so far as possible, the elimination of the various causes.

An occupation which requires constant use of the eyes for near work may cause symptoms to a person who previously has been most comfortable. Commercial artists, draftsmen, printers, and bookkeepers are in high number on this list. With "fusional reserve" built up, however, and with correction of the "convergence insufficiency" that is usually acquired in such cases, it is rare for these patients not to be made perfectly comfortable again, and equally rare for it to be necessary for them to change their type of work.

Psychologic problems

The last, and certainly the most difficult problem, is the psychologic condition encountered in some individuals. These patients are the ones referred to earlier in this paper. Their measurements may be small but their symptoms are excessive. The inconsistencies, which are so typical of these patients, must not be confused with those of patients whose readings on the Maddox rod are far less than a cover test would indicate—discrepancies that may be explained by the inherent desire for binocular vision and a large "fusional reserve."

Far from being placid individuals, the patients who present psychologic problems are usually introspective, nervous, and of the anxious type. A frequent factor is unhappiness, either in the home or at work, but whatever the origin of the disturbance, the prognosis is not good unless the underlying cause is removed or at least recognized. Once this is done, these patients usually respond amazingly well to treatment.

Although it does not belong to the heterophorias, there is another condition so closely related in many aspects as to deserve attention. The symptoms are rather vague although the patient is most insistent about not being comfortable either with glasses or without them.

Examination will usually disclose a relatively small refractive error and near orthophoria. Upon closer questioning these patients reveal that they have consulted sev-

eral doctors about their nerves only to be told that they are in good condition. When further pressed for information regarding their eyes, they may state that objects or people will look much closer to them at one time than another, or perhaps smaller and then larger. If taken to a window where they may view a nearby brick wall they may also state that the bricks are not consistent in size and shape. Certainly an aniseikonia test is indicated here and will usually reveal an overall or meridional image size difference of one half to three percent. Correction by an iso-iconic lens is usually successful in "curing" this patient's symptoms. Fusional exercises are also given as aids in stabilizing fusion and increasing the accuracy of stereoscopic vsion.

Aim of treatment

The phorias fall into four groups: esophoria, exophoria, hyperphoria, and cyclophoria. Before considering the treatment for each of these conditions, however, it is well to understand the aim of such treatment.

The aim of treatment is to relieve the patient's symptoms, not to achieve orthophoria. Although orthophoria is achieved in some cases, in other cases the measurements may show little or no improvement.

Maddox stated with regard to the treatment of heterophoria: "It is impossible to make rigid rules, since it is not a disease, but only a symptom to collate with other symptoms, as well as the patient's temperament, and the constitutional blood and nerve state." This being true, I can think of no instance where imagination and a real desire to help may be better displayed, for it must be remembered that one is treating individuals, not types.

Gain patient's confidence

The approach made during the first treatment is all-important. It can mean the difference between success and failure. Devoting a half hour to explaining the patient's particular condition, making him realize that an effort of will is absolutely necessary, assuring him of your understanding and sympathy will require tact and patience but will add much to the prognosis. Prepare the patient for discomfort, including nausea (especially exo's and convergence insufficiencies). After the confidence and coöperation of the patient have been won, follow up by showing enthusiasm when the first positive effects are demonstrated. Not infrequently this may be on the second or third visit.

Exercises for home work

All patients should be given motility exercises for home work—the six cardinal positions plus convergence, with emphasis on their weakest position. A 3-mm. white-headed pin inserted in the top of a pencil is ideal for fixation. Three 5-minute exercise periods a day are more beneficial than one 15-minute period. A fusion-stimulating exercise should also be given. Use a piece of red Kodaloid and a small light, preferably a pencil flashlight, and work from reading distance to infinity. (With the red Kodaloid held over one eye, the light must be seen "single" and pinkish in color). This exercise also aids in breaking up the suppression that occurs in a large percentage of heterophorias and is quite possible in all phorias on certain occasions.

Exophoria treatment

General treatment for exophoria consists of (a) correction of suppression, (b) good N.P.C., (c) prism convergence, and (d) good accommodation.

With a 3-mm. pin in a pencil held at reading distance, hand prisms may be placed (base out) before the eyes until an average of 15$^{\Delta}$ is reached. Each time the prisms are increased (by units of 2$^{\Delta}$) the patient should look alternately right and left, coming back to the pin each time, making sure it is "single and clear." This should be followed by fixing on the muscle light (at 20 feet) and, if possible, a light in the upper right-hand and upper left-hand positions

(about 7 feet high), and the same amount of prism convergence repeated as for near. An addition of 10Δ each week is sufficient, with the maximum of 75Δ reached usually by the seventh week.

Next the patient is placed at a major amblyoscope and careful attention given to suppression—both on convergence and divergence. Use of fusion slides with small central controls are best. Flashing is very helpful, after which convergence may be started. Side movements are important both from the standpoint of suppression and muscle coördination. The Stereo-Orthoptor is particularly well fitted to phoria treatment because of its automatic features. A Worth hand amblyoscope is also very good for homework at this stage because of its hand-eye coördination value.

Hand-eye coördination

Hand-eye coördination is of inestimable value and should be utilized in every possible way. These patients are usually slow to accommodate and change focus, therefore, at about the fourth visit two ink dots should be placed on a pin for home exercise. This requires accommodation as well as convergence (to be seen clearly) and looking from pin to small objects such as door knobs or light switches at distances of 5, 10, 15, and 20 feet builds up accommodation and the ability to change focus quickly.

Also, at about this time, physiologic diplopia should be taught and practiced. Later, it should be followed by bar reading. At the 7th or 8th visit a Keystone stereoscope and base-out cards may be borrowed for home training. The Ortho-fuser is also very good for home training. Usually 12 weekly treatments are required to complete this routine. The patient should have experienced some relief of symptoms early in the training but if treatments are stopped before completion, the symptoms are quite apt to return in a few months. Patients with exophoria are quite often poor readers, have a tendency to transpose, and are sensitive to light. This last, no doubt, explains why many have had tinted lens prescribed.

Standard of cure

At the conclusion of treatment the patient should be reëxamined. Usually the axis will have changed position a few degrees, with a decrease in the sphere—particularly plus but sometimes minus. In many cases of a small refractive error, glasses may be discarded entirely, and frequently presbyopic patients will require less addition. This I do not believe due to an actual change of refractive error (as tested by cycloplegic) but to the better seeing habits and skill developed, with most efficient use of extrinsic and ciliary muscles.

A standard of cure could be: (1) No symptoms, (2) prism convergence (70Δ to 75Δ), (3) prism divergence (7Δ to 8Δ), (4) good N.P.C. (25 mm.), (5) accommodation (Prince rule).

Esophoria treatment

General treatment for esophoria consists of: (a) Correction of suppression, (b) prism divergence, (c) good accommodation.

The esophoric patient usually complains of blurring or diplopia in the distance, with headache and discomfort for reading or near work. Change of focus is slow, probably due to effort of straightening visual axes. A poor near point of convergence also exists in many cases.

The first step in treating this patient is to teach him the difference between "accommodation" and "relaxation of accommodation." This may be done simply and quickly by placing a red glass, or red Kodaloid, before one eye while the patient fixes on the muscle lights (20 feet). Told to "clear" the lights he will find that they go much farther apart (homonymous). When told to relax and "blur" the eyes, the images will be much closer—sometimes even fusing.

After recognizing this fact he is told to see "clearly" while effort is maintained to

fuse the lights. A prism (base out) of the necessary amount to get fusion is placed before one eye. This is decreased, 1Δ at a time, until none is required. Then starting with a prism, 1Δ, base in, increase to an approximate 7Δ, base in. An aid to effort will be gained by having the patient look "up and over," pulling hard, then back at the light when fusion becomes difficult or unstable.

On the major amblyoscope fusion slides are joined at the patient's angle—the patient again having been told to see "clearly." Special attention must be given to suppression and side movements after which divergence is started. Amplitude is usually found to be low, necessitating the teaching of good convergence as well. After a maximum of divergence has been reached—approximately 7Δ—the patient should be taught to disassociate accommodation from convergence. This may be done by inserting −1.0D. sph. and clearing the picture at "O" followed in turn by −2.0D. and −3.0D. spheres.

A Keystone stereoscope with base-in cards is excellent for home use. The Orthofuser or Remy separator may also be used. Physiologic diplopia and bar reading are invaluable aids—both to stabilization and accommodation—but must not be attempted too soon. Divergence is not a natural anatomic feature such as convergence; therefore, progress is much slower and relapses more frequent. The myopic patient presents an even greater problem but may still be considered a good orthoptic risk.

Standard of cure

A standard of cure could be: (1) No symptoms, (2) prism convergence (50Δ), (3) prism divergence (5Δ to 8Δ), (4) good N.P.C. (25 mm.), (5) good accommodation (Prince rule).

Pure hyperphorias

Pure hyperphorias are rare. The patient complains at times of vertical diplopia, is usually nervous, and is more conscious of his cosmetic appearance than either the esophoric or exophoric patient.

General treatment is the same as for the preceding phorias. On the major amblyoscope the patient should join the fusion slides with the least possible vertical adjustment. Again special attention must be given to central suppression, after which supravergence and infravergence are stressed. Both supravergence and infravergence are much improved by good prism convergence and prism divergence. The Orthofuser or a Keystone stereoscope, with both base-in and base-out cards, may be given for home exercise; the use of red Kodaloid is particularly helpful in these cases, with physiologic diplopia and bar reading taught and practiced as early as possible. It is entirely possible to correct a hyperphoria of 14Δ and make the patient comfortable. Many times a hyperphoria of small degree will be found in conjunction with an exophoria or esophoria, particularly the former, in which case, correction of the lateral will usually be all that is needed.

Cyclophoria

Cyclophoria is perhaps the least known and considered of the phorias. Symptoms are headaches, nausea, and possible head tilting.

In all cases of head tilt in which the patient is found to be orthophoric or nearly so, a careful test should be made to determine the possibility of cyclophoria. The Synoptophore is well equipped to detect and measure deviations as well as correct this condition. Fusion slides are joined at the necessary oblique, or torsion angle and the image gradually straightened while fusion is maintained. Hyperphoria may also be found in conjunction with cyclophoria; or, due to the effort to overcome hyperphoria, a resultant cyclophoria may occur. In either case the treatment is the same. Correct the hyperphoria.

Another cause of cyclophoria is oblique

astigmatism and, as Maddox has pointed out, "in uncorrected oblique astigmatism, corrective torsion becomes a life habit." When strong cylindrical lenses are prescribed, care must be stressed not only with regard to the correct axes but to the constant maintaining of proper adjustment.

Convergence insufficiency

Convergence insufficiency is not considered a member of the heterophoria group but deserves special attention as it probably causes more discomfort than any other one condition. It is also, as a rule, one of the easiest to correct. Convergence insufficiency may be acquired by long hours of close work, fatigue, or lack of muscle tone due to ill health. Frontal headaches, tired eyes, and at times an actual aversion to anything requiring near vision, are common symptoms. These patients will be found, in most instances, to be monocular readers. Indeed, many of them are aware of it, either when having it pointed out to them, or by volunteering the information. Certainly one whose near point of convergence is 40 cm. (16 inches) would be unable to maintain fusion.

Suppression —deep suppression—is the main characteristic of this condition and must be borne in mind throughout the entire treatment. It is even advisable to use a red glass, or red Kodaloid, over one eye when taking the N.P.C.

Complete motility exercises should be given in addition to convergence with a pin. Again the red Kodaloid should be used (during convergence) as it is entirely possible to get muscular coördination and continued suppression. The two dots placed on the pin are very good, as an alternate exercise, because these patients need incentive and this in turn helps accommodation. Vergence exercises on the Synoptophore or Stereo-Orthoptor are the same as for a phoria, with particular attention to suppression. Physiologic diplopia and bar reading should be taught as soon as good convergence permits, and last, but of equal importance, is the teaching of voluntary convergence. Usually 4 to 6 treatments are sufficient.

The incorporation of prisms in glasses is a method of treatment which we do not recommend. It has been our observation that an additional amount must be added from time to time and after a few months, or years, the patient is unable to tolerate the added weight and chromatic aberration of prisms strong enough to correct a phoria of any considerable degree. Before starting orthoptic treatment of patients wearing prisms, new glasses are prescribed, without any prism whatever.

A practice which should be given careful consideration is the one of patching where a phoria exists. There is grave danger of a resultant tropia. If you feel that it is absolutely necessary, then a week or 10 days should be the limit of time, with frequent observation.

It has been a very great pleasure recently, either to reëxamine or to talk with patients who were given orthoptic treatments during the past six years. In none have the symptoms returned, except fleetingly when tired, and not one, so far, has required a refresher course.

Conclusions

1. Phorias are important.
2. Phorias respond readily to treatment.
3. The aim of treatment is not orthophoria, but the relief of symptoms.
4. This group is composed of your most satisfied patients.

TISSUE RESEARCH AND CELL CULTURE OF THE CORNEA

DORIS HOOF, M.D.
Wiesbaden-Biebrich, Germany

Although we can be proud of the progress that has already been made in keratoplasty (especially in the use of donor material), our final aim is to create conditions whereby the host cornea will accept the transplanted material completely so that a later cloudiness, which so often develops in transplantations of the same species but of different blood groups, will not mar the end result.

In view of the fact that the literature on keratoplasty reports unsatisfactory results in a majority of cases, it would seem pertinent to question why the implant (of the same species) becomes cloudy and to ask whether or not colloidal chemistry might offer an approach to the problem. It would seem that a study of the chemical and physical (such as swelling) factors of the albumin which form the base of horny tissues might suggest a solution to some of the difficulties of corneal transplantation.

It may be that the donor cornea, especially the cadaver cornea, loses its own specific characteristics under the effect of artificial culture and becomes an indifferent piece of tissue that cannot be changed by later assimilation with the host tissue. As far as I can learn from a study of the literature, the following possibility has never been fully considered.

If the transplant is kept alive by means of slow-growing cell culture, and if the plasma content of the blood of the recipient is increased before the transplant is made, it might be that the original structure of the albumin of the transplant could be so changed that it would gradually become assimilated with the albumin of the host.

Loehlein was of the opinion that if corneal tissue were carefully kept alive by means of culture passages, conditions might be created which would permit a gradual and delicate balance between the host and the donor tissues. Loehlein and Salzer both came to the conclusion that not only did corneal tissue (carefully kept alive) of dead human bodies (in my opinion the best means to accomplish this is through sterile culture) make the best transplants and cause the least reaction with the surrounding tissues, but also that homologous tissue furnishes the most favorable conditions by providing a frame for the gradual regeneration of tissue.

According to Widal, corneal cloudiness results chiefly from "protein shock" or the coming together of two antagonistic colloids. We know that the albumin of the plasma reacts to the sudden introduction of chemicals or to plasma of a foreign type. In his discussion of the so-called "crises of blood types," which led to his observations on the process of protein shock, Widal says: "The shock is not confined to the colloids of the blood; it also exists in all the plasma, making itself felt even in the plasma colloids which constitute our cellular elements."

Widal's highly interesting conceptions of the colloidal processes are not only applicable to the colloids of the blood, but they apply wherever proteins are involved. In my opinion, these observations can provide an explanation of the cloudiness of corneal transplants.

It is now pertinent to mention the changes which it is possible to produce in the chemical structure of albumin and which may account for the assimilation of the donor albumin with that of the host organism.

We learn from the earlier publications of Obermeyer and Pick that the specific grouping of the same kind of albumin molecules is influenced by the various arrangements of albumin atoms. These authors, by introducing nitroiodine and diazo groups, succeeded in changing the so-called "original" structure of the albumin into a "constitutional" one. The "host" organism of the injected animal reacted only upon the changed

albumin in a "specific" manner and while the species characteristic was completely extinct.

Since these structural changes in the albumin molecule depend upon the regrouping of the albumin atoms in the chemical ring, it would be the aim in cell culture for corneal transplantation to produce, by influencing the chemical structure of the molecule, such gradual changes as would be equivalent to an assimilation of both kinds of albumin. Evidence as to whether, as a result of cell culture, this assimilation was taking place would be cloudiness appearing more or less rapidly, for, after all, growth in cell culture means a fundamental transformation.

It would seem that further assimilation could be induced by changing certain physical factors affecting albumin, such as, for example, swelling. So far, the nature of this factor of swelling is not completely understood, but its uniformity in the healthy cornea presupposes the existence of a most accurate and complete method of regulation. The forces which bind together water and the colloidal albumin molecule are extremely great. They represent the so-called swelling pressure or, according to Schade, the colloidosmotic pressure.

In the literature on corneal transplantation, it has been remarked that, only after keratoplasty in interstitial keratitis, has perfect clearing been observed and then with deeply located, thick, cloudy specks. Imre is of the opinion that this is due to colloidochemical changes of the corneal tissue, changes which are reversible.

Thoenes, an investigator of tissue colloids, followed the laws of water binding that had been examined by Rübner, Müller-Thurgau, H. W. Fischer, and Bobertag. He believed that there are changes which have something to do with a progressive growth, and he says, "With progressive growth not only the total amount of the tissue water is diminished, but also a change in the physical structure of the tissue colloids takes place at the same time, leading to a diminution of the water bound to the protoplasm molecules."

These observations lead one to consider the possibility that, through the gradual growth of the cell culture in vitro, it may be possible to create such delicate methods of regulation as the eye afflicted with interstitial keratitis is capable of creating when a keratoplasty is performed upon it.

Another factor—that of the same blood group—which, in my opinion, may play a part in the clouding of corneal transplant has no importance according to the literature on the subject (Loehlein, Salzer, Imre, Nižetić, Magitot, and others).

Cell-culture experiments

The controversy as to whether the corneal graft continues to live as an independent tissue or is replaced by regenerated corneal tissue of the host has never been definitely settled by the ophthalmologists. Loehlein, Salzer, Bonnefon and Lacoste, Leonardi, and others believe that the transplant tissue never remains intact as such, but that it is replaced slowly and gradually by ingrowing tissue from the host. Filatov, Castroviejo, Leoz, Ortin, Ascher, Sommer, and others, however, are of the opinion that the graft, if remaining clear, will continue its existence as independent tissue.

In view of this difference in opinion, it seemed important to watch the growth of the different parts of the cornea. As a preliminary to my attempt to obtain corneal transplants that did not become cloudy, I examined the growth of the different layers of the cornea. Corneas of rabbits, guinea pigs, and chicken embryos were supplied by Dr. Vollmar of the Department of Tissue Research, Forschungs-institut für Chemotherapie, Frankfurt. Cadaver corneas were furnished by Professor Lauchle of the Pathological Institute.

We are indebted to Imre for some good reports on histologic findings in corneal transplants. His histologic specimens show again and again the typical corneal cloudiness. The epithelium is denuded, Bowman's

membrane is not recognizable, the upper layers of the cornea contain hyaline deposits—granular and filamentous calcium deposits—the substantia propria is replaced by coarse, granulated tissue streaked with vessels.

A specimen of clearly healed-in graft is rarely obtained. One specimen of a clear graft, mentioned by Imre, had been removed four weeks after transplantation because the inner layers had become opaque.

Imre says that the epithelial and border membranes were well preserved. The endothelium could be recognized behind Descemet's membrane. The epithelial layer consisted of 4 to 5 rows in those parts of the graft near the border. At the center, however, the epithelial layer consisted of only two rows.

In the cell cultures which I made, it was interesting to watch the growth of the epithelial layer. I was able to obtain particularly fine cultures from rabbit corneas. (Reports of typical cell-culture growth of the epithelium borders of rabbit corneas have been published by Dr. Vollmar.) I was best able to observe the growth of spindlelike fibroblasts in corneal cultures of chicken embryos.

Mention has been made in the literature for tissue research and cell culture of a stage in cell growth intermediate between epithelial cells and fibroblasts. It is supposed that these cells originate from the corneal endothelium. Since, however, I have never been able to find a detailed description nor illustrations of this cell growth, I shall describe my own observations in detail.

The best growth of this intermediate type of cells that I have observed was in cultures of human corneas removed immediately after death (fig. 1). I received these cultures in a sterile state; that is, after the whole conjunctival sac had been washed out with boric-acid solution. It would seem that the boric acid has some growth-inhibiting effects upon the culture, since growth is not so extensive after its use. Because it is necessary to obtain sterile cultures, it might

Fig. 1 (Hoof). Cell culture of a human cornea removed immediately after death. This shows 24-hour growth at 37° C. (Magnification ×130.)

be that better results could be obtained through the use of some chemicotherapeutic agent that would specifically stop the growth of the bacteria without affecting the tissues.

In experimenting with the culture of the corneas of guinea pigs upon plasma of a different species (rabbit), no growth whatsoever took place. When fresh embryonal extract and the plasma of chicken or fresh guinea-pig plasma and a sterile buffer solution were employed for infusion, a surprising growth of the cornea took place.

Microscopic examination of these cultures showed a multitude of shapes. Just as illustrations in a zoology textbook depict groups of Polymedusae, with the freshwater polypi stretching out their tentacles, or the footlike fringes of the Rhizopoda floating around a one-cell Algae, so the microscope revealed the cells in the corneal cell culture moving out of the substantia propria, at first being attached to it like fixed species of Infusoria and later like

Fig. 2 (Hoof). Cell culture of guinea-pig cornea. This shows 48-hour growth at 37° C. (Magnification ×130.)

freely swimming shapes which were small, rounded-off lumps of protoplasm extending themselves.

The growth advanced and kept on moving until the starlike, branched-out cells, with the long and small cores, and the long threads of the cell protoplasm formed a broad circle around the substantia propria. The protoplasm also contained fine granules. Only in a 48-hour culture of guinea-pig corneas (fig. 2) have I seen this protoplasmic picture.

(In their histologic structure, the cells of guinea-pig cornea do not differ greatly from human corneal cells. These typical cells, located in the substantia propria, are represented by clumsy, irregular, and much perforated protoplasm layers, with either broad or long-draw-out, thin anastomoses [Schaffer].)

Comment

These preliminary experiments in tissue culture show the possibility of growth of the parenchyma cells out of the substantia propria. They would seem to substantiate the theory that the corneal graft lives as an independent tissue within the host's cornea, as advanced by Marchand, Fuchs, Filatov, Castroviejo, Leoz, Ortin, Ascher, Sommer, and others.

COMPARISON OF EYE CONDITIONS AMONG 1,000 READING FAILURES, 500 OPHTHALMIC PATIENTS, AND 150 UNSELECTED CHILDREN*

THOMAS H. EAMES, M.D.
Boston, Massachusetts

This is a comparative study of the eye conditions of 1,000 poor readers, 500 ophthalmic cases, and 150 unselected children. The median ages of the groups were 9 years and 8 months, 11 years and 6 months, and 10 years and 8 months, respectively. The median intelligence quotients for the groups were 102, 103, and 109 in the same order. All of the cases were examined by the same doctor with the same equipment and the same tests. The routine was that of the usual eye examination plus tachistoscopic measurements.

Refractions were made without a cycloplegic in order to permit observation of the pupils' use of their eyes in the reading situation. Careful retinoscopic and subjective refraction was carried out in all cases. The tachistoscopic data were collected with an instrument and method described previously.[1, 2] There is a great deal of variation in the tachistoscopes now in use, particularly in such variables as test types, vocabulary level of test words, object size, reading distance, intensity of illumination, and so forth. Results obtained from different makes of tachistoscopes are not likely to be mathematically comparable and so *tendencies* rather than mathematical values are significant except when instrument and test conditions are identical.

The results of all tests were distributed in each group, and frequency and central tendency were determined for each. This was followed by comparison of the groups.

The poor readers and the unselected pupils exhibited closely comparable frequencies of vision below 20/30, while the frequencies of vision below 20/40 were fairly close but not so much so. Both groups differed widely from the ophthalmic cases, as might be expected. The frequency of amblyopia was somewhat similar in the reading failure and unselected groups but the incidence among the ophthalmic patients was about twice as great for the left eyes as in the other two groups.

The frequency of hypermetropia of one diopter or more was greatest in the ophthalmic group, 7 percent less in the reading-failure group, and approximately 30 percent less among the unselected. The incidence of myopia of one diopter or more was practically the same in the reading failure and unselected groups, while the ophthalmic patients presented twice as high a frequency. The unselected cases exhibited a somewhat higher frequency of hypermetropic astigmatism than the ophthalmic group, while the poor readers displayed a still higher incidence. The step up from group to group was only 2 percent, however, making the frequencies fairly comparable in all groups. The incidence of myopic astigmatism was the same throughout all classifications. Both the reading-failure and ophthalmic groups exhibited frequencies of anisometropia that were quite close and about twice that of the unselected group.

Exophoria of 6 prism diopters or more in distant vision was most frequent among the unselected and least among the reading failures, while exophoria of the same magnitude in near vision was greatest among the reading failures and least among the unselected. Esophoria of a similar amount was slightly more frequent in near vison than in distant vision among the reading failures and the ophthalmic groups, the former displaying lower frequencies at both distances than either of the others. Hyperphoria did not appear in the unselected group but occurred in distant vision only to the extent of 1 percent in the others.

* From the School of Education, Boston University, Boston, Massachusetts.

Convergent strabismus was more frequent among the poor readers than among the ophthalmic cases, while divergent strabismus occurred equally in these two groups. No oblique deviations were noted in either group. No cases of strabismus were encountered in the unselected group. The greatest frequency of fusion deficiency was found among the reading failures. It was less frequent among the unselected and least among the ophthalmic cases.

Right eyedness occurred most often in the ophthalmic group and 11 percent less frequently among the reading failures, with the incidence in the unselected group falling between the others. The incidence of left eyedness was closely similar in the reading-failure and unselected groups, with the ophthalmic group presenting a lower frequency. Ambieyedness occurred as frequently in the poor reading and ophthalmic groups; rather less so among the unselected children.

TABLE 1

FREQUENCY OF EYE CONDITIONS IN READING FAILURE, OPHTHALMIC, AND UNSELECTED GROUPS

Condition	Reading Failures		Ophthalmic		Unselected	
	Right	Left	Right	Left	Right	Left
Number of cases	1000		500		150	
	percent		percent		percent

Word recognition	49		17		25	
Object recognition	22		18		25	
Intelligence quotient below 90	24		11		6	

* R. D. = reading distance.

On the other hand, right handedness was less frequent among the poor readers, slightly more so in the ophthalmic group, and most frequent in the unselected classification. Left handedness occurred most often among the poor readers, least often among the unselected, while the incidence in the ophthalmic group fell between the others. Ambidextrousness was equally frequent among the poor readers and ophthalmic cases, but it failed to appear in the unselected group. Thirty-two percent more poor readers than ophthalmic cases, and 24 percent more poor readers than unselected cases exhibited significant degrees of retarded speed of word recognition. Important retardation in the speed of object recognition occurred most frequently among the unselected, slightly less so among the poor readers, and still less so among the ophthalmic cases.

The measure of central tendency used in this study was the median. The ophthalmic group presented a slightly lower median visual acuity than the other two groups in which the medians were equal and at the normal level. The median amblyopia was the same in all groups.

The unselected and ophthalmic groups presented equal medians for hypermetropia while the other group exhibited a 0.25D.-less median hypermetropia. The median myopia was approximately equal in all groups. Hypermetropic astigmatism occurred to a greater median degree in the ophthalmic

TABLE 2

CENTRAL TENDENCY OF EYE CONDITIONS EXHIBITED IN READING FAILURE, OPHTHALMIC, AND UNSELECTED GROUPS

Condition		Median of Reading Failure Group	Median of Ophthalmic Group	Median of Unselected Group
Age		9 yrs., 8 mo.	11 yrs., 6 mo.	10 yrs., 8 mo.

* R.D. = habitual reading distance.

group as one might expect, while the other two classes presented equal and somewhat lower medians. The median myopic astigmatism was markedly higher in the unselected group, while the medians in the two other groups were considerably, lower and very close to one another. In distant vision, the median exophoria was very close in all groups, but in near vision the reading failures and the ophthalmic cases presented medians that were twice as great as that of the unselected group. The median esophoria in distant vision was highest in the ophthalmic group, lowest in the unselected group, with that of the poor readers exactly between the others.

The median speed of word recognition was lowest among the reading failures and highest among the unselected, while the median speed of object recognition was equal and at the upper level in the reading failure and unselected groups but at a considerably slower level in the ophthalmic group. The latter exhibited a faster median speed of word recognition than of object recognition, suggesting that many of these people may have recognized the words by minimal cues without seeing them discriminatingly. The faster median speed of object recognition than of word recognition among the poor readers, on the other hand, suggests that language difficulty and unfamiliarity with word form may have influenced the scores of these pupils.

A difference of 10 percent in frequency was regarded as significant. Applying this more or less arbitrary standard it was found that the poor readers exhibited more frequent hypermetropia of one diopter or more, more exophoria of 6 prism diopters or more at the reading distance, greater retardation in the speed of word recognition, and more frequent intelligence quotients below 90 than did the unselected. This group also displayed more frequent left eyedness, more retarded speed of word recognition, and more intelligence quotients below 90 than did the ophthalmic group. As would be expected, the latter group exhibited a greater frequency of low vision than either of the others and a higher incidence of hypermetropia of one diopter or more, of anisometropia, and of exophoria at the reading distance than did the unselected group, being closer to the poor readers in these areas.

The differences between the medians of the various measurements in the three groups were not great. The ophthalmic cases presented a slightly lower median visual acuity than either of the others as might be expected. The difference in the medians of the various refractive conditions were less than one diopter except in myopic astigmatism, where the unselected group presented a somewhat higher median. The difference between the medians of the various phoria measurements ranged up to 3 prism diopters. It is noteworthy, however, that the poor-reading and ophthalmic groups presented medians of 6 prism diopters of exophoria at the reading distance as against 3 prism diopters among the unselected cases. This, as well as the higher frequency of the condition at the reading distance in the same groups, supports earlier findings.[3, 4]

The difference in medians of the speed of object and word recognition in the three groups ran about as one would expect, the medians for the poor readers and the unselected children being equal and high for object recognition, while that of the ophthalmic group was slower. The median speed of word recognition was slowest among the poor readers, faster but still retarded among the ophthalmic cases, and at a satisfactory level in the unselected group. The differences in median intelligence quotient in the three groups were too small to be important.

Conclusions

This study indicates that, for the present group at least, hypermetropia, exophoria at the reading distance, retarded speed of word recognition, and intelligence quotients below 90 occur more frequently among poor readers than in the other groups tested but

that the median amount of defectiveness is not appreciably greater in any of the groups. This is in line with the clinical observation that reading failures are often troubled to a greater extent than others by such handicaps as low degrees of hypermetropia and other eye defects.

SLEEP WITH HALF-OPEN EYES (PHYSIOLOGIC LAGOPHTHALMUS)

Adalbert Fuchs,* M.D., and F. C. Wu,† M.D.
Shanghai, China

I spoke once in Shanghai with a Chinese colleague about my paper in which I described the diminished resistance of the cornea due to general disturbances of nutrition (Am. J. Ophth., 30: 721-727 (June) 1947.) and to intoxication, and we spoke about the bad consequences of a slight lagophthalmus, when the general condition of the patient is poor. Prof. C. H. Chou then told me that many people in China sleep with half-open eyes and that his son has his palpebral fissure open from 3 to 4 mm. and that the cornea is also exposed. The globe sometimes turns around during sleep. Prof. C. C. Ho, head of the eye department of the Red Cross Hospital, who was listening to our conversation, declared with a smile that his lids did not close during sleep but that his cornea was not visible.

Even in the old Chinese history we find a narrative of the physiologic lagophthalmus of the Chinese.

In the time of the three kingdoms (230-264 A.D.) there lived a general, Chang Fei, whose habit was to keep his eyes open when he was fast asleep.

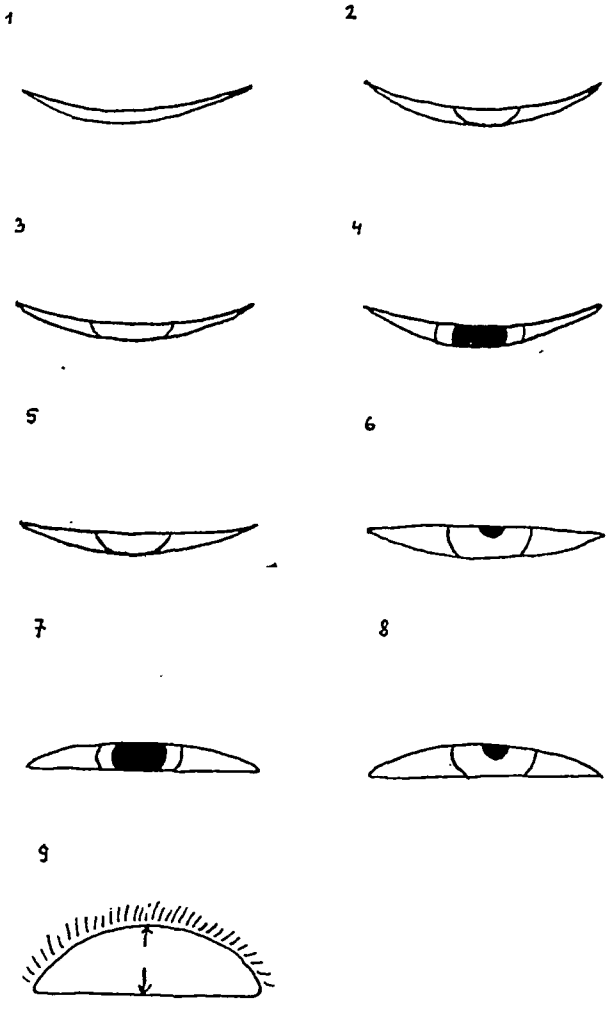
One day, he ordered a group of tailors to make 3,000 suits of uniforms in mourning fashion for his troops on account of the death of his "sworn brother"—the famous general Kwan Yu. This arduous task was assigned to be finished within a limited time of three days.

It was physically impossible to execute the order within such a short space of time, but General Chang insisted that it must be done or, failing this, all the tailors would be put to death. The tailors saw that death was inevitable and became desperate. They took council together and decided to assassinate the general and bring his head to the enemy, as the only way to save their own lives.

During the next night, two tailors made an attempt on the general's life. When they sneaked into his bedroom, to their great surprise, they found the general in his bed, rolling his widely opened eyes. They beat a hasty retreat, thinking that he was awake. A few minutes later they heard the general snoring loudly. The assassins entered the general's room again and purposely made some noise in order to see whether he was asleep or not. As he was not disturbed by the entry of the assassins, the two tailors stabbed the general several times, with fatal result.

The turning of the globe and cornea described in this story is the same as that seen in the son of Professor Chou, who moves his eyes, apparently to moisten the cornea and thus to hinder its desiccation.

In Nanking, I found that the wife of Dr. Chang, one of the assistants of the eye department of the Central Hospital, does not close her eyes entirely during sleep; apparently this happens not only in deep sleep during the night, but also when she takes a nap after lunch. The eye fissure during sleep is



* UNRRA-WHO, Shanghai.
† Shanghai Army Hospital.

2- to 3-mm. wide and shows the lower third of the cornea.

Since this phenomenon appeared to be rather frequent I asked Dr. F. C. Wu, assistant of the Ophthalmological Department of the Shanghai Army Hospital to examine during the night a large group of students who live in the Army Medical College.

Examination of students

Dr. F. C. Wu. I examined the palpebral fissures of 500 healthy young Chinese students of the Army Medical College (aged 20 to 30 years) during their sleep. They were free of any pathologic factor which could affect the closure of the lids, such as scars of the lid, facial paralysis, thyrotoxicosis, and so forth.

Figs. 1 to 9 (Fuchs and Wu). Appearance of various degrees of lagophthalmos is shown in Figures 1 to 8. Diagram of tarsus height is shown in Figure 9.

Of these 500 cases 23 (4.6 percent) had their lids open 1 to 2 mm. during sleep and two cases (0.4 percent) had their lids open 3 to 4 mm. during sleep.

In the first group four different positions of the cornea were observed: (1) In 4 cases the cornea was not visible (fig. 1). (2) In 10 cases the lower margin of the cornea just touched the border of the lower lid (fig. 2). (3) In 3 cases about 1 mm. of the cornea was covered by the lower lid (fig. 3). (4) In 6 cases the central part of the cornea and parts of the pupil were not covered and were visible in the palpebral fissure (fig. 4).

As these cases show, a considerable number of persons with lagophthalmus do not show Bell's phenomenon during their sleep. The pupil is apparently not always narrow, as physiologic textbooks would lead one to believe.

In the second group of two students with palpebral fissures opened 3 to 4 mm. during sleep, the first student, aged 25 years, revealed an open fissure of 3 mm. on the right. The lower edge of the cornea touched the border of the lower lid (fig. 5). The left eye was exposed 4 mm. during sleep, the lower part of the pupil was visible, and the lowest millimeter of the cornea was covered by the lower lid (fig. 6).

The second student, 23 years of age, had both eyes open to an extent of 3 mm. The middle of the cornea and pupil were visible; about 2 mm. of the lower cornea was covered by the lower lid (fig. 7).

Later on, a third student, aged 20 years, was found to have a lagophthalmus of 3 mm. in both eyes during sleep. A small piece of the pupil was visible and about 1 mm. of the lower cornea was hidden by the lower lid (fig. 8).

Comment

Dr. A. Fuchs. From the report of Dr. Wu and the three eye doctors, Professor Chou,

Professor Ho, and Dr. Chang, it is clear that, in a considerable number of cases, the lids are not closed during sleep, a condition of which I have not heard anything in Europe. The frequency is emphasized when in addition to the statistics of Dr. Wu, it is known that three ophthalmologists have the condition themselves or in a member of their families.

Two possible causes of this physiologic lagophthalmus have to be considered: (1) a shortness of the upperlid, as is seen in cases of congenital familial ptosis. Nothing of this nature could be recognized in the eyes of the eye doctor and the son. It is also certain that these people close their eyes in a normal way during day.

A second possibility would be that (2) the facial nerve does not have a sufficient and constant effect on the musculus orbicularis. It is known that in unconscious persons, the relaxed middle position of the lids leaves part of the palpebral fissure open. During sleep, a special tonus or spasm of the orbicularis must be present, just as a tonus of the sphincter of the rectum and of the urinary bladder is physiologically present.

TABLE 1

HEIGHT OF UPPER EYELID IN 100 CHINESE

Sex	No.	Age	Eyelid Height		
		(Aver.)	Max.	Aver.	Min.
Female	10	25.6 yrs.	9.5 mm.	8.25 mm.	6 mm.
Male	90	26 yrs.	9.5 mm.	7.95 mm.	6 mm.

ROLE OF TRACHOMA SCARS

After examining several hundred cases of trachoma in China, I was astonished to find that the characteristic scars of trachoma in the sulcus subtarsalis, usually illustrated in European textbooks, are by no means common in China. More frequent is another type of trachoma scars which come from the upper edge of the tarsus and from the fornix and radiate like flames into the tarsal conjunctiva. The following possible causes of this type of trachoma scars suggested themselves:

1. That the blood vessels, which perforate the middle part of the tarsus and supply the tarsal conjunctiva, are not present in the lids of the Chinese. One assumes that the infiltration of the submucosa advances along these vessels into the tarsus and so causes the typical scars in the sulcus subtarsalis.

Since an anatomic examination of the lids was not possible, I was not able to pursue this probability.

2. Possibly the height (fig. 9) of the tarsus is much smaller in China than in Europe. If the tarsus is less high, it would be easy to understand the absence of the scar formation in the sulcus subtarsalis and the boat-shaped distortion of the tarsus so characteristic of trachoma in Poland, Russia, and the Near East.

Since the shortness of the tarsus could play a considerable rôle in physiologic lagophthalmus, I begged Dr. Wu to examine a number of students and measure the height of the tarsus.

TABLE 2

VARIATIONS IN HEIGHT OF UPPER TARSUS

Height	Percent of Subjects
6 mm.	3
6.5 mm.	2
7 mm.	11
7.5 mm.	20
8 mm.	31
8.5 mm.	16
9 mm.	13
9.5 mm.	4

Examination of tarsus

Dr. F. C. Wu. The height of the upper eyelid in the Chinese (fig. 9) was examined in 100 normal persons—90 males and 10 females. The results are shown in Tables 1 and 2.

A tarsus of 6 mm. was present in two men and one woman. A 9.5-mm. tarsus was present in two men and two women. The average height of the upper tarsus in Chinese is apparently between 7.5 and 8.5 mm. The incidence of high tarsus is apparently greater in women than in men.

In three cases of lagophthalmus during sleep, in which the patients showed an opening of 3 mm. or more, the upper tarsus measured 8.5 mm. in height in two cases and 9.5 mm. in one case.

Conclusion

Dr. A. Fuchs. Apparently the upper tarsus in the Chinese is less high than the tarsus of European people. Examination of 10 Europeans residing in China showed only one 7.5-mm. measurement and several of 9.5 mm. and 10 mm.

Certainly this little difference in height of the upper tarsus cannot be the cause of the physiologic lagophthalmus of the Chinese, since the upper tarsus of the three persons with open palpebral fissures of 3 mm. and more had a tarsus height which was maximum.

From this it would seem that the second supposition—that the tonus of the orbicularis is weakened during sleep—is more probable. Since the cornea is exposed, it is interesting to conjecture why the cornea does not become desiccated. The cause may be that these globes, when the Bell's phenomenon is not active, are rolling during sleep and so moisten the cornea. The story of the Chinese general, Chang Fei, and the observations of Professor Chou, who reported that his son makes slow, rotating movements of the eyes during sleep, would seem to substantiate this.

INTRAOCULAR PRESSURE OF NORMAL AND GLAUCOMATOUS EYES AS AFFECTED BY ACCESSORY LIGHT STIMULI*

R. B. ZARETSKAYA, M.D.
Moscow, U.S.S.R.

The influence of accessory stimuli upon the visual functions has now been safely established. On the basis of the data available it can be assumed that accessory stimuli also affect such an objectively recordable function of the eye as the intraocular pressure.

The present investigation is concerned with the effect of a special accessory light stimulus in the form of illumination of the second eye from a white or colored light source.

I. EXPERIMENTS WITH WHITE LIGHT

METHODS

The patient, reclining on his back, was allowed to adapt himself for 10 minutes to the illumination of the room in which the experiment was to be made. Then, the intraocular pressure of his right eye was measured with a Schiøtz tonometer after it had been anesthetized with a 1-percent dicaine solution.

The light was then switched off, and the patient was left in an absolutely dark room for one hour. After this, one eye of the patient was covered with a black eye shield, and the other eye was illuminated for 30 minutes by means of a special device arranged in the following manner. A cone-shaped tube 40 cm. in length, was suspended over the left eye of the patient. The tube contained at its base a 75-watt frosted bulb. The brightness of the lightest spot of the bulb was equal to about 16 foot-candles. The left eye of the observer had to be fixed on this spot. The illuminating cone had several lateral apertures which reduced the possible effect of temperature.

During the time that the left eye was exposed to the light stimulus, the patient's right eye was repeatedly subjected to tension measurements at approximately 5-minute intervals. The tension of this eye was also measured some 15 to 20 minutes after the elimination of the accessory stimulus; that is, under the initial illumination conditions of the laboratory room.

The experiments were carried out on 35 subjects, 14 of whom had normal eyes, and 21, glaucomatous eyes. The investigative procedure just described was applied to both normal and glaucomatous subjects. The glaucoma subjects were divided into two groups. One group comprised cases of clearly pronounced glaucoma. In the second group were patients displaying prodromal glaucoma, as well as the "normal" eyes of glaucomatous patients.

RESULTS

The results obtained demonstrated that, under the influence of unilateral illumination of one eye, the intraocular pressure of the other eye was reduced. Our experiments likewise showed that the variation in the tension of glaucomatous eyes exposed to light or to dark follows the same general course as that revealed by our experiments on normal eyes.

In glaucomatous eyes, however, the reduction in the intraocular pressure is more sharply pronounced, as a rule. A certain smoothness of the curve, typical of a normal eye, vanishes, giving place to a curve which is not infrequently distinguished by its broken shape.

Typical curves illustrating the drop of intraocular pressure resulting from illumination of the second eye both in normal and glaucomatous observers, are plotted in Figure 1, A and B.

* From the Laboratory for Physiological Optics of the Helmholtz Central Ophthalmological Institute. Head of the laboratory, Prof. S. V. Kravkov; director of the Institute, Prof. A. A. Kolen.

The pupillary reflex does not seem to have any appreciable bearing upon the variation in the intraocular pressure, when the second eye is exposed to light. From 16 experiments carried out upon 12 patients whose pupillary reflexes were eliminated by means of homatropinization, it may be seen that under these conditions the tension of the tested eye is likewise reduced by illuminating the second eye (fig. 2).

The reduction of tension is dependent on the brightness of light acting upon the second eye. Thus, by exposing one eye to a light intensity of 3.3 or 0.28 foot-candles, we obtained, in an average of 26 tests, a maximum drop of tension in the second eye of 2.7, 5, and 9 mm. Hg, respectively. The tests also showed that an increase in the brightness of the light stimulus is accompanied by an increase in the rate of reduction of intraocular pressure in the second eye.

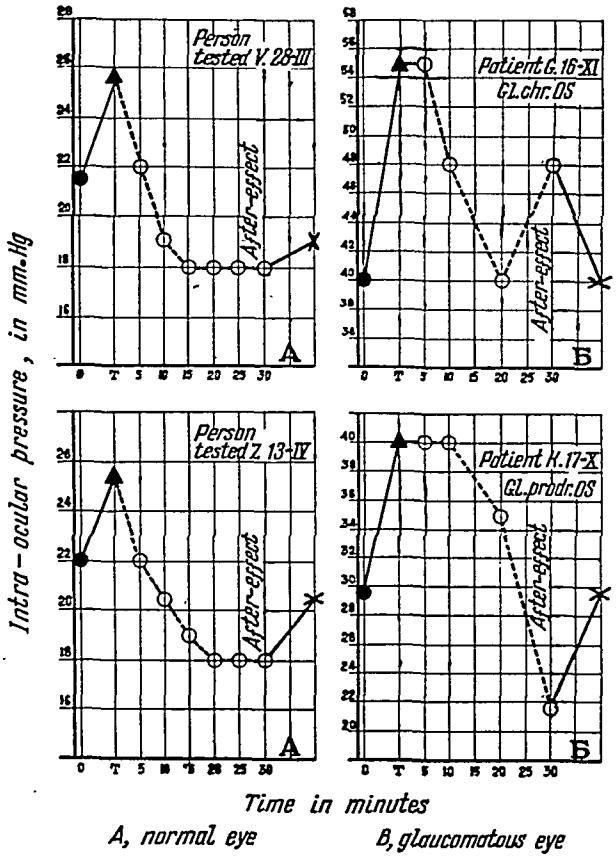


Fig. 1 (Zaretskaya). Intraocular pressure of one eye as affected by illumination of the other eye. Along the ordinate are plotted the values of the intraocular pressure in mm. Hg; along the abscissa, time in minutes. Black circles denote the initial tension found under general illumination of the experiment room; black triangles stand for points corresponding to the level of tension measured after dark adaptation of the eye for one hour; open circles and broken line denote data obtained by *illuminating the second eye for 30 minutes*; a solid line with crosses shows values obtained under initial light conditions, 15 to 20 minutes after exposure has been stopped.

Discussion

The mechanism underlying the influence of dark or light upon intraocular pressure still remains obscure. But the material available does not seem to corroborate the purely mechanical interpretation given this phenomena by certain authors, who ascribe the main role in the changes of tension to the pupil reaction (Grönholm, Seidel).

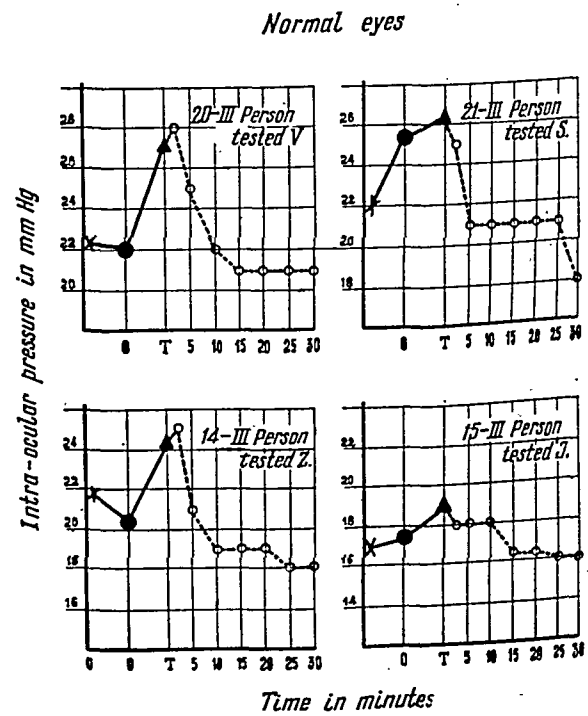

Fig. 2 (Zaretskaya). Intraocular pressure of the right eye as affected by illumination of the left eye. (Homatropine test.) Along the abscissa is plotted time in minutes; along the ordinate, intraocular pressure in mm. Hg. A cross denotes intraocular pressure at the start of measurement; a black circle, tension measured upon instillation of homatropine; a triangle, data obtained after one hour of dark adaptation; open circles and broken line, tension in the illuminated eye.

Feigenbaum's interpretation; namely, that the vascular system of the eye is affected by light through the vasomotors appears more plausible. The action of light may in this case be effectuated through the pituitary body and the vegetative centers whose excitation results in vasomotor reactions involving the optic apparatus, as well.

What are then the decisive conditions responsible in a glaucomatous eye for an increase in its tension, when kept in the dark, and for a reduced tension, when exposed to light?

Most of the authors look for an answer in a definite state of the neurovascular system of a glaucomatous eye; that is, in the so-called neurovascular reflex of Kalfa. This problem has not yet received any definite or satisfactory solution.

II. Experiments with color illumination

Thanks to the experiments carried out by Prof. S. V. Kravkov, it has been established that the green- and red-sensitive apparatus of our vision responds in an opposite way to such vegetative drugs as adrenalin and pilocarpine. It seemed, therefore, consistent to anticipate that the vegetative reactions of the organism will also be different in the case of the eye exposed to red or green stimulants.

Method

The procedure adopted was similar to that employed in our experiments with white light herein described.

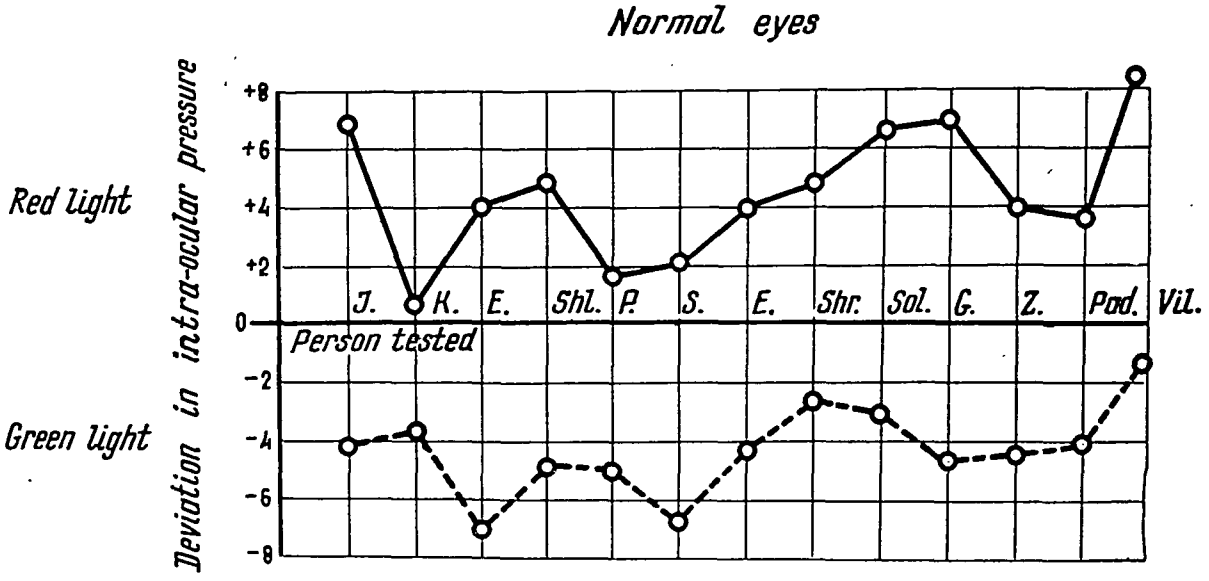

Fig. 3 (Zaretskaya). Effect of light stimulation of the one eye by colored light upon intraocular pressure of the other eye. Along the ordinate is plotted the maximum change in the intraocular pressure (in mm. Hg) from the level of dark adaptation. Along the abscissa are plotted the different persons tested. Circles and the solid line denote changes in intraocular pressure obtained by stimulating the other eye with red light; circles and the broken line, the results for the green light.

A 150-watt incandescent lamp served as a source of light stimuli. It was placed in a special pasteboard cone 40-cm. long, adjusted to the eye of the person tested, and supplied either with a green or a red gelatine filter. The green filter was transparent for rays approximately within the range of 433 to 586 mμ; the red filter for 578 to 720 mμ. Both the red and green light were equal in brightness.

The eye of each observer was exposed for 30 minutes, one day to red light, another day to green light. The experiments were carried out on 17 persons with normal eyes and on 25 glaucomatous patients.

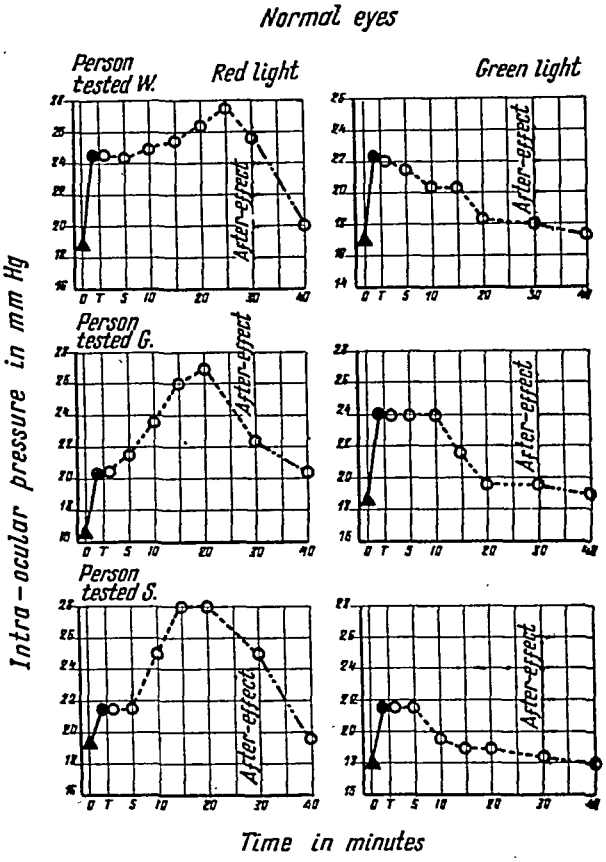

Fig. 4 (Zaretskaya). Curves of intraocular pressure (red or green light applied to the other eye). Along the ordinate are plotted the values of intraocular pressure in mm. Hg; along the abscissa, time in minutes. Triangles denote the initial pressure measured under general illumination of the room; black circles show the level of pressure with dark adaptation of the eye; open circles and broken line are readings obtained when the second eye was exposed either to red or green light; circles and dotted line show tension values found after stopping exposure of the second eye to the light stimulus (that is under the initial illumination conditions).

Results

The experiments with normal subjects showed the reaction of the intraocular pressure to be a reverse one, according to whether red or green light was employed.

The exposure of the second eye to green light brought a reduction of the intraocular pressure of the investigated eye; with the red light, the effect was reversed (fig. 3).

A similar picture of a reverse reaction to the red or green light is offered by Figure 4, which shows individual curves plotted for several patients tested by us.

As borne out by Figure 4, the curves obtained with red or green light show a different run.

Comment

Glaucomatous eyes display a well-pronounced specific reaction of their intraocular pressure for the same color stimuli. Thus, in all experiments carried on by us an appreciable reduction in tension was observed when the second eye of the subject under test was exposed to green light; the hypotonic effect in experiments with glaucomatous eyes was much stronger, however, than in experiments with normal eyes.

The hypotonic effect of green light appears still more conspicuous if compared to the effect of white light even of a higher brightness applied to the same glaucomatous patients (6 subjects) for sake of experimental control.

Table 1, as well as Figure 5, substantiate this observation.

Patients with a sharply pronounced form of glaucoma display a conspicuous deviation

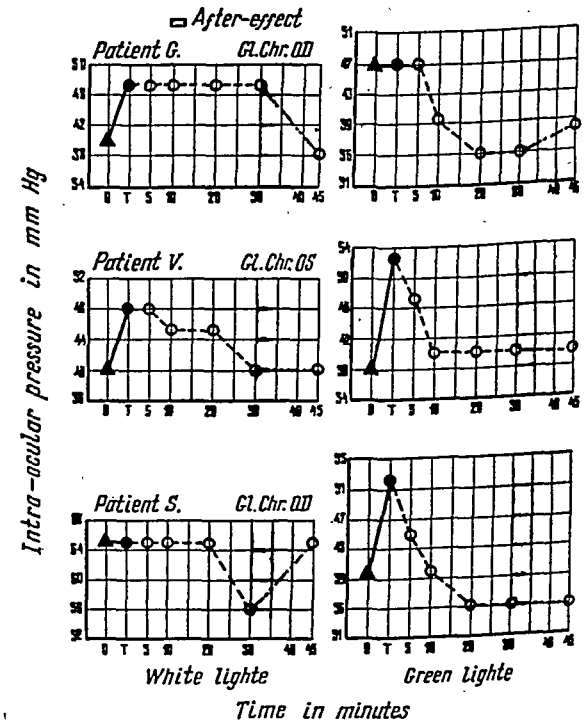

Fig. 5 (Zaretskaya). Intraocular pressure of one eye when the other eye is illuminated with green or white light. (For chart details, please see legend of Figure 4.)

TABLE 1

INTRAOCULAR PRESSURE IN GLAUCOMATOUS EYES AS AFFECTED BY WHITE OR GREEN LIGHT STIMULI

5	R	Glaucoma absol.	0	− 8.5
6	Sa	" "	0	−17.0

from the normal in the reaction of their intraocular pressure to red light. In normal subjects, however, the stimulation of the one eye with red light almost always results in a rise of the intraocular pressure of the second eye; no increase of intraocular pressure has, as a rule, been observed in glaucomatous eyes.

The intraocular pressure of the glaucomatous eye either remains stable, or may even show a slight tendency to decrease (fig. 6).

A similar picture of different responses to the red and the green light may be seen also in Figures 7 and 8, representing individual curves bearing out the results of experiments carried out on definite days.

DISCUSSION

The reaction of intraocular pressure in response to red light, which is missing in glaucomatous patients, points to a definite disturbance between their color-perceiving apparatus and their autonomous nervous system. The green-perceiving apparatus of these patients may possibly be more active than in normal subjects.

It is of interest to recall the remark made by Khodin as early as 1897 (*Journal for War Medicine,* 1897, in Russian), namely, that the increase in intraocular pressure is accompanied with a definite shift of color perception toward the green.

Wessely (1927) has described the presence of scotoma for the red as a symptom of glaucoma.

Some changes in color sensitivity have also been described in glaucomatous patients by Colomba (1932), who is likewise inclined to regard the analysis of color per-

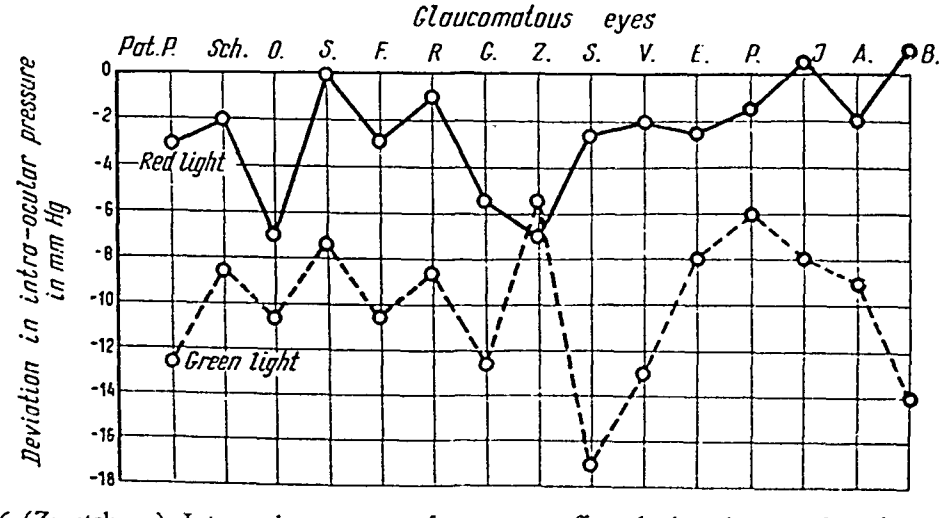

Fig. 6 (Zaretskaya). Intraocular pressure of one eye as effected when the second eye is exposed to colored light. (For chart details, please see legend of Figure 3.)

ception as one of the tests helpful in an early diagnosis of glaucoma.

Pointing out the importance of the investigation of color-vision disturbances for the diagnosis of glaucoma, Oloff (1932) remarks that they are of rather frequent occurrence in subjects affected by this disease.

Conclusions

Without claiming to have deciphered the mechanism of action of the accessory stimuli applied by us upon the intraocular pressure in a normal or a glaucomatous eye, the author, nevertheless, feels justified in advancing the following conclusions based upon her experiments.

1. The lowering intraocular pressure caused by vegetative reactions due to accessory stimuli is less in normal eyes and proceeds in a more uniform way, along a smoother curve, than in eyes of glaucomatous patients.

2. Fluctuations in intraocular pressure caused by darkness and light are likewise much more sharply expressed in glaucomatous eyes than in normal ones.

3. The pupillary reflex produced no appreciable effect upon the change in intraocular pressure when the second eye was exposed to the light stimulus.

4. The reduction in the intraocular pressure of the eye tested is dependent upon the brightness of the light stimulus applied to the second eye.

5. The opposite nature of the change in intraocular pressure, as brought about by the green or the red light stimuli, is evidence of the fact that the excitations of the green-perceiving apparatus of vision and of its red-perceiving apparatus produce two an-

tagonistic reactions of the autonomous nervous system.

6. The fact that, in contrast to unaffected subjects, glaucomatous patients do not show the usual increase in intraocular pressure in response to red stimuli of the eye, gives us ground to believe that the determination of the response of the intraocular pressure to the red light may become a supplementary method for diagnosing glaucoma.

7. In so far as stimulation with green light is followed by a particularly marked drop in intraocular pressure in glaucomatous patients, there seems to be some hope that green light may be applied to such patients for therapeutic purposes in the form of green spectacles used for reducing their intraocular pressure.

NOTES, CASES, INSTRUMENTS

A SIMPLIFIED TANGENT-SCREEN TECHNIQUE USING A PANTOGRAPH ATTACHMENT

ADOLPH POSNER, M.D.
New York

The pantograph attachment shown in the accompanying figure was designed for the purpose of transferring the field from the tangent screen onto a chart. When employed in conjunction with the technique to be described, it offers several advantages over the methods in general use.

1. It reduces the time consumed in tangent-screen examinations and eliminates the necessity for freehand drawing by making the procedure of transferring the field quick and automatic.

2. It enhances the accuracy of the field chart and thus makes possible more careful comparative field studies, so essential in the evaluation of the course of a case of glaucoma.[1]

3. It permits the use of an unmarked screen, so that the examiner is not influenced by the outline of the normal blind spot or by the other markings.

4. It makes it possible to relegate to an untrained assistant the task of charting the field.

5. It enables the perimetrist to use the same screen at any desired distance by selecting the chart appropriate for that distance.

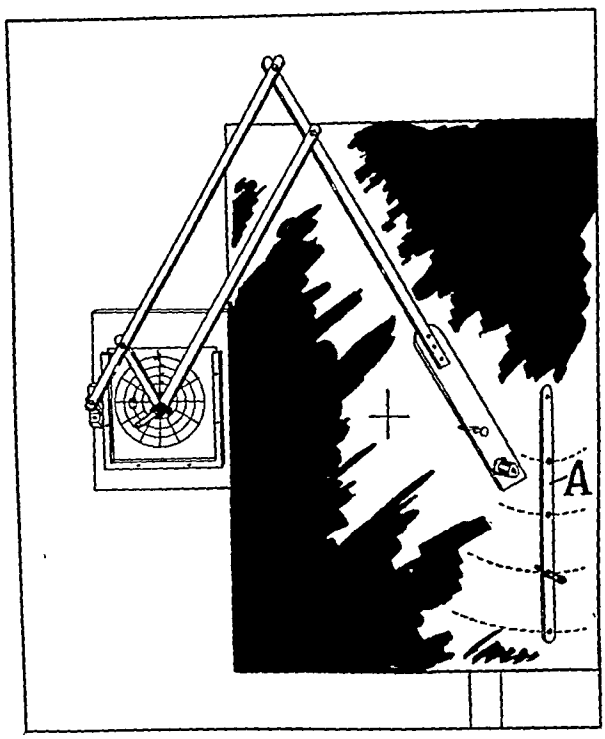

Fig. 1 (Posner). *Pantograph attachment for tangent screen.* This device is used for transferring the field automatically onto a chart. It has a reduction ratio of 1:8. The end segment is made of a transparent plastic. The tangent screen is left unmarked. A wooden rod (A) may be used for drawing temporary markings on the screen. Perforations placed at 5-degree intervals accommodate a wax crayon. The rod thus serves both as a ruler and compass.

The pantograph is a device widely used by artists and draftsmen for reducing and enlarging drawings accurately and automatically. Its use in connection with the tangent screen was suggested by Downey[2] and by Marks.[3] The devices described by them failed to gain popularity, probably because they were intended for automatic registration, rather than for copying the field, and thus could not help but be too cumbersome and obtrusive to be practical.

The pantograph attachment designed for use with the tangent screen reduces the field to one eighth its actual size. If a screen, one-meter square, is used, the corresponding field on the chart would be five-inches square. The writing arm is provided with a bushing which accommodates either a lead pencil or a colored crayon. The end section of the tracing arm is made of a transparent plastic, so that both the tracing style and the screen markings are under continuous observation. The frame which holds the chart is adjustable, so as to permit exact centering of the chart with reference to the screen. This adjustment also allows for a considerable range in screen sizes which

may be used with the same pantograph.

The technique of tangent screen perimetry, as herein briefly outlined, is well suited for use in conjunction with the pantograph attachment. The tangent screen is one-meter square and is made of black wool felt stretched over a wooden frame. A wooden disc, six inches in diameter, is attached to the frame behind the screen in such a way as to serve as a support for the central part of the screen. The screen does not carry any markings and is thus adaptable for use at other distances. The subject is seated so that his eyes are at one-meter distance from the center of the screen and on the same level. Uniform, shadowless illumination of about 5 to 7 foot-candles is provided by a Circline fluorescent tube mounted on a floor stand which carries an adjustable chin rest for head fixation. This accessory unit will be more fully described elsewhere.

The test objects which were found most useful are the white spherical ones devised by Evans. They range in size from 0.4 to 1.5 mm. The set* also contains larger disc-shaped test objects which may be used either as white or as colored stimuli by coating them with chalk of the desired color.

The field is plotted on the screen with colored chalk, using different colors to represent different sizes of stimuli and different eyes. A simple notation, made in the corner of the screen with each color used, serves as a key for the identification of the lines in the subsequent charting of the field. For example: "R-1" written in the blue chalk means that the blue line represents the field of the right eye as plotted with a 1-mm. white test-object. The colored chalks should be dry, nonwaxy, and of dark shades.† The chalk marks may be removed with a soft brush. Occasionally the screen should be cleaned with a vacuum cleaner. A felt screen is preferable to a woven one, since the chalk dust remains close to the surface.

The method of plotting the field is an adaptation of that employed by Evans for angioscotometry. For a detailed description the reader is referred to Evans' excellent monograph.[4] One fundamental principle might bear emphasizing here: *The stimulus should always be moved perpendicularly to the border of the scotoma.* This presupposes a knowledge of the shapes and locations of the typical scotomas for each condition, together with the most common variants.

Tangent-screen perimetry is an integral part of the ophthalmologic examination and, as such, should preferably be carried out by the ophthalmologist himself, if the findings are to have any clinical significance. Good perimetry requires special study and experience, which can be gained only by careful work and by correlating the field with the clinical picture. It is hoped that the pantograph attachment here described, by reducing the time consumed and by eliminating the need for free-hand drawing, will extend the use of the tangent screen in ophthalmologic practice.

THE PREVENTION OF CYCLOPLEGIC GLAUCOMA

DANIEL SNYDACKER, M.D.
Chicago, Illinois

"What precautions must be used in daily practice to assure adequate examinations of eyes at any age without danger of cycloplegic glaucoma?" was one of the questions asked in the American Academy's Home Study Course on Refraction. In spite of the obvious importance of the question, the answers given by the students were, almost without exception, very unsatisfactory. This communication has two aims, therefore: (1) to find out why the answers were so poor, and (2) to focus attention of all prospective students on a correct approach to the problem. It must be remembered that the home study course stresses the academic approach with particular emphasis on the basic sciences; and, as a consequence, the reading which is required of the students is the standard accepted textbooks on any given subject.

REVIEW OF REFERENCES

Review of these references for the subject of refraction showed that the standard textbooks left much to be desired in their discussion of the problem. Thorington,[1] Fuchs,[2] and Cowan[3] briefly mention in a scant sentence or two that cycloplegics should not be used in the presence of glaucoma. May[4] mentions the fact that the tension should be checked, but does not specify a tonometric tension. Duke-Elder[5] states that the presence of glaucoma should be excluded before using mydriatics, and that miotics should be instilled afterward. The *American Encyclopedia of Ophthalmology*[6] suggests taking the tension first, and also says it is "a good plan" to instill a miotic afterward. O'Rourke in Berens[7] says that caution is indicated, and that a cycloplegic should not be used until a fundus examination is made and the tension tested digitally, and, if there is any doubt, tonometrically. Gifford,[8] although brief, gave the most complete answer when he said that the intraocular pressure should be estimated in all people over 25 years of age, the fundus observed through undilated pupils to rule out the presence of a glaucomatous cupping, and a miotic instilled in all people over the age of 20 years, at the conclusion of the examination.

Discussions in these same textbooks under the heading of glaucoma were no more complete in so far as this particular question was concerned. Here the problems of diagnosis were discussed with regard to provocative tests, perimetry, and tension curves in early stages. Such procedures obviously are extremely important in confirming a suspected case, but they can hardly be carried out as routine on every case for cycloplegic refraction.

PRECAUTIONS TO OBSERVE

What then are the precautions to be observed? What steps must be taken to prevent a cycloplegic glaucoma? First, it is important when the history is being taken to ask specifically whether the patient has ever seen halos around lights, whether there is any history of glaucoma in the family, or whether the patient has ever had any episodes of ocular inflammation suggestive of attacks of acute glaucoma. It goes without saying that the visual acuity must be determined, and in those cases where it is possible a manifest refraction should be performed.

The next step is to make an external examination of the eyes, paying particular attention to the size of the cornea, the depth of the anterior chamber, the size of the pupils, and the pupillary reactions. Any deviation from the normal in the way of a small cornea, a shallow anterior chamber, or pupils which seem unduly large and do not react to light briskly should arouse suspicion and require that further study be made to rule out glaucoma. A careful ophthalmoscopic inspection of the optic discs

must be made in every case, and any case in which there is any suspicion of a cupping, must have a complete study.

Clinical routine

It is a good clinical habit to check the tactile tension in every case, but no clinician can appreciate a difference of 5 mm. Hg by this technique. Therefore, it is extremely important to check the intraocular pressure *tonometrically* on all patients over 25 years of age before a cycloplegic is instilled. This measurement should be rechecked tonometrically after the pupils are dilated. Any case in which there is an increase of intraocular pressure of 5 mm. Hg or more, following dilatation of the pupils, is suspect and requires an immediate careful workup and prolonged follow-up. Gradle[9] has shown that in 2.8 percent of 500 eyes, there was an increase of 5 mm. Hg or more in the intraocular pressure following the use of cycloplegic for refraction.

Following the use of a mydriatic it is important to instill a miotic to hasten recovery from the effects of a dilated pupil in all cases. In those cases in whom there is an abnormal increase in intraocular pressure under mydriatic, it is absolutely necessary to keep the patient in the office or clinic until both the tension and pupils have returned to normal with the use of the miotic. Subsequent treatment is then decided on after a careful glaucoma work-up.

The importance of these procedures cannot be over-emphasized. The practice of routinely dilating all pupils without adequate examination is not only poor ophthalmology, it is dangerous, and it is important that all those who are responsible for the teaching of our young men recognize and emphasize this point.

QUININE AMAUROSIS*

B. L. Braveman, M.D., D. S. Koransky, M.D., and M. M. Kulvin, M.D.
Hines, Illinois

Quinine in many instances is the drug of choice for the prophylactic and active treatment of malaria. With the return of many servicemen who have suffered from malaria and the easy availability of quinine at present, toxic reactions to the drug will probably be seen more frequently.

The toxic action of quinine in the retina is reported as being (1) directly toxic to the ganglion cells and (2) acting upon the retinal arterial system to produce extreme vasoconstriction with resultant ischemia and damage. Patients in most of the reported

* Published with the permission of the Chief Medical Director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or the conclusions drawn by the authors.

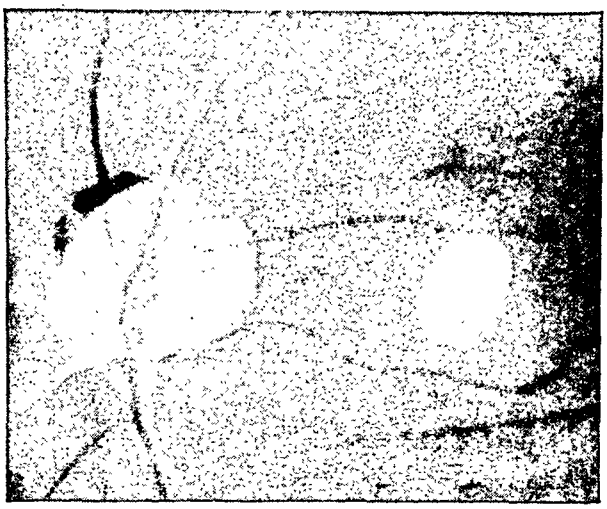

Fig. 1 (Braveman, Koransky, and Kulvin). Fundus picture in a case of quinine amaurosis four weeks after poisoning showing optic atrophy and silver-wire arteries.

cases recovered much of their central vision. However, varying amounts of peripheral constrictions remained. Duke-Elder states, "In all cases the tendency is for recovery: in the milder degrees of poisoning the vision may recover in a few hours but in more severe cases amaurosis may persist for several days or even weeks, and in this event some degree of atrophy of the nerve and some permanent loss of vision is inevitable. Permanent blindness, however, has not been recorded."

The following case is the report of an individual who ingested a large overdose of the drug and developed severe toxic cardiovascular and retinal damage.

Report of a case

A 42-year-old white man, a bartender, was admitted to the hospital on December 29, 1946, in a comatose condition. No history was obtainable.

On initial examination systolic blood pressure was 60, diastolic pressure could not be recorded. The pulse rate was not obtainable. An emergency electrocardiogram recorded a ventricular tachycardia. The patient was given immediate emergency management of oxygen, and so forth. The tachycardia and low blood pressure persisted for a period of eight hours. Gradually the blood pressure rose, the pulse rate fell, and the patient responded to treatment. Within 48 hours after admittance, the patient regained consciousness and at that time stated that the room was dark.

An ophthalmologic examination revealed light perception and projection to be absent in both eyes. The pupils were round, measured 4½ mm., and fixed to light and accommodation. Ocular movements, adnexa, and anterior segments were normal. Both fundi revealed well demarcated, flat discs. The retinas appeared markedly pale and somewhat edematous. The maculas were cherry red against the pale retinal background. The arterial tree was markedly attenuated, the arteriovenous ratio being approximately 1 to 4, and the arterial tree could only be followed out to the region of the equator.

Diagnosis. A provisional diagnosis of retinal ischemia was made and vasodilators were administered in large doses (intravenous sodium nitrite, papaverine, and niacin by mouth).

Course. Within 72 hours, the retinal edema receded and the fundi regained a normal color. However, the vascular tree remained constricted.

Seven days after the original eye examination, the arterial tree was completely sheathed and had the appearance of silver wire. The discs became progressively paler and were dead white in appearance by the second hospital week and have remained so.

Fifty days after admission faulty light perception and projection were obtained; shortly thereafter finger counting at 18 inches could be elicited. The pupils remained fixed to light and accommodation and field studies could not be obtained.

Five days after admission, a history of excessive doses of quinine was obtained from the patient and confirmed by his wife. He stated that it was his custom to take 45 grains of quinine daily when he felt an attack of malaria coming on. On December 28, 1946,

he took all of the quinine that he had available, which consisted of approximately 100 tablets varying in dose from 2 to 5 grains each. At that time the diagnosis of quinine intoxication was established. The patient did not complain of impaired hearing, but audiometric examinations revealed partial nerve deafness bilaterally.

Summary

This is a case of quinine poisoning with bilateral amaurosis persisting for a period of at least 50 days. The probable dose was at least 200 grains (Goodman and Gilman state that the fatal dose is 120 grains). The patient also suffered from a cardiovascular episode which consisted of a ventricular tachycardia which persisted for a period of eight hours and was associated with the marked fall in blood pressure. The outstanding findings in the fundi was the markedly persistent vasoconstriction that led to severe retinal damage.

Historical Miniature

Thomas Young, who first described astigmatism when he published measurements of his own eyes in 1801, was also the first to discover the very common occurrence of hypermetropia. The recognition of this fact, which Donders did not mention in his "Refraction and Accommodation," in 1866, is of far greater importance than the description of an isolated case of extreme hypermetropia which was published by Janin in 1772.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

May 5, 1947

DR. BENJAMIN FRIEDMAN, *president*

SURGICAL ANATOMY OF THE EYE

DR. RAYMOND E. MEEK discussed this subject during the instruction hour.

BIFOCAL SEGMENT SELECTOR FOR SPECTACLE FRAMES

DR. AARON ROTH demonstrated an attachment to spectacle frames. This can be incorporated in the frames, and allows the wearer to move his bifocal segment up so that he can use it directly in front of his eyes if necessary.

CENTRAL SEROUS RETINOPATHY

DR. EMANUEL ROSEN presented two cases of central serous retinopathy following vaccination. He demonstrated that the macula may be involved after vaccinia inoculation. Such an involvement usually occurs within an incubation period of 7 to 11 days. Histologically, it simulates the picture seen in the brain in cases of postvaccinial encephalitis. Dr. Rosen stated that we may assume this to be an allergic response with specific localization in the macula.

PERIPHERAL VISUAL ACUITY WITH SPECIAL REFERENCE TO SCOTOPIC ILLUMINATION

DR. JOSEPH MANDELBAUM'S paper (Louise L. Sloan collaborating) was published in the JOURNAL 30: 581 (May) 1947.

In his concluding remarks Dr. Mandelbaum said that:

1. Scotopic peripheral acuity does not parallel the rod population or the light sensitivity of the retina.

2. Maximum scotopic acuity can be achieved by 4- to 8-degrees' eccentric fixation.

3. Light intensity is not as critical a factor in peripheral acuity as it is in central acuity.

4. At the lowest scotopic levels, visual acuity is fairly constant from 4-degrees to 30-degrees' eccentric fixation.

5. A considerable overlap occurs between cone and rod function, the paracentral rods dominating discriminatory function at light intensities well above the cone light threshold.

6. For 25- and 30-degrees' eccentric fixation, the rod cells dominate form discrimination even at intensity levels as high as one millilambert.

USE OF PLACENTAL EXTRACT IN VIRUS DISEASES OF THE CORNEA

DR. BERNARD KRONENBERG described the preparation of aqueous placental extract, lipoid extract, immune gamma globulin from placental blood, and placental tissue coagulant. He gave a preliminary report on the use of aqueous placental extract in the treatment of herpetic keratitis and superficial punctate keratitis. In view of the favorable results obtained in these cases, Dr. Kronenberg stressed the need for further clinical investigation.

Dr. Kronenberg reported the use of immune gamma globulin in the treatment of uveitis. He said that the immunologic rationale and the favorable results obtained suggest the need for further investigation in this disease. The favorable results obtained in the treatment of retinitis pigmentosa with placental extract by Filatov was not corroborated by Dr. Kronenberg. Old corneal opacities, tuberculous episcleritis, diabetic retinopathy, and vascular changes

in the retina did not respond to treatment with placental extract.

Dr. Kronenberg also described the use of placental tissue coagulant, preoperatively, to lower the blood clotting time in diabetics.

Syndrome of glaucomato-cyclitic crises

Dr. Adolph Posner and Dr. Abraham Schlossman presented nine cases which form a homogenous group and exhibit signs of mild glaucoma, associated with cyclitis. The clinical features were as follows:

Unilateral attacks of ocular hypertension occur without congestion, pain, or marked impairment of vision. These attacks last from a few hours to two weeks. Cells in the aqueous and keratic precipitates appear either simultaneously with hypertension or within 24 hours after the onset of the hypertension. Posterior synechias are never observed. The precipitates are not numerous and disappear spontaneously within one month. Individual attacks may occur without precipitates. Heterochromia was present in one third of the cases and anisocoria in one third of the cases.

Gonioscopy showed the angle to be open in all four cases examined. In two of the cases it was wide, and moderately narrow in the other two cases. The attacks are self limited.

Pupillographic examinations gave normal curves in all six cases examined. In three cases the curve was of the type found in primary glaucoma, while the other three cases showed evidence of disturbances of the central sympathetic nervous system.

Dr. Posner said that treatment does not shorten the total duration of the attack. Pilocarpine (½ to 2 percent) usually lowers the tension. Homatropine is not dangerous and its action is not dependable. Surgery does not prevent recurrence of the attacks.

This syndrome of recurrent attacks of unilateral glaucoma with mild cyclitic signs forms a clinical entity intermediate between primary and secondary glaucoma, since it exhibits features of both types of the disease.

Discussion. Dr. Ludwig von Sallmann agreed with Dr. Posner and Dr. Schlossman that cases of patients with recurrent attacks of increased intraocular pressure as was described should be classified as a definite syndrome. He said that these cases can be distinguished from typical primary glaucoma with a few deposits on the cornea, from secondary glaucoma, and from the so-called sympathicus glaucoma with and without heterochromia.

In regard to the pupillographic examinations, Dr. von Sallmann raised the question as to whether, in view of the unilaterality of the lesion, a disorder in the subordinate ciliospinal center of Budge can be completely disregarded.

Dr. von Sallmann said that in addition to the hypothalamic disturbance, Dr. Posner assumes the coexistence of a peripherally operating mechanism as, for instance, a labile peripheral autonomic system; this factor must be present unilaterally. There seems to be a considerable range of doubt or alternate explanations. One could visualize that the functions of the terminal nerves or the capillariomotoric response of the other intraocular mechanisms of regulation are at fault in the one eye. In view of the presence of infective foci and strong allergic reactions of some of the patients, the question arises whether an antigen-antibody reaction or a toxic factor couldn't be responsible for the onset of the periodic attacks in a disposed eye. That is, the cells in the aqueous and the precipitates on the cornea could be the expression of a transient low-grade inflammation rather than of a primarily nervous disturbance.

What further studies may reveal on the interrelationship between disorders of sympathicus centers and between the centers and a peripheral mechanism remains to be seen. At the present time it is likely that a transient increase in the permeability of the

ciliary capillaries is the most important single peripheral factor, which has a bearing on the development of the recurrent attacks. In the last year, studies were conducted in the Knapp Laboratory on an experimental glaucoma induced by increased permeability of the ciliary capillaries. Various therapeutic approaches were studied on experimental animals. The effects of adrenergic drugs, of pituitrin, of substances acting on the intracellular cement, as Ca ions and adrenal cortical hormone, and of a series of histamine antagonists were tested, and promising results were obtained both in respect to the reduction of increased permeability of intraocular capillaries and the lowering of intraocular pressure. There is some hope that one or the other of these therapeutic measures will be of help in the glaucomato-cyclitic crises described by Dr. Posner and Dr. Schlossman.

Bernard Kronenberg,
Secretary.

SOCIEDAD OFTALMOLOGICA DE MADRID

May 16, 1947

Syndrome of Van der Hoove

Dr. Mier read a paper on Syndrome of Van der Hoove. The patient, 32 years of age and 1.38 meters tall, had suffered three fractures, which were corroborated by X-ray pictures. The X-ray films also showed considerable osseous rarefaction of the epiphyses of the long bones and a very small and dense sella turcica in the shape of a kettle and covered with a bony layer, in the interior of which was the strangulated hypophysis. The patient showed hypophyseal disturbances. Both the middle and internal ears showed otosclerosis.

Discussion. Dr. Marion Amat congratulated Dr. Mier on his brilliant dissertation and recalled the fact that he had published in the *Semana Medica Española* of December, 1940, an interesting clinical observation which presented the complete triad of the Syndrome of Van der Hoove; namely, blue sclerotic, multiple fractures and otosclerosis and, in addition, cranial asymmetry, alterations in the basal metabolism, and calcemia.

Visual disturbances as the first subjective manifestation of a tumor of the hypophysis

Dr. Marin Amat and Dr. Marin Enciso presented a paper on this subject.

Marfan's syndrome

Dr. Marin Enciso and Dr. Lopez Garcia presented a paper on "Marfan's Syndrome: Extraction of Subluxated Crystalline Lenses." They presented a girl who showed this syndrome with excessive length of the limbs, especially the hands, feet, and fingers, very large arms, congenital subluxation (ectopia) of both crystalline lenses complicated by ocular hypertension which necessitated an iridectomy in both eyes and later extraction of both subluxated, transparent crystalline lenses. The operations were accomplished without any loss of vitreous or any complication.

Discussion. Dr. Mario Esteban. Arachnodactylia is one of those dystrophies, the study of which is always interesting. The pathogenic interpretation of the condition lends itself to the formulation of hypotheses which leave behind them not one, but many questions.

Evidently there is an anomaly of development of germinal origin which affects the mesoderm. But what is the fundamental cause of the dystrophy? Why are there other malformations and ectopia of the crystalline lenses and such excessive length of the bones of the hands and feet that the flexor tendons become relatively short causing a permanent contraction of the finger joints?

One may suggest the theory that there is hypophyseal disfunction, and perhaps also

parathyroid disfunction, which start in fetal life.

Professor Carreras. Marfan's syndrome does not constitute an isolated symptomatic complex, but forms part of a much larger and more general syndrome for which Schmidt proposes the name of "Congenital Mesodermal Dysmorpho-dystrophy." Marfan's syndrome is one of its clinical types and another (at least until now) is the syndrome of Marchesani in which there is microphakia and spherophakia in addition to brachydactylia. There have been cases of brachydactylia with ectopia of the crystalline and of spherophakia with arachnodactylia, which proves there is some common basis for the aforementioned changes. At times there are frustrated and asymptomatic forms. In addition to luxation of the lens and spherophakia, which are the most characteristic features, there may exist other ocular anomalies (megalocornea, aniridia, coloboma, and so forth). Of the different theories proposed to explain this syndrome, the mesodermal theory of Weve seems best.

The disturbance which affects the development of the mesodermal structures could be explained by the action of some chemical or prehormonal substance, since in the embryonal period, when these events seem to begin, one cannot speak of actual hormones. Delayed involution or partial persistence of the tunica vasculosa lentis could originate these zonular deficiencies which would later cause the changes in the crystalline lens. Although the lesion attacks ectodermal organs and formations, such as the crystalline, the origin of the disturbance is rooted in the mesoderm. Heredity also plays a role. The typical cases of the disease, or even the incomplete and frustrated forms, are transmitted by heredity of the dominant type. The asymptomatic forms, on the other hand, are generally transmitted by the recessive type.

Dr. Marin Enciso (closing). In the first place I wish to thank Dr. Esteban and Professor Carreras for their remarks on the subject. With reference to Dr. Esteban's suggestion on the endocrine origin of the syndrome, this has been partly answered by Professor Carreras. The disturbance begins in embryonic life at a time when one could not very well speak of fetal endocrine influences. The morphologic peculiarities of the patients with Marfan's syndrome suggest, however, the influence of endocrine factors, especially of the hypophysis, but actually this idea can be only a suggestion, since it is not based on definite data.

With regard to the substance which is affected, it seems that in Marfan's syndrome the changes in the mesenchyme dominate to such an extent that some include it in the congenital mesenchymal dysplasia. However, it is not rare to observe cutaneous and neurologic changes which lead one to think of simultaneous changes in several blastodermal parts. The disturbance probably depends on a juncture of genetic factors combined in diverse ways in various cases.

Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 700 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

TERRY-OWENS DISEASE

Since retrolental fibroplasia was described by Terry in 1942, our knowledge of this disease of premature infants has been fragmentary, and conflicting hypotheses have been advanced in an attempt to explain it. These hypotheses, have been based upon (a) clinical observations of patients seen in advanced stages of the disease, and (b) upon histologic examinations of eyes removed when the lesions were far advanced. It is natural, therefore, that these examinations made during the late stages of the disease have led to inadequate and conflicting premises as to its nature.

To understand retrolental fibroplasia, it is necessary to follow the clinical course of the disease from its onset to the development of the final characteristic picture. Dr. William C. Owens and Dr. Ella U. Owens have investigated the problem of retrolental fibroplasia from this standpoint. Their findings will be reported in an article entitled, "Retrolental Fibroplasia in Premature Infants," which will appear in a subsequent issue of the JOURNAL. As part of their study

on retrolental fibroplasia, they routinely examined all the premature infants weighing 2,000 grams or less born in The Johns Hopkins Hospital or admitted to the Premature Nursery of The Johns Hopkins Hospital for a period of two years.

In their report they describe the clinical course of retrolental fibroplasia as it occurred in 10 premature infants in whom they observed the lesion develop. In every case observed, the lesion had its onset after birth. The lesion did not result from an overgrowth or persistence of any structure characteristic of an embryonic or fetal stage of development such as the tunica vasculosa lentis or the primary vitreous, as had formerly been supposed. They found that the earliest changes occurred in the retina and the retinal vessels. The retinal vessels became enlarged and tortuous; the retina became gray, swollen, and elevated; and the vitreous became hazy. As the disease progressed, large masses of elevated retina fused and gradually covered the retrolental space, producing the picture that has been described as typical of retrolental fibroplasia, which in reality is the end stage of the lesion. In the cases described, the lesion began to develop about two months after birth. It gradually increased in activity and intensity until about the fifth month after birth, when it began to subside, the later changes being due to contracture of the retrolental tissue.

The article of Dr. William C. Owens and Dr. Ella U. Owens is particularly interesting for their observations throw an entirely new light on the nature of retrolental fibroplasia. The disease has a definite onset in postnatal life. It occurs primarily in the retina and retinal vessels; it is not related to an abnormal persistence or hyperplasia of the tunica vasculosa lentis or of the primary vitreous. The fact that the lesions in some of the cases subside spontaneously suggests the possibility that, if the cause of the disease can be found, the institution of proper therapy may result in a regression of the lesions, leaving eyes with almost no remaining abnormality.

The disease that Terry described and upon which Owens has elaborated so convincingly is, therefore, surely an entirely separate entity from that of the overgrowth or persistence of fetal developmental tissue within the eye. In discussing the paper by Owens at the recent meeting of the Wilmer Residents Association, Verhoeff pointed out that the term "retrolental fibroplasia" is not truly significant of either of these two conditions, and thus its employment adds to the confusion. Although eponyms are unscientific, the use of the term "Terry-Owens Disease" can be practiced in this event until a more suitable, or at least scientific, name is evolved.

Much pride is taken in proposing that the name "Terry-Owens Disease" be made an integral part of our medical and ophthalmic nomenclature. Tularemia conjunctivitis was the first ophthalmic disease discovered by ophthalmologists in the United States and "Terry-Owens" disease is the second. We are growing up.

Derrick Vail.

COLOR BLINDNESS; NO CURE

During the examinations in the enlistment and drafting of men and women for admission to the armed forces—Army, Air, and especially the Navy—many of them were astonished, not to say shocked, when informed that they were "color blind." Because they had never experienced difficulty in their lives, and, doubting the recruiting examiner's judgment, they sought examination elsewhere. When convinced that they had shown uncertainties in their estimates of the colors shown them, they were inclined to believe they were ignorant of colors, or that they had some temporary and unsuspected diminution of their sight in general. They sought means for educating themselves in the appreciation of colors, adopt-

ing exercises by which they might so correct their defects as to be able to pass the prescribed tests.

The term "color blindness" is a rather cruel designation of the state of the sight which prevents an individual from easily recognizing colors and makes him hesitate to declare the name of a color and to display an ability to match it and blend it with other colors.

The appreciation of *color* is a physical property of the sight—occasioned by the breaking up of light when broken into rays of differing quantities. This action is shown when one holds a prism of glass before the light as it comes from the sun and observes the reflection thrown into various colors, like those of the rainbow after a storm, exhibiting the red at one end and violet at the other. Now, there are some persons who cannot see red, or green, or violet; these are the true actual so-called color blind. And there are others who have difficulties in appreciating some colors when they are shown under varying conditions of light, or in matching or blending a given color with another. Few, very few, persons are absolutely blind to all the colors.

Scientists have given another name to color blindness—it is spoken of as "achromatopsia," and those who, while recognizing all the colors as such, have difficulty in manipulating any or all of the rainbow colors are the "anomalous." These anomalous persons have been divided into classes depending upon the number of the colors with which they have difficulty, or the replies which they make in the testing—thus "deuteranopes" and so on in each degree, the main color is given a Greek numeral to indicate the result. There is no blindness in the ordinary sense.

In practice and experience in railway, naval, and other forces, red and green have been the colors employed as signals of safety or danger. So, in general, because of the employment of those two colors, such achromatics have been spoken of as the "red-green blind." This defect has long been recognized and largely has had a place made for it, since the subjects, as a rule, exhibit the defect in all their avocations. Those who, in bright light make out to the satisfaction of all, are prone to go astray when in reduced light, or in cloudy weather, or at sundown and daybreak. This class is more dangerous in action than the known red-green individuals as they cannot instantly distinguish the colors set.

The cause of color blindness is not known; many theories are held, and it is amusing to stand on the sidelines and watch the fierceness of the fights which go on between the advocates of one adopted theory who struggle to have opponents accept their pet ideas. As a working hypothesis, most ophthalmologists are willing to accept the Young-Helmholtz theory that each color has its own nerve, the rays carried over it to be appreciated by the brain.

At present, ordinary cases of color blindness present no visibly known cause for their trouble. Their eyes are healthy and show no departure in structure from what is obtainable in the examination of the perfectly normal cases. But, color deficiencies are complained of by those who have had distinct disease of their eyes, or of the nervous system, as in optic atrophy and in some cases of cataract.

The appreciation of color was recognized in the earliest known records of humanity. The recognition of the "Arch in the Heavens" was an index of man's ability to distinguish the different bands in the rainbow. At the time of the Flood, doubtless, not all the colors as known to man today were recognized by primitive man. Even nowadays savage peoples in the remote lands do not employ all the civilized colors. We may conclude that *color* has been a developed sense. May we hope that, in the future, the civilization of the, until recently, savage inhabitants of the Oceanic Islands can be observed by

scientific inquirers so that many new facts concerning the color vision of such backward peoples can be made known to us?

It was a common expression of those who had been rejected by the Armed Services, that they were "color-ignorant." It is true that some persons do not know what names to give to modern tints and shades of common colors, they cannot say what is "cerise" or what "mauve"; yet, these same individuals, when shown the red, green, blue, yellow, and white lanterns in the railways and street crossings, accurately and promptly called the names of the colors.

Now, because of having been rejected, many, eager for enlistment or employment, have sought means to educate themselves or so to develop their senses that they can pass the same tests which they failed to pass a short while before.

Color blindness has been closely observed since about the end of the 18th century. Many are the ludicrous stories told of well-known persons' mistakes, such as a staid Quaker appearing at First Day's breakfast in a flaming red coat of his own selection, having indignantly objected to the practice of his wife's insistence on choosing the cloth for his clothing. Or, the more serious story of a trusted railway engineer, who for 40-odd years had guided his train to a distant city without a broken record. He declared that he "knew every tie from the one point to the other with his eyes shut," but when examined after a short illness, was found to be deficient "with his eyes open."

Color blindness is found in males, rarely in females, but a woman of a color-blind family may be a "carrier" and transmit the affection to her male descendants, the females of the family serving as carriers to their male children.

At the beginning of the scientific study of color vision, common colored articles were employed. Since these did not have fixed qualities, efforts were made to standardize the coloring of objects employed and to have the standards accepted by all interested nations as the international standard.

Lamp lights were devised and wool skeins dyed to a fixed degree. Later cards were printed. All these were first standardized and then modifications of them were adopted, and "mistaken colors" arranged so as to enable the examiner to have an idea of what the defective one might offer as his conception of the true colors. The cards, or plates, have various figures formed of the test-color, surrounded by similar color formations but of the "confusion color." This makes the set figure indefinite and has the property of confusing the examinee, thus demonstrating to the examiner the true state of his vision.

To repeat, it has been the endeavor of the true scientist to seek means at least to increase a deficient's powers, but without success. It is to be recorded, alas, that designing persons, or perhaps misguided enthusiasts, have prepared schemes arranged with standard and obscuring colors, with which they have held out to would-be "clients" assured prospects that by daily practice with these devices, they can "cure" this color blindness and safely pass all the color tests prescribed by the Government.

I have been concerned all my medical life with practical observation of known and suspected color deficiencies—my professional observation confirming facts I had become aware of in my early days and in school and college life. In deep sympathy for those found to be so defective that they have been forced to leave their chosen, and otherwise efficient, employment because of their "color blindness," I have pursued every available means to be practiced for such studies. My experience has been in practical-every-day environment, not in complex laboratory surroundings. In no case have I been rewarded by results so perfect or of such cheering success that a color-blind man or a woman, under all sorts of conditions devised, has been

able to pass the tests conducted by another disinterested observer. In the cases of excessive use of tobacco, especially of an alcoholic, there have been recorded recoveries from that kind of toxic amblyopia after a season of abstention from "nicotine and its tincture."

In May, 1947, there was published in the *Archives of Ophthalmology* an extensive report by Roswell Gallagher and his colleagues of their analyses of the "Efforts of Training Methods on Color Vision" observed in the case of 40-odd individuals in which they state:

"Training which enables a person (previously classified as a deficient in color vision) to achieve a test rating comparable to that of persons who have normal color vision apparently does not result in the development of the ability to differentiate colors in all situations and under all conditions with the accuracy and speed possessed by those who have normal color vision." When testing objects, not hitherto employed, were exhibited, the subject failed to recognize them correctly.

And, at the meeting of the American Ophthalmological Society held in June, 1947, at Hot Springs, Virginia, it was unanimously ruled that—"The conclusion reached after consultation with various groups interested in the subject of defective color sense was 'to the effect that color deficiency cannot be remedied by diet, training, or any other treatment now known to Science.'" This judgment was confirmed by the American Medical Association, and was repeated at the meeting of the association at Atlantic City in June, 1947.

It is by reason of these pronouncements that this paper has been offered for the benefit of those who might have been induced to enter into schemes devised to improve their color defects.

Burton Chance.

OBITUARIES

ERNEST F. KRUG
(1877-1948)

Dr. Ernest Frederick Krug died on February 28, 1948, after a long illness. He was born in Cleveland, Ohio, a son of Prof. Joseph Krug, supervisor of instruction in the German language in the Cleveland public schools, and of Magdalena Weinhardt Krug.

After completing his education in Cleveland, Dr. Krug came to New York to study medicine and was graduated from the College of Physicians and Surgeons of Columbia University in 1900. He then interned at the Lennox Hill Hospital in New York and from that time on was always associated with that institution.

He became an assistant to Dr. Emil Gruening and later to Dr. Wilbur Marple. He also took postgraduate work abroad, studying for some time under the eminent ophthalmologist Prof. Dr. Ernst Fuchs. He successfully practiced ophthalmology and otolaryngology for many years, but from 1922 on he limited his practice to diseases of the eye. During World War I, Dr. Krug served in the medical corps. He held the rank of major.

After fulfilling various appointments at the Lennox Hill Hospital, Dr. Krug became attending ophthalmologist in 1920, from which position he was retired, in 1942, to become a consultant in his department. Through his untiring efforts, a modern and well-equipped eye department was established and he devoted a great deal of his time to teaching and training the younger ophthalmologists. He was always interested in the younger men and was happy to pass on to them the knowledge which he had gained from his long years of experience. He was always willing to offer them guidance and encouragement. Many of these doctors continued throughout his lifetime to seek his advice and often called him in consultation.

Dr. Krug held the appointment of associate professor of ophthalmology at the Post Graduate Medical School for many years and, until 1946, he was associate attending ophthalmologist at the Post Graduate Hospital and Dispensary. He also served for some time as attending ophthalmologist at the Central Neurological Hospital at Welfare Island.

He was a Fellow of the New York Academy of Medicine, a member of the American Ophthalmological Society, the American Academy of Ophthalmology and Otolaryngology, and the New York Ophthalmological Society.

Dr. Krug was a thorough ophthalmologist in every field, a keen observer, an accurate diagnostician, and a very skillful surgeon. His methods were simple and direct. He loved his chosen work deeply and he gave unstintingly throughout his long career of himself and of his knowledge to those who were afflicted. He will be remembered by all who knew him for his genial good nature, ready wit, and quick repartee.

His contributions to ophthalmic literature were few, but they were important. They were as follows: "An investigation of the ferment activity of the rabbit's vitreous" (1931); "Foreign substances injected into the vitreous of the rabbit," Ernest F. Krug, M.D., and George L. Rohdenburg, M.D. (1932); "Venous angioma of the retina, optic nerve, chiasm and brain," Ernest F. Krug, M.D., and Bernard Samuels, M.D. (1932); "A cyst of the posterior chamber with a microscopic study of the eye" (1937); "A case of tuberous sclerosis," Ernest F. Krug, M.D., and Francis A. Echlin, M.D. (1943).

In 1911 Dr. Krug was married to Miss Louise P. Hoffmann, who survives him. He also leaves two sons and three grandchildren.

Joseph H. Krug.

WILLIAM TARUN
(1870-1948)

Dr. William Tarun was graduated from the University of Maryland Medical College in the class of 1900. He began his special training at the Presbyterian Eye, Ear, and Throat Hospital almost at once under Dr. J. Frank Crouch in otology and later under Dr. Hiram Woods in ophthalmology. Dr. Woods shortly appointed Dr. Tarun chief of the Eye Clinic at the University Hospital and associate professor of ophthalmology and otology which position he held until Dr. Woods retired from the university.

In his earlier years of practice, Dr. Tarun had a large following in both otology and ophthalmology but later limited his practice to ophthalmology. With his keen mind and excellent training he soon became one of the leading ophthalmologists of Baltimore.

He was a member of the American Medical Association, the American College of Surgeons, the Medical and Chirurgical Faculty of the State of Maryland, and the American Ophthalmological Society to which he was elected in 1917 and whose meetings he always attended.

His original contributions were not numerous but he was active in the discussion of the papers presented. His hobbies were golf and gardening in both of which he excelled.

Dr. Tarun was an able physician, a good citizen, a Christian gentleman, and a most genial companion. His relationships to his colleagues were always characterized by the highest ethical standards. His passing followed a distinguished career of work well done, and his memory will long live in the hearts of his many friends and patients.

Clyde A. Clapp.

ERVIN TÖRÖK
(1877-1947)

By the death of Ervin Török, ophthalmology has lost an accomplished surgeon

and a man of attractive personality. Dr. Török was a native of Hungary, where he was graduated from the University of Budapest and received his doctor's degree in 1899. He obtained his preliminary education in ophthalmology at the University Clinic of Schulek in Budapest. After several years of postgraduate training with Grosz and Blaskovics in Budapest and with Hirschberg in Berlin, he arrived in the United States, in 1905, with a letter of introduction to Dr. Herman Knapp. He then became resident and a member of the staff at the New York Ophthalmic and Aural Institute where he inaugurated a tuberculin clinic and was one of the first to use this method of treatment in this country. He was a successful teacher in the postgraduate course of instruction which was then being given at that institution. He became full surgeon in 1913, when the hospital moved to 57th Street and its name was changed to the Herman Knapp Memorial Eye Hospital. He resigned as surgeon, in 1927, to become professor of ophthalmology at the New York Polyclinic Hospital.

In 1912, Dr. Török was appointed ophthalmologist at the Beth Israel Hospital in New York City; he organized the department of ophthalmology at this rapidly growing hospital and remained its chief for 25 years, until his resignation in 1938. It was here that he showed his ability as an organizer and capable administrator.

His other hospital affiliations included the Beekman Street Hospital and several institutions in Westchester County. His excellent clinical knowledge associated with an unusually clear and logical approach to ophthalmic problems won for him a very active field as a consultant for several of the larger accident insurance companies and as expert witness in medico-legal claims.

He became a member of the American Ophthalmological Society in 1912.

Dr. Török published some excellent papers, mostly on surgical subjects, and he was the author, together with Dr. Gerald H. Grout, of "Surgery of the Eye: A Handbook for Students and Practitioners," which was published in English in 1913; a second edition appeared in 1925, and was translated into Spanish. The book describes the surgical technique of the Blaskovics clinic.

A sound and resourceful surgeon, his skill in operating was striking. He was one of the first in this country to perform the scleral resection (Müller's operation) for retinal detachment in high myopia. He also modified the method of forceps intracapsular extraction by grasping the anterior capsule of the lens with a blunt forceps and then extracting the lens by traction and by exerting pressure according to the usual von Graefe procedure.

He was a man of attractive presence and of an exceptionally charming personality. Always courteous, never ruffled or impatient, his tender sympathy endeared him to his patients by whom, and by his many colleagues, his passing will be greatly deplored. He is survived by his wife, who was Louise B. Felter.

Arnold Knapp.

CORRESPONDENCE

Dr. van Heuven replies

Editor,
American Journal of Ophthalmology:

In reply to the correspondence on page 484 of volume 31, April, 1948, American Journal of Ophthalmology, I want to state that I take no responsibility for the report of my lecture on "Retinal Detachment," held at Cleveland's Ophthalmological Club in January, 1947. Further:

That I was dismissed from lecturing at the Utrecht University by the Germans on Monday, April 12, 1943, and, after the liberation of Holland, was restored, in 1945, by Royal Appointment;

That I never secretly subscribed to the Nazi organization of physicians;

That indeed two scientific papers from my hand appeared in German scientific journals; the copy of these, however, had left my house before the outbreak of the war;

That together with all patriotic colleagues I resigned my membership of the Dutch Medical Association during the war, and that after the liberation I have never applied for membership again on account of disagreement with their leaders (I shared this view with several distinguished colleagues);

That I still am a member of various scientific Dutch societies. I enclose translation of a statement of the secretary of the Dutch Ophthalmological Society that my resignation of membership had nothing to do with politics or political dispositions.

During the war I was a regular member of the Dutch Medical Underground sharing all their activities and being penalized for it by the Germans. Besides I played an active roll in the Fighting Underground. I enclose a statement from my direct superior as to these, my activities.

I regret that a young oculist, whom I only met once or twice and who has no personal knowledge of my affairs, has badly confused gossip and gospel and made himself the speaking trumpet of others.

(Signed) J. Alexander van Heuven,
New Haven, Connecticut.

STATEMENT FROM DR. ROELOFS

I, the undersigned, Dr. C. Otto Roelofs, secretary of the Dutch Ophthalmological Society, declare herewith that the reason why Dr. J. A. van Heuven, ophthalmologist at Utrecht, decided to resign his membership of this Society in October, 1945, had *nothing* to do with politics or political dispositions.

(Signed) C. Otto Roelofs,
Amsterdam, Holland.

STATEMENT FROM UNDERGROUND SUPERIOR

During the occupation there was in my house a center for the food supply and armament of the underground forces. For many years I knew Dr. van Heuven as a patient and when I approached him with the question whether he would dare to do something on behalf of the underground work he did not hesitate for a moment and at once consented.

We all trusted him fully; right from the beginning he was in perfect knowledge of everything which happened at my house. He took an active part in the food supply of the underground movement and had to do many jobs which were most unfamiliar to him, paid our secret caterers, and was present at our daily conferences.

When the commander of the first Division, Leo Berk, was shot and we were unable to find him, Dr. van Heuven searched all the hospitals as a doctor to find Berk and did not even hesitate to penetrate for that purpose into the St. Anthony Hospital which was entirely occupied by the Germans. In identifying men who were murdered by the Huns he has rendered great services to us.

We were very painfully struck by the fact that, after the liberation, various gossip was told about Dr. van Heuven, while we knew for certain that this man was politically perfectly trustworthy.

I am always willing to provide any further explanation wanted.

(Signed) W. J. M. Bordewijk,
Utrecht, Holland.

PREDILECTION OF LEFT EYES FOR GLAUCOMA

Editor,
American Journal of Ophthalmology:

In the October, 1947, number of the JOURNAL, Holst published a statistical study of glaucoma in which he shows the incidence of glaucoma to be higher in the left eye. Ascher, one of the leading experts of

ocular hemodynamics, explains for this fact in the Correspondence column of the February, 1948, issue of the JOURNAL.

I think that it is only possible to decide a question of such importance on the basis of a large number of cases. In 1935 I published in *Klinische Monatsblätter für Augenheilkunde* the most extensive statistics of glaucoma based on 3,214 cases of the Budapest University Ophthalmic Clinic. In these statistics the incidence of occurrence in the right or in the left eye was not taken into account. Holst's publication inspired my revision of the 1935 publication completing it with the material from the Eye Department of the Jewish Community Hospital in Budapest.

I have found monocular glaucoma in 669 cases. Bilateral glaucoma in which that of one eye was absolute occurred in 761 cases. Of the monocular cases, 359 occurred in the right eye and 310 in the left. Of the bilateral cases in which absolute glaucoma was present in one eye, 363 occurred in the right eye and 398 in the left.

Consequently it cannot be stated that, as regarding glaucoma, the left eye would be in a less advantageous position.

(Signed) P. Weinstein,
Budapest, Hungary.

BOOK REVIEWS

NEUROLOGY OF THE OCULAR MUSCLES. By David G. Cogan, M.D. Springfield, Illinois, Charles C Thomas, 1948. Clothbound, 229 pages, 121 illustrations. Price, $6.00.

In his preface, Dr. Cogan finds himself ". . . in the ambiguous position of simplifying in the interest of lucidity and yet being critical of simplification in such a complex field as the ocular motor system." He has succeeded extremely well in attaining his goal and has done it in such a pleasing style that one fails to hear the wheels turn.

The chief disappointment, if there be one, is in the brevity of the book. Upon finishing it, the reader is left with the definite impression that Dr. Cogan had much more to say, but hesitated to do so for fear of making statements which might later prove to be erroneous. The desire of the student is always for a pedagogic presentation and there is comparatively little pedagogy in the book.

The practicing ophthalmologist will find much of interest and the neurologist even more. The first section of the book is concerned with the anatomy and physiology of the ocular muscles. The next section is on the anatomy of the cranial nerve supply. A third section is devoted to supranuclear connections of the ocular motor system. The last two sections deal with the pupil and nystagmus respectively.

Two points make the book extremely worthwhile to all who are even remotely interested in the neurology of the ocular muscles. These are: first, the superb illustrations and, second, the very comprehensive bibliography containing 825 references in many languages. The only fault, in the mind of the reviewer, is a very small one. It is in the use of the term "ductions" rather than the more preferred one of "vergences" —at least if one follows the ideal of Lancaster.

Every ophthalmologist is sure to find the book a valuable addition to his library and one which will doubtless whet his appetite for more knowledge along the same lines. We can only hope that the second edition will be twice as thick as the first.

Richard G. Scobee.

TRANSACTIONS OF THE SOCIÉTÉ BELGE D'OPHTHALMOLOGIE. Meeting of December 1, 1946, pp. 1-174.

This volume of the Transactions of the Société Belge d'Ophthalmologie brings the membership lists of the society, the minutes of the business meeting, the reports of the scientific session, and the obituaries of Dr.

H. Coppez, Dr. L. Leplat, and Dr. J. Moorkens. At the scientific meeting 20 papers and case histories were presented.

L. Weekers and R. Weekers discussed nonperforating cyclodiathermy. M. and J. Wibo combined iridectomy with a preceding coagulating cyclodiathermy, using the pyrometric electrode. They reported on 10 patients in whom the operation was a success.

P. Huwart reported his striking success with sulfosine (sulfur in oil) in otherwise refractory cases of ocular syphilis. F. Roussel presented his studies on the intraocular application of penicillin in discussing his animal experiments and three clinical cases. He recommends the injection of penicillin into the anterior chamber in severe intraocular infection. Injections into the vitreous are extremely dangerous and should be used only as a last resource in cases of endophthalmitis.

R. Rubrecht's surgical treatment of active corneal lesions by partial excision of the diseased corneal tissue and superficial conjunctival flaps met with some opposition as in previous publications.

Among rare case histories was one by Elise Soil who removed a door handle from the bottom of an orbit without injury to the eyeball. De Walsche presented a case of an extremely large corneal papilloepithelioma. F. Bonhomme described the present technique in the fitting of contact lenses and indications for prescribing them. L. Alearts found syphilitic reagins in the anterior chamber and outlined their diagnostic possibilities in this preliminary report. He also presented a patient with larvae on Descemet's membrane.

Other presentations were made by M. Appelmans and N. Lanoy on superficial punctate keratitis in onchocerciasis and by Jean Coppez on nummular keratitis.

Alice R. Deutsch.

TRANSACTIONS OF THE OPHTHALMOLOGICAL SOCIETY AT PARIS AND OF THE OPHTHALMOLOGICAL SOCIETIES OF THE EAST, OF LYON, AND OF THE WEST. Meetings of March-April, 1947. No. 2, pp. 120-294.

This issue brings a résumé of the meetings of the Ophthalmological Society at Paris on March 15, 1947, and April 19, 1947, and of the Ophthalmological Society of the East on March 16, 1947. It is divided into three parts. Each part gives a report of the scientific sessions of one day.

The first part contains 10 papers about various topics. Three papers deal with the experiences with penicillin. Dubois-Poulsen and Vouters describe its effect in metastatic uveitis; Guilloumot and J. P. Baillart have used this drug in orbital osteoperiostitis; Carlet-Soulages summarizes his experiences with penicillin on gonococcus conjunctivitis when he was stationed in the Far East with the French expeditionary forces.

A. Dubois-Poulsen's and A. Rozan's graphic study with Howe's ergograph on the ciliary muscle and the relationship of the objective signs of fatigue of this muscle to asthenopic complaints are very interesting. So are M. R. Onfray's presentation of Dvorine's color plates and Peron's and Desvigne's case report of a periarteritis nodosa, localized on the arteries of the conjunctiva.

The second part contains the minutes of the business meeting and 10 papers of varying importance. P. Halbron, F. Lepage, Leconte, and H. Mowas report on the substitution of penicillin for silver nitrate in the prophylactic treatment of the newborn, an especially interesting topic because of similar research work in this country. E. Haas discusses the characteristics of gonococcic iridocyclitis, its specific reactions and treatment. P. Michaud emphasizes the importance of mountain air and rest in ocular tuberculosis. There were also case reports on

chorioretinitis and periphlebitis in hereditary syphilis; of uveitis in leptospirosis; and of a choroidal angioma complicated by intractable glaucoma which followed an injection of tetanus antitoxin.

A symposium on the essential shrinkage of the conjunctiva was the highlight of the session on March 16, 1947. Beauvieux delivered the lecture which dealt with the clinical description, pathology, etiology, differential diagnosis, and treatment of this comparatively rare disease.

The topics of the following 17 papers were many and their presentation and subjects of varying interest. A. Bronner and P. Pouliquen gave another lecture on penicillin therapy with especial emphasis on the technique of subconjunctival, anterior chamber, and vitreous injections in otherwise hopeless external eye infections.

Mathieu describes an original modification of intracapsular cataract extraction of an intumescent lens wherein a micropuncture to decrease the tautness of the capsule precedes the extraction. R. Bruckner combines a case report on toxoplasmosis with a detailed study of this disease. The origin and the manifestation of uveal carcinoma were discussed by J. Nordmann and G. Hoerner, and sarcoma of the choroid by J. C. Poirot.

A detailed case report of a nevocarcinoma of the lacrimal sac was given by Gallois and Michel-Gallois. Two cases of perforating scleromalacia were described by C. Henry and B. Algan. Beau, Thomas, and Bénichaux report a case of bilateral pulsating exophthalmus and explain the pathology and the treatment, which consisted in the ligature of the right common carotid. The pathogenesis of the ocular structures in methyl-alcohol intoxication was the topic of Rohr's paper.

The closing paper was read by Christian Henry. He reported on his research concerning the diastolic hypotension of the central retinal artery in fatal coma. He stresses the importance of the diastolic retinal pressure on the outcome of every kind of coma. A comparatively high diastolic pressure is of favorable prognosis as it is the sign of a cellular edema which is reversible. A decreasing diastolic pressure indicates cerebral degeneration which continues unrelentingly toward death. Even so the toxic cause should be removed. Alice R. Deutsch.

LA PROPHYLAXIE DE LA CÉCITÉ EN ROUMANIE (1940-1947). By Dr. Nicolas Blatt. București, Imprimeria Națională, 1947.

In this 68-page monograph, Blatt discusses the problem of blindness in Roumania. He briefly displays statistics, considers the causes of blindness, and gives a critical review of such social measures as the laws that apply to vaccination against smallpox, the application of the Credé procedure, and industrial accidents, schools for amblyopes, pensions for the blind, eugenics, and social insurance.

F. H. Haessler.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

1

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Crosby, E. C., and Henderson, J. W. **The mammalian mid-brain and isthmus regions. Part II. Fiber connections of the superior colliculus. B. pathways concerned in automatic eye movements.** J. Comp. Neurol. 88:53-92, Feb., 1948.

The paper deals primarily with the pathways underlying certain automatic eye movements. The studies were made on the midbrain of the monkey. The authors stimulated selected areas of the exposed brain by a minimal faradic current and noted the eye movements produced.

VEGETATIVE PHYSIOLOGY, BIOCHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Ajo, Aarni. **On the refractive index of the retina.** Acta Physiol. Scandinav. 13: 130-149, 1947.

The author's measurements were made on the retinas of cows, newly born calves, pigs, and horses. The refractive indices for these animals are reported. The values were higher in the light adapted retinas since the visual purple exudes water when bleached.

Francis M. Crage.

Barany, E. H. **The action of atropine, homatropine, eserine, and prostigmine on the osmotic pressure of the aqueous humour.** Acta Physiol. Scandinav. 13:95-102, 1947.

Aqueous solutions of these drugs were instilled into the conjunctival sacs of male albino rabbits. Atropine and homatropine showed a tendency to lower the osmotic pressure of the aqueous. Eserine and prostigmine caused a reduction in the osmotic pressure in previously untreated eyes. An initial phase of rise in intraocular pressure and intense iris hyperemia was followed by a hypotonic phase in which the tension was lowered and there was increased protein content and visible flare in the aqueous. The protein increase and flare were attributed to the increase of capillary permeability. In the previously treated eyes these miotic drugs produced none of these changes except a moderate reduction in the intraocular pressure. In these eyes, habituated to eserine and prostigmine, the osmotic pressure remained practically unchanged. Increased capillary permeability

was considered as the probable cause for the decrease in the osmotic pressure.

Francis M. Crage.

Babudieri, B., and Grignolo, A. **Three new methods of micro-dosage of penicillin.** Reports of the Superior Institute of Health. V. 10, 1947.

The authors describe three new and simple methods for the biological micro-dosage of penicillin. These methods make it possible to assay the penicillin contained in a volume of 0.05 to 0.002 $cm.^3$ and are so sensitive as to detect as low an amount as 0.000004 O.U. of the antibiotic, equal to only 2×10^{-12} gr. of pure sodium salt of penicillin.

Eugene M. Blake.

Bachi, S. and Borsello, G. **The effect of olfactory stimulation upon retinal arterial pressure.** Rassegna ital. d'ottal. 16:418-432, Nov.-Dec., 1947.

The author studied the retinal arterial pressure following the use of various types of odorous stimulants and found that purely olfactory stimulants do not affect the pressure at all, while those substances which act upon the trigeminal nerve elevated the retinal pressure in a high percentage of cases. No effect was observed in anosmic individuals. This would indicate that there is no synergistic action between the olfactory and the trigeminal nerves as a result of olfactory stimulation by odors. Eugene M. Blake.

Friedenwald, J. S., and Woods, A. C. **Introduction and outline to the studies on the physiology, biochemistry, and cytopathology of the cornea in relation to injury by mustard gas and allied toxic agents.** By members of the staff of the Wilmer Institute. Bull. Johns Hopkins Hosp. 82:81-101, Feb., 1948.

The preliminary studies showed that intracorneal injection caused more severe damage than did dropping the toxins on the cornea. Some products cause damage only when used in massive concentrations and others will cause damage in small doses. The recognizable clinical and histologic changes which follow chemical damage of the tissue are only remotely and indirectly connected with the initial chemical injury. Among many facts discovered; the excellent tolerance of the ocular tissues for di-isopropyl-fluorophosphate is worthy of special note. In mustard injury to the cornea it was felt that antibacterial agents could be given without danger of increasing the injury and would protect the eye from secondary infections. An effective ointment base in which BAL could be incorporated was found. Mustard was found to penetrate the cornea more rapidly than it did the skin. All compounds which were found most effective as antidotes to mustard contain sulfhydryl groups whose acid dissociation is below pH 7. Threshold doses of mustard cause transitory inhibition of mitotic activity in corneal epithelium. Glutathione in the intact cell is relatively inaccessible to mustard. The inhibition of mitosis is the most sensitive index of mustard injury. Studies on cohesion of epithelium with the stroma were undertaken because a loosening of the corneal epithelium is one of the earliest pathologic findings. Studies on corneal metabolism show that mustard causes a diminished oxygen consumption. There is a close metabolic interaction between the epithelium and stroma especially in the utilization of glucose and lactate. (1 table.)

H. C. Weinberg.

Friedenwald, J. S. **Summary and some possible interpretations.** Bull. Johns Hopkins Hosp. 82:326-337, Feb., 1948.

In this paper the effects of mustard on corneal metabolism and the possible rela-

tion of these effects to the loosening of the corneal epithelium are discussed.

The metabolic interaction of corneal epithelium and stroma is reviewed, and it is emphasized that the epithelium normally assists the stroma in maintaining a supply of carriers for energy-rich phosphate transfers. There appears to be a special hydrogen transport system for the utilization of the stroma lactate independent of that concerned with the utilization of endogenous lactate in the epithelium. Pyruvate transfer and utilization remains unaffected after mustard injury to the cornea. Lactate and serine transfer and utilization is disturbed after mustard injury. The metabolic factors involved in lactate utilization are discussed.

The cohesive system is highly complex and there is a correlation between the loosening of the epithelium after mustard injury and the utilization of lactate from the stroma. Mustard causes loosening of the tissue under aerobic conditions but not under anaerobic. The boundary of epithelium and stroma may contain components of the hydrogen transport system for the utilization of stroma lactate. The oxidation of some of these components destroys some of the cohesive forces. Mustard injury appears to affect the nuclear boundary early.

H. C. Weinberg.

Friedenwald, J. S. **Note on karyolysis of the corneal stroma cells.** Bull. Johns Hopkins Hosp. 82:178-181, Feb., 1948.

A method is described for preparing the cornea for the study of its stroma.

Extra fluid must enter the stroma to enable the nuclei to swell. This is obtained when the epithelial and endothelial barriers are injured. After exposure to mustard and other injurious agents the nuclear boundary becomes more fragile. The nuclei burst after exposure if incubated ten hours at 37 degrees C. Large doses of mustard or nitrogen mustard cause pycnosis of all types of corneal cells. (4 figures.) H. C. Weinberg.

Friedenwald, J. S., and Buschke, W. **Nuclear fragmentation produced by mustard and nitrogen mustards in the corneal epithelium.** Bull. Johns Hopkins Hosp. 82:161-177, Feb., 1948.

Mustards and nitrogen mustards applied to the cornea cause a small percentage of cells in the basal layer to die by nuclear fragmentation. Pathologic mitosis occurs which is similar to the prophase and metaphase of normal mitosis. Lowered temperatures and anoxia cause inhibition of normal mitosis and inhibition of nuclear fragmentation of corneal epithelium exposed to mustard. Immersion of the tissue in Ringer's solution suppresses nuclear fragmentation and mitosis. Cells injured by mustard in the premitosis stage go on to nuclear fragmentation which is a pathologic mitosis. Because of injury the cells can not go back to the resting state. Exposure to hypotonic solution, solutions of low pH, and to nitrogen mustard dissolved in hypotonic solutions of low pH, causes an increase in the number of cells susceptible to this injury of nuclear fragmentation. (2 figures.) H. C. Weinberg

Friedenwald, J. S., Buschke, W., Scholz, R. O., Snell, A., and Moses, S. G. **Primary reaction of mustard with the corneal epithelium.** Bull. Johns Hopkins Hosp. 82: 102-120, Feb., 1948.

The method used for exposing beef eyes to mustard vapor is described. There is an uptake of 3.3 micrograms of mustard per square cm. per minute and 8 percent of the mustard absorbed disappears per minute. The effective dose that produces minimal mitotic inhibition of rat cornea epithelium is 2.5×10^{-10} micrograms per cell. In the intact cell, glutathione is rel-

atively inaccessible to reaction with mustard.

A method is described to determine the electrical resistance of the cornea which is used as an index to the integrity of the cell membrane. Exposure to mustard does not result in any primary injury to the corneal epithelial cell membrane that is detectable by this method. Histologic studies show that tissue contaminated with mustard vapor has an increase in acidophilia, and that the region of the nuclear membrane and the basement membrane may be among the sites of primary mustard reaction. (8 figures, 5 tables.) H. C. Weinberg.

Friedenwald, J. S., Buschke, W., and Scholz, R. O. **Effects of mustard and nitrogen mustard on mitotic and wound healing activities of the corneal epithelium.** Bull. Johns Hopkins Hosp., 82:148-160, Feb., 1948.

Slow inhibition of mitosis in the corneal epithelium of the rat exposed to mustard and nitrogen mustards is produced by doses too small to cause recognizable signs and symptoms of damage. Recovery from this inhibition occurs spontaneously but the inhibition can be made to last for several weeks by repeated instillations of the poison. During prolonged inhibition of mitosis the basal cells of the corneal epithelium increase in size.

Wounds of the corneal epithelium heal at a normal rate even in the absence of mitotic activity. Large doses of the toxic agent may slow down the whole mitotic cycle. Cells that are in mitosis at the time of exposure to the toxin in moderate doses will complete their division normally. Systemic administration of the poisons in MLD 50 dosage causes an inhibition of mitosis in corneal epithelium, bone marrow, and in intestinal mucosa. Inhibition of mitosis represents the lowest threshold effect so far recognized in the reaction of tissues to these poisons. (4 figures, 3 tables.)

H. C. Weinberg.

Friedenwald, J. S., Buschke, W., and Moses, S. G. **Comparison of the effects of mustard, ultraviolet and X-radiation, and colchicine on the cornea.** Bull. Johns Hopkins Hosp. 82:312-325, Feb., 1948.

A comparison of the effect on the cornea of mustard, ultraviolet and X-radiation and colchicine is given because of the similar effects of these substances in causing erythema, vesiculation, and ulceration of the skin. The administration of mustard causes the same effect on the viscera as that produced by exposure to any of the penetrating radiations. The inhibition of mitosis by ultraviolet and mustard show similar properties with those factors which cause nuclear fragmentation. In cells in which mitosis has been markedly inhibited by X-rays there was no nuclear fragmentation.

Loosening of corneal epithelium and the increased NPN content of the cornea after exposure to ultraviolet and mustard show no correlation with nuclear fragmentation or inhibition of a mitosis. The mechanism of loosening of the epithelium produced by colchicine may be different from that induced by mustard because of the production of increased NPN in the latter. (2 figures, 5 tables.)

H. C. Weinberg.

Friedenwald, J. S., and Moses, S. G. **A mechanical device for the extraction of soluble compounds from the cornea and other tough tissues.** Bull. Johns Hopkins Hosp. 82:350-352, Feb., 1948.

By simply squeezing a tissue that is placed in a vessel the extraction of soluble compounds is obtained as well as by the squeezing and shearing manipulation used in the grinding of the tissue in a mortar. A specially fitted plunger is at-

tached to a lever which reduces the amount of energy needed for this process. The device can be attached to a motor and six samples can be extracted simultaneously. (2 figures.) H. C. Weinberg.

Herrmann, Heinz. **The effect of histamine and related substances on the cohesion of the corneal epithelium.** Bull. Johns Hopkins Hosp. 82:208-212, Feb., 1948.

Histamine in concentrations of 5 to 10×10^{-6} M. causes a loosening of the corneal epithelium. Chemically related natural bases such as histidine and tyramine have no such effect in concentrations up to 1×10^{-2} M. Adrenalin, ephedrine, and physostigmine cause a loosening of the corneal epithelium in concentrations of the order of 10^{-3} M.

This histamine effect develops slowly after some hours of incubation. The loosening produced by histamine occurs at the boundary between the basal epithelial cell layer and the overlying epithelium, not between the basal cells and the underlying stroma as is the case with other agents which were studied. (3 tables.) H. C. Weinberg.

Herrmann, H., and Hickman, F. H. **Loosening of the corneal epithelium after exposure to mustard.** Bull. Johns Hopkins Hosp. 82:213-224, Feb., 1948.

In beef eyes a loss of cohesion between the corneal epithelium and the stroma is a prominent feature of mustard injury. This is not due to an inflammatory reaction nor is it a manifestation of death of the epithelial cells. This occurs before nuclear fragmentation. Anoxia and lowered temperatures aid tissues to recover to some degree from mustard injury. Exposure to adequate dosage of mustard causes corneal epithelium to slough with edema of the corneal stroma. The capillary endothelium of the conjunctiva likewise is affected. Petechial hemorrhages with packing of the red cells that cause obstruction to the circulation with a loss of plasma into the tissue are further manifestations of tissue damage.

Three phases of mustard injury are, the primary chemical reaction of mustard and tissue components which takes a few minutes, a second symptom-free period during which neither physiologic nor histopathologic changes are recognized and which may last up to twelve hours and the stage of recognizable symptoms of damage to the tissue. The pathologic mechanism of mustard injury suggests abnormal utilization of oxidative energy or the inhibition of some normally balancing reductive process. (8 tables.)
H. C. Weinberg.

Herrmann, H., and Hickman, F. H. **The adhesion of epithelium to stroma in the cornea.** Bull. Johns Hopkins Hosp. 82:182-207, Feb., 1948.

A simple mechanical device is described for the quantitative estimation of the adhesion of the epithelium to the corneal stroma. Loosening of the corneal epithelium occurs after exposure to temperatures over 45 degrees C. or to freezing with subsequent incubation. Exposure to proteolytic enzymes also causes a loosening of the epithelium. The cohesion of the tissue is diminished on exposure to high concentrations of calcium chloride and sodium thiocyanate. No loosening of the epithelium was observed on altering the pH from 3 to 9.

No evidence was found to demonstrate the presence of an intercellular cement in the cornea. The adhesive forces may originate in the attraction of non-polar hydrocarbon residues in the boundary surface. The coherence surface may be a protein lipoid multilayer. The phenomenon of epithelial loosening in the cornea

is somewhat analogous to vesication in the skin. (10 tables, 6 figures.)

H. C. Weinberg.

Herrmann, H., and Hickman, F. H. **Exploratory studies on corneal metabolism.** Bull. Johns Hopkins Hosp. 82:225-250, Feb., 1948.

The glycogen content of the epithelium of the beef cornea is like that of muscle, 1 percent. The phosphate fraction is the same as in the intestinal mucosa. The adenosine phosphate content is the same as in muscle also. The lactic acid content of epithelium is seven times as high as that of the blood. The glycogen content of the epithelium decreases 25 micrograms per hour by phosphorolysis and is not inhibited by iodoacetate. In the supravital cornea 1000 micrograms of glucose is metabolized in twelve hours but the process is completely inhibited by the addition of iodoacetate and is partially inhibited by fluoride. As long as glucose is supplied to the cornea the carbohydrate breakdown suffices for the maintenance of oxidations. In the excised cornea glycogen and lactate together do not provide sufficient substrate for the saturation of the oxidative mechanism. Lactate production from carbohydrate precursors takes place at a comparable rate in both the epithelium and in the stroma. Enzymatic oxidation is restricted to the epithelium, whereas the metabolism of the separated stroma is essentially anaerobic. (14 tables.)

H. C. Weinberg.

Herrmann, H., and Hickman, F. H. **The effect of mustard on some metabolic processes in the cornea.** Bull. Johns Hopkins Hosp. 82:251-259, Feb., 1948.

Mustard injury to beef cornea inhibits utilization of lactate and causes a decrease in the oxygen uptake which is equivalent to that required for the complete combustion of the utilized lactate. The decline in oxygen uptake lags behind the decline in lactate consumption by one or more hours. The metabolic change preceeds the loosening of the corneal epithelium and is caused by the same dosage of mustard. Under anaerobiosis the loosening of corneal epithelium does not occur. After incubation of 15 hours the normal corneal lactate reservoir is depleted but the oxygen uptake rises instead of declining as it does after the utilization of lactate is inhibited by the mustard. Glucose and glycogen are utilized at a normal rate in mustard-treated corneas and their utilization is not associated with an extra accumulation of lactate except under anaerobiosis. In the cornea there is a special hydrogen transport system for a major part of the lactate oxidation which is damaged by mustard. A component of the system becomes oxidized and causes a loosening of the epithelium. (6 tables.)

H. C. Weinberg.

Herrmann, H., and Hickman, F. H. **Further experiments on corneal metabolism in respect to glucose and lactic acid.** Bull. Johns Hopkins Hosp. 82:260-272, Feb., 1948.

Beef corneal epithelium consumes the lactate produced by the stroma and the rate of glucolysis in the stroma is influenced by the epithelium. The corneal epithelium exhibits a typical Pasteur effect in that glycogen is consumed more rapidly under anaerobic than under aerobic conditions. One quarter of the carbohydrate requirement of the epithelium is furnished in the form of lactate by the stroma.

Mustard injury causes a loss of cohesion between stroma and epithelium. The metabolic interaction between stroma and epithelium is connected with the mechanism for maintenance of tissue cohesion. Injury to this mechanism results in the loss of cohesion and in the loss of meta-

bolic interactions. The mechanism by which the epithelium consumes its endogenous stores of lactate is less susceptible to mustard injury than is the mechanism by which it acquires and consumes the lactate from the stroma. (10 tables.)

H. C. Weinberg.

Herrmann, H., and Hickman, F. H. **The consumption of pyruvate, acetoin, acetate, and butyrate by the cornea.** Bull. Johns Hopkins Hosp. 82:273-286, Feb., 1948.

Pyruvate is consumed very rapidly by normal corneal tissue but very slowly by denuded corneal stroma. Anaerobiosis, or exposure to mustard, iodoacetate, fluoride or arsenite do not influence the consumption of pyruvate by the whole cornea. Half of the pyruvate can be recovered as lactate. One mole of carbon dioxide can be recovered for each four moles of pyruvate lost. Acetoin is consumed by the cornea during pyruvate consumption and is not inhibited by mustard. The very slow consumption of butyrate by the cornea is inhibited by exposure to mustard. (9 tables.)

H. C. Weinberg.

Herman, H., and Hickman, F. H. **The utilization of ribose and other pentoses by the cornea.** Bull. Johns Hopkins Hosp. 82:287-294, Feb., 1948.

Beef cornea utilizes d-ribose and d-xylose one-tenth as fast as it utilizes glucose and one-half as fast as it utilizes lactate and glycogen. D-lyxose is used one-half times as fast as is d-ribose. There is no utilization of d-arabinose. An unknown intermediary compound is formed in the utilization of ribose. The breakdown of ribose in the cornea may involve phosphorylation.

Utilization of ribose is markedly inhibited by iodoacetate and fluoride, but is only slightly inhibited by mustard. In the presence of ribose the utilization of glycogen and of the lactate depot in the cornea is suppressed. (7 tables.)

H. C. Weinberg.

Herrmann, H., and Moses, S. G. **Studies on non-protein nitrogen in the cornea.** Bull. Johns Hopkins Hosp. 82: 295-311, Feb., 1948.

The nonprotein nitrogen content of the beef cornea on prolonged incubation is quite constant. Exposure of a cornea to mustard causes a rise in extractable NPN from its protein. Six micrograms of mustard are taken up after ten minutes exposure by each square cm. of cornea. This is approximately 70 moles of nitrogen for each mole of mustard bound and approximately equal to the available SH groups to nitrogen in some proteins.

The oxidation of some proteins that react with mustard may increase their susceptibility to hydrolysis and may account for loosening of corneal epithelium after exposure to mustard. The NPN is increased before the loosening of epithelium appears. Anaerobic incubation of corneas exposed to mustard protects them against loss of cohesion.

Serine and lactate are normally consumed by the intact cornea but not by the denuded stroma. After exposure to mustard the concentration of serine rises in the stroma and falls in the epithelium. After injection of serine into the stroma and subsequent incubation the concentration in the epithelium was found to rise rapidly and to reach a level far higher than in the stroma. (11 tables.)

H. C. Weinberg.

Hughes, W. F., Jr. **The tolerance of rabbit cornea for various chemical substances.** Bull. Johns Hopkins Hosp. 82: 338-349, Feb., 1948.

This paper consists of one large table in which data are compiled on the reac-

tions in 304 rabbit eyes when various chemicals are injected in varied concentrations. The chemicals include solvents, protein precipitating agents, mucoid dissolving agents, metals, arsenicals, oxidizing agents, quinones and hydroquinones, reducing agents, sulfhydril binding agents and dyes. (1 table.)

H. C. Weinberg.

Maumenee, A. E., and Scholz, R. O. **The histopathology of the ocular lesions produced by the sulfur and nitrogen mustards.** Bull. Johns Hopkins Hosp. 82:121-147, Feb., 1948.

The conjunctiva of rabbits' eyes, when injured by mustard, shows edema of the stroma with a necrosis of the epithelium. In the capillaries there is a loss of endothelium, packing of the red cells and occlusion of the lumen. The corneal epithelium shows fragmentation of nuclei of the basal layer of cells which later become detached from the stroma, show pycnosis of the nuclei and slough.

Injury to the stroma is manifested early by edema of the posterior portion. The nuclei become pycnotic and may burst eight hours after injury. The polymorphonuclear leucocytes appear within twenty-four hours. The first evidence of damage to the corneal endothelium is a sloughing of the cells. Iris damage occurs especially after exposure to HN_2 and is first evidenced by a loss of the capillary endothelium with a packing of red cells and occlusion of the lumen. Repair of the conjunctival epithelium is accomplished by migration of cells from uninjured adjacent epithelium. Macrophages remove the debris. Occasionally "pearly white" avascular areas are observed as well as areas with new capillaries. The corneal epithelium is repaired by a sliding of adjacent uninjured corneal epithelial cells. In the corneal stroma polymorphonuclear leucocytes remove the debris and large macrophages are transformed into keratoblasts. Scarring with blood vessels appears if the injury is severe. The repair of the endothelium begins ten days after injury by a migration of uninjured cells. Repair of the iris is essentially the same as that of conjunctiva. (26 figures, 1 graph.) H. C. Weinberg.

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Angius, Tullio. **Research concerning accommodation.** Rassegna ital. d'ottal. 16:460-466, Nov.-Dec., 1947.

Angius shows that the accommodative power varies with somatic conditions and with age. As much as three diopters difference may be found in normal individuals. His studies of the 19 to 26-year age group show the same curve as that of Duane. A plea is made for more exact study of the accommodation and for more precise instruments of investigation.

Eugene M. Blake.

Belmonte Gonzales, N. **Observations on corneal astigmatism.** Arch. Soc. oftal. hispano-am. 7:1169-1172, Dec., 1947.

In fitting contact lenses Belmonte was impressed with the fact that they usually correct the total astigmatism of the eye. This raises a question as to the existence of a lenticular astigmatism, to which the discrepancy between ophthalmometric data and the total astigmatism of the eye is usually attributed. The sources of error in ophthalmometric measurements are discussed, and it is suggested that an ophthalmometer without these defects could be constructed. In the meantime the author finds the bicylindric method of Marquez the most accurate means for determining the ocular astigmatism.

Ray K. Daily.

Blanchi, G. **A new explanation for the variation in refraction in diabetics.**

Rassegna ital. d'ottal. 16:433-440, Nov.-Dec., 1947.

The various theories to explain the sudden changes in refraction in patients with diabetes are reviewed. The author suggests a new explanation, namely an axial displacement of the lens, and shows by some rather complex formulas how it is possible for this to occur. Two cases of rapidly developing hypermetropia are reported. Eugene M. Blake.

Dascalopoulos, N. **Acquired inversed astigmatism.** Ann. d'ocul., 180:688-695, Nov., 1947.

Operations which alter the corneal curvature all produce an inverse corneal deformity. This occurs at the point of least thickness and in the direction of least resistance. Inverse astigmatism also occurs in myopia, glaucoma and hyperthyroidism and with chalazion and scleral keratitis. The corneal curvature basically depends upon the ocular tension, the pull of the extraocular muscles and the supporting structures, namely the orbit behind, and the lids anteriorly. Any condition which disturbs the equilibrium of these forces vertically or horizontally may produce inverse astigmatism. Chas. A. Bahn.

Hardy, L. H., Rand, G., and Rittler, M. C. **A screening test for defective red-green vision.** Arch. Ophth. 38:442-449, Oct., 1947.

The authors have selected 18 plates from the Pseudo-Isochromatic Plates for Testing Color Perception, compiled in 1940 by the American Optical Company. When these 18 plates are used under standard conditions of illumination, they serve as a satisfactory screening test for red-green defects. It is neither qualitative nor quantitative; that is, it does not classify the type of deficiency in red-green vision, or the degree of deficiency. No provision is made for detection of the rare forms of defective blue-yellow vision. Using these plates, an incorrect response to five or more plates indicates defective red-green vision.

John C. Long.

Latorre, S. **High transitory corneal astigmatism in a case of sphenoidal ethmoiditis.** Arch. Soc. oftal. hispano-am. 7:1009-1012, Oct., 1947.

In the course of an orbital cellulitis, an extension of an ethmoidal sinusitis, a nine-year-old child developed an astigmatism of 3.50 diopters. The astigmatism disappeared after recovery, indicating that it was caused by compression of the eyeball. Another patient could temporarily abolish a corneal astigmatism of four diopters by pressure of the upper lid against the cornea. Ray K. Daily.

Littwin, Charles. **Use of one contact lens in correction of high unilateral myopia.** Arch. Ophth. 38:259-260, Aug., 1947.

In a patient with 13 diopters of myopia in one eye and only one quarter diopter of myoptic astigmatism in the other fusion and comfort could be obtained by the use of iseikonic lenses only with the eyes in the primary position. When a contact lens was prescribed for the myopic eye, comfortable binocular vision could be obtained in all directions of gaze.

John C. Long.

Mathewson, W. R. **Rapid retinoscopy.** Med. Press 219:101-102, Feb. 4, 1948.

The author describes a rapid method of performing retinoscopy. It is a modification of a procedure described by Harrison Butler and the principal instruments are a Purvis Streak retinoscope and a Hamblin retinoscopy lens rack. The

work is done at a distance that is at slightly greater than one-half meter.

Francis M. Crage.

Matteucci, P., and Toselli, C. **The accommodation time in paralysis of the cervical sympathetic and in accommodative spasm.** Rassegna ital. d'ottal. 16:407-417, Nov.-Dec., 1947.

In the patients affected by Horner's syndrome the paralysis of the sympathetic did not modify the speed of accommodation nor the amplitude. Spasm of accommodation provoked a prolongation of this act, for distance or for near, or for both. Astigmatic and hyperopic eyes always showed an increased power of accommodation. Low grade myopes and emmetropes showed little variation in the accommodative time for near.

Eugene M. Blake.

Pacalin, G. **The diploscope in the prescription of glasses.** Ann. d'ocul. 180:696-701, Nov., 1947.

The diploscope of Remy has been much more widely adopted in France than elsewhere. It is based on the principle that a person looking through two apertures which correspond with the binocular line of fixation will see three horizontal letters if properly distanced and sized. They will be in their regular order and correctly placed if binocular vision is normal; but, if abnormal, the letters will either be doubled, omitted or improperly arranged. The diploscope is therefore used as a simulation test to educate binocular vision, verify the respective sizes of the retinal images in each eye, verify the accuracy of refractive corrections especially in anisometropia, to detect ocular motor and convergence disequilibrium and abnormal levelling of the two eyes. If convergence is insufficient or relative exophoria exists, crossed diplopia will result. With convergence excess or relative esophoria there is homonymous diplopia.

Chas. A. Bahn.

Radnót, Magda. **Data on the occurrence of calcification in the eye tissues.** Brit. J. Ophth. 32:47-54, Jan., 1948.

The zonular opacity seen in the region of the palpebral aperture as an opaque band is a calcified degeneration of the layers under the epithelium. It occurs as an occupational disease in hat makers and is caused by the deposition of rabbit hairs on the cornea. A second type is primary in otherwise healthy eyes and a third is secondary to ocular damage; the latter usually follows severe uveitis. In this report, 12 such cases of corneal calcification are presented in each of which there was also lime in other tissues of the eye. These deposits occurred in the lens, choroid, detached retina, optic nerve and in old chorioretinal scars. In some of them actual formation of bone was found. (14 figures.)

Morris Kaplan.

Ronchi, V. **Recent developments in the theory of form and color vision.** Arch. Soc. oftal. hispano-am. 7:959-1000, Oct., 1947.

This is a general review of physiologic optics, from the time of Rayleigh's investigations. The author's work on the resolution of visual images is based on the data obtained from the study of the resolution of photographic emulsions. He applies Hecht's photochemical theory to color vision as well as to form vision, by assuming that the impulses of form and color vision differ in frequency. He demonstrates the similarity between retinal physiology and the phenomena of photographic emulsions, points out the possibility of transformation of visual radiations into acoustic stimuli, and advances a unitarian theory of the mechanism of sensory functions.

Ray K. Daily.

Vila-Coro, A. **Fukala's method of treatment of high myopia.** Arch. Soc. oftal. hispano-am. 7:1013-1026, Oct., 1947.

Vila-Coro is an enthusiastic advocate of lens extraction for the arrest of progressive myopia. Discission in patients under 15 years of age, discission followed by a linear extraction in adults with transparent lenses, and intracapsular suction extraction in adults with opacities in the lens are the procedures advocated. The indications for the operation are progressive myopia of not less than ten diopters, and myopia in patients over 40 years of age who have incipient lenticular opacities. Vitreous, choroidal, or retinal hemorrhages are regarded as contraindications to surgery. Degenerative lesions which do not involve the macula do not contraindicate the operation. To arrest the progress of myopia, and to improve ocular nutrition, both eyes should be operated, with an interval of six to eight months between the operations.

Ray K. Daily.

5

DIAGNOSIS AND THERAPY

Azzolini, U., and Pascucci, F. **Streptomycin therapy in Reiter's infections.** Giorn. ital. di oftal. 1:14-22, Jan.-Feb., 1948.

Streptomycin was used in the treatment of three men afflicted with Reiter's disease of long duration. There was marked improvement in the urethral and conjunctival condition, but none in that of the joints. Francis P. Guida.

Dollfus, M. A., Barrois, P., and de Grénédan du Plessis. **Tissue therapy of Filatov.** Ann. d'ocul. 180:681-687, Nov., 1947.

The details of the Filatov treatment have been so repeatedly recently abstracted or described in this journal that the preparations of the placenta and its extracts, dead skin, cod liver oil, and details are here omitted. The author restates the conclusions of the article by Filatov and Verbitskaia in which the progress is measured in such small units as to be understood only by God, and from which one draws the conclusions that figures don't lie, but—. The authors report on two cases of retinal pigmentary degeneration treated by the Filatov method, one of which was possibly functionally improved. Six cases of high myopia were also treated without any appreciable improvement functionally or structurally. Chas. A. Bahn.

Dubois-Poulsen, A. **A new instrument in surgery of the face: the dermatome.** Ann. d'ocul. 180:664-671, Nov., 1947.

The dermatome of Padgett which was observed in action by the author during the recent war has been modified by him, making it smaller. This instrument consists essentially of a rectangular, metal frame with a hand grip on one end. Attached to the base is a razor-like blade with a micrometer adjustment. This adjustment is regulated by a swinging arm. Thus the section of the skin is accurately regulated, and the swinging arm propels the excised skin forward to facilitate its preservation. This instrument is considered of signal service especially in entropion, and also in orbitoplasties. In the latter the skin is accurately fixed to the free lid border and the graft is held in place by an acryllic mould.

Chas. A. Bahn.

Greeves, R. A. **Technical ophthalmological details.** Tr. Ophth. Soc. U. Kingdom 65:341-346, 1945.

The paralysis of the orbicularis muscle is obtained by blocking the facial nerve in the cheek. Peripheral iridectomy has been discarded for the complete one. The

trephine should be applied slightly obliquely and the lateral hinge finally separated with scissors to prevent its loss into the anterior chamber. Greeves advises against the use of a miotic immediately following a trephine operation as a quiet chronic iritis may follow and the pupil become firmly adherent posteriorly. Beulah Cushman.

Grignolo, Antonio. **Clinical and experimental use of streptomycin in ocular tuberculosis.** Minerva med. 39:16-20, Jan., 1948.

Grignolo inoculated the anterior chamber of the eyes of 33 guinea pigs with a virulent strain of human tubercle bacilli. One group was used as a control and one received full doses of streptomycin six days after the inoculation. Another group was treated with streptomycin 15 days after inoculation, and the fourth with streptomycin and sulfone. The group treated early showed marked inhibition of the tuberculous process. Those whose treatment was commenced on the fifteenth day were no better than the control group, thus demonstrating the advantage of early treatment, at least in the experimental animal.

Seven patients with ocular tuberculosis were treated with streptomycin. In two with choroiditis there was a favorable response and in two with anterior uveitis no improvement. One patient with miliary pulmonary disease and choroidal foci was greatly benefited, whereas two with phlyctenular keratitis were not improved.

Eugene M. Blake.

Grignolo, Antonio. **Clinical research on the employment of streptomycin in non-tuberculous ocular lesions.** Minerva med. 1:271-275, March 17, 1948.

In 72 patients streptomycin was administered by instillation, unguent, ocular baths, subconjunctival injection and injection into the anterior chamber. The dosage was that of tolerance, avoiding the state of streptomycin resistance. Good results were obtained in blepharitis ulcerosa, acute staphlyococcus and Koch-Weeks conjunctivitis, but no better than with penicillin. Gonococcic infections improved under treatment with streptomycin but were not cured. In one case of inclusion conjunctivitis, the inclusion bodies disappeared rapidly. In 12 cases of florid trachoma the conjunctival sac was rapidly sterilized, but the nodules were unaffected. No improvement was noted in the treatment of corneal ulcerations due to pneumococcus, staphylococcus or streptococcus, nor in herpes, epidemic keratoconjunctivitis or dacryocystitis. Streptomycin appeared to be effective against b. coli, b. Friedländer, b. proteus and a few other organisms.

Eugene M. Blake.

Iliff, C. E. **Beta irradiation in ophthalmology.** Arch. Ophth. 38:415-441, Oct., 1947.

The majority of reports on radiation therapy of the eyes are concerned with gamma rays. Beta rays possess the same qualities as other rays in the power of selective tissue destruction, but in contrast to gamma rays, they penetrate about 3 mm. of tissue only. In no case in which beta ray therapy has been used has damage to the lens been observed. Treatment is carried out with a special radon applicator. Excellent results are reported from the use of beta irradiations in vernal conjunctivitis, tuberculosis of the anterior ocular segment and in small benign tumors of the anterior segment. The agent is ideal for preventing superficial vascularization after keratectomy and keratoplasty. Granulation tissue, conjunctival flaps and pterygiums can be made avascular with contact therapy. Encouraging results are obtained in acne rosacea

keratitis. Corneal dystrophies, sarcoid, lupus erythematosus, pemphigus, punctate keratitis and corneal ulcers due to pyogenic infections are not benefited by beta rays, and may be made worse by their use. John C. Long.

López Enríquez, M. **Retinography with a short focus camera.** Arch. Soc. oftal. hispano-am. 7:1038-1041, Oct., 1947.

To convert the large Gullstrand ophthalmoscope into a fundus camera, Enríquez increased the illumination, by using a stronger nitra lamp, and attached a Leica camera to the ocular by means of a collar. (2 illustrations, 4 fundus photographs.) Ray K. Daily.

Morón-Salas, José. **For corneal examination.** Arch. Soc. oftal. hispano-am. 8:90-92, Jan., 1948.

Morón-Salas devised a mounting to hold a twenty-diopter lens and a piece of blue glass. This device serves as a substitute for an ultraviolet light, to intensify fluorescin stained corneal defects, to demonstrate corneal lesions such as keratitis filamentosa, and to check on the fit of contact lenses. It does not bring out the fluorescence of the lenticular cortex. (3 illustrations.) Ray K. Daily.

Traquair, H. M. **Pre-operative and post-operative treatment in eye operations.** Tr. Ophth. Soc. U. Kingdom 65: 356-365, 1945.

This paper deals with the various circumstances and factors with which the surgeon is concerned other than the operation itself. Psychological disturbance is much more common than physical disease, therefore, pre-operative treatment is largely psychological. The patient should be encouraged to take the operation in his stride. Local preparatory measures should be reduced to a minimum. After operation the patient may walk back to bed or be taken on a cart if the operating theatre is some distance away. The patient should be comfortable in bed after operation especially after cataract operations. Hemorrhage into the anterior chamber is frequently due to disturbed sleep. The patient's personal habit of taking cathartics should not be changed because of the operation. Post-operative embolism may be reduced by having the patients move the legs freely several times a day for about five minutes. Dark glasses are recommended and the patients are warned not to rub the face with a towel for six weeks, until the wound is well healed.

Beulah Cushman.

OCULAR MOTILITY

Adler, F. H. **Some confusing factors in the diagnosis of paralysis of the vertically acting muscles.** Am. J. Ophth. 31: 387-397, April, 1948. (17 figures.)

Aguilar y Menoz, José. **Diagnosis and treatment of heterophoria with the heteroscope.** Arch. Soc. oftal. hispano-am. 7: 1027-1037, Oct., 1947.

Aguilar's heteroscope is devised on the principle of Remy's diploscope and is used in a similar manner. The instructions for its use are given in detail. It is urged that orthoptic training should be continued to the point of simultaneous perception before surgery is done for strabismus, and to the point of binocular vision after it, in order to avoid a recurrence. (16 illustrations.)

Ray K. Daily.

Arriago Cantullera, José. **Postanesthetic ocular paralysis.** Arch. Soc. oftal. hispano-am. 7:1199-1208, Dec., 1947.

The literature is reviewed, and three cases of ocular paralysis are reported,

which followed the injection of 6 cgr. of estovain between the first and second lumbar vertebrae. In the first patient paralysis came on in both eyes one week after the operation. The patient made a complete recovery under intensive therapy with vitamin B. Two others are still under treatment. The various theories on the pathogenesis of this accident are discussed and no new viewpoints are presented. Ray K. Daily.

Hudelo, A. **Syndrome of Hertwig Magendie.** Ann. d'ocul. 180:702-705, Nov., 1947.

In a nine-year-old boy, disassociation of gaze and voluntary ocular movements was observed. He had defective dental articulation. Vision in the right eye was 0.9 and in the left, 0.6, and there was slight strabismus. In this syndrome vertical disassociation of the visual axes is present with proprioceptive inadequacy. Chas. A. Bahn.

Latorre, S. **Sensomotor orbital postoperative ophthalmoplegia.** Arch. Soc. oftal. hispano-am. 7:1173-1175, Dec., 1947.

Latorre reports a very unusual occurrence after a retrobular injection of 4-percent novocain solution used in the course of removal of a traumatic cataract. At the end of the operation the levator of the upper lid was paralyzed. At the end of 48 hours when the bandage was removed, the patient presented a picture of complete ptosis, paresis of the inferior and internal recti, and anesthesia of the skin innervated by the frontal and external nasal nerves. There was slight anesthesia of the upper half of the cornea. There was no hematoma in the orbit. Intensive vitamin B therapy brought about an improvement in two weeks, and a complete cure in two months. Ray K. Daily.

Lisman, J. V. **A triple-armed suture for resections.** Am. J. Ophth. 31:466, April, 1948. (2 figures.)

Orzalesi, F. **Heredofamilial degeneration of the cornea: histological report.** Rassegna ital. d'ottal. 16:393-406, Nov.-Dec., 1947.

An instance of corneal degeneration in an 8-year-old girl is carefully described by the author. Although the lesion probably belongs in the heredofamilial group, there were atypical features. The principal alterations were situated exclusively in the anterior layers of the parenchyma and consisted of small foci of destruction of the corneal lamellae and spaces, either empty or filled with corneal detritus. The basal layer of epithelium showed vascularization, especially over the stromal foci. Bowman's membrane presented defects in some places.

The author suggests that to the three types of corneal degeneration described (Groenow's nodular, Dimmer's reticular and Feher's granular) there be added a fourth type. More intensive study of the fatty elements could perhaps clarify the picture. (5 figures.) Eugene M. Blake.

Scobee, R. G., and Green, E. L. **Relationships between lateral heterophoria, prism vergence, and the near point of convergence.** Am. J. Ophth. 31:427-441, April, 1948. (8 figures, 7 references.)

7

CONJUNCTIVA, CORNEA, SCLERA

Allenic. **An interesting case of conjunctivitis sicca.** Ann. d'ocul. 180:706-707, Nov., 1947.

A woman, aged 62 years, after a short attack of unexplained fever developed a diminution of tears and salivary secretion with parotid inflammation. After approximately a week, all the symptoms subsided. The author associates these symp-

toms with the syndrome of Sjögren which may be due to parasympathetic hypofunction involving the vagus nerve.

Chas. A. Bahn.

Azzolini, U. **A report of mycosis of the conjunctivia in self-pitying individual.** Riv. di oftal. 2:112-118, March-April, 1947.

In a young self-pitying woman afflicted for eight years with a unilateral chronic conjunctivitis of the lower fornix, myces of the Macrosporium were found in the secretions. The canaliculus was not involved. It was decided that the lesion was due to a self-induced injury secondarily infected by the fungus.

Francis P. Guida.

Bodian, Martin. **Trachoma.** Arch. Ophth. 38:450-460, Oct., 1947.

Of 100 natives working at an American Army base in Fiji 22 percent had clinical evidence of active trachoma and 42 percent harbored Prowazek-Halberstädter inclusions in the conjunctival epithelium. Of the natives with clinical trachoma, 68 percent showed typical conjunctival inclusions. Inclusion bodies morphologically indistinguishable from those observed in frankly trachomatous patients were found in 34.6 percent of the natives with no clinical evidence of the disease. This observation suggests the existence of a carrier state in trachoma. Transmissibility and pathogenicity of the virus of trachoma from these patients still await demonstration. Fifty American soldiers based in Fiji for from one to three years failed to show clinical trachoma or inclusion bodies.

John C. Long.

Casari, G. F. **Histological study of the conjunctival nodules in erythema nodosa.** Rassegna ital. d'ottal. 16:467-472, Nov.-Dec., 1947.

Erythema nodosa developed in a 14-year-old girl whose general health was excellent, but who had previously had a dry pleurisy. An eruption appeared at the inner and outer angles of the bulbar conjunctiva of each eye. Microscopic examination showed no changes in the pavement epithelium, below which was fibrous and hyaline tissue, with edema and necrosis. There were scattered areas of perivascular lymphocytic infiltration. There were some epithelioid elements with fragmentation of the nuclei. The ocular condition was believed to be a para-allergic manifestation of tuberculosis.

Eugene M. Blake.

Castroviejo, R. **Keratoplasty and keratectomy—indications and contraindications.** Ann. d'ocul. 180:577-586, Oct., 1947.

Generally speaking, keratoplasty is preferable to keratectomy because of better visual results. Active inflammation and glaucoma are contraindications to either operation. Eyes should be free from inflammation for at least six months, and hypertension should be adequately controlled before any surgical treatment can be considered.

Three groups of patients are analyzed. 1. In the most favorable group are those with slight corneal opacities, especially those due to keratoconus and interstitial keratitis. 2. In the less favorable group are most cases of corneal dystrophy without vascularization but with normal stroma and endothelium. Included are the types of Fleisher, Haab-Dimmer, Groenow, and Salzman. 3. In the least favorable group the patients have more extensive cicatrization especially with vascularization, extensive pupillary zone involvements, adherent leucomas, less favorable dystrophies, severe thermal and chemical burns, corneal opacities in aphakic and amblyopic eyes, calcareous deposits and other degenerative diseases such as pemphigus. Preliminary radium

therapy to reduce vascularization, partial or complete keratectomy, iridectomy and other measures may be advisable adjuncts. The surgical risks involved must be justified. Chas. A. Bahn.

De Laet, H. **The profile of circular corneal grafts.** Ann. d'ocul. 180:629-638, Oct., 1947.

Is especially the marginal profile of corneal trephined grafts modified by differences of curvature, pressure and tension? Experiments on pigs' eyes, human eyes, and on rubber tubes made to simulate the human cornea, were carried on to elucidate the physical laws involved as well as their practical applications in both the donor and enucleated corneas. Theoretically some deformity does exist, but practically the construction of the human cornea overcomes this tendency. The lamellar structure of the stroma with its elastic fibers sandwiched between two non-elastic membranes, those of Bowman and Descemet, prevents distortion of the disc. The author, however, favors the removal of the disc from the donor cornea by a stamping rather than a sawing motion of the trephine. For this purpose the donor cornea is placed on a corresponding plastic disc. Chas. A. Bahn.

Dor, Louis. **Chronic conjunctivitis in cholesterolemia.** Ann. d'ocul. 180:708-709, Nov., 1947.

The association of some chronic conjunctivitides and palpebral eczemas with quantitative and qualitative lipid abnormalities is briefly discussed. The administration of a drug, chophytol, which apparently is a choline preparation, was in some patients followed by more rapid improvement than otherwise might have been expected. Chas. A. Bahn.

Heyrowsky, K. **A case of vicarious bleeding into the conjunctiva and bloody tears.** Wien. klin. Wchnschr. 59:702-704, Oct. 24, 1947.

A 26 year old woman, the fourth one presenting the same symptoms, had a polyglandular disturbance, genital hypoplasia and recurrent vicarious bleeding into the eye. Her female ancestral tree is presented and other members of her family were found to have the same vicarious bleeding. The patient was given various hormonal extracts, her medical condition was improved by general regime and after 1½ years of treatment the patient had no recurrences.

Theodore M. Shapira.

Hughes, E. L. **Local sulphonamide therapy of dendritic ulcer.** Brit. J. Ophth. 32:43-46, Jan., 1948.

Local sulphonamide therapy in the form of albucid ointment was used in 16 consecutive cases of dendritic ulcer. Thrice daily 6-percent ointment was instilled and the entire corneal surface was painted daily with 30-percent solution. Of the 16 eyes, 12 responded well. Improvement seemed to be directly proportional to corneal sensitivity; the greater the loss of sensitivity, the less favorable was the result. Those that did respond well were clinically cured within eight days.

Morris Kaplan.

Kettesy, A. **On results obtained by total conjunctival hooding of the cornea for serpiginous ulcer.** Brit. J. Ophth. 32: 36-43, Jan., 1948.

Total hooding of the cornea by a conjunctival flap was first introduced for the treatment of Mooren's ulcer and in the author's hands was so very satisfactory that in his clinic it has become routine treatment for serpiginous ulcer as well. In this report 56 consecutive cases of serpiginous ulcer so treated are described and are compared to twice as many treated in the ordinary, routine

way which did not include the use of penicillin. The results were uniformly satisfactory. The conjunctiva is undermined above, is brought down and is sutured to the normally attached conjunctiva below the cornea. The procedure failed only when the sutures were placed across the cornea. The hood was left in place for six months and then removed with scissors. In all cases pain ceased immediately. Visual improvement was well over twice that obtained by other measures and the hospital stay was reduced from 14 days to six.

Morris Kaplan.

Larsson, S. **Treatment of perforated corneal ulcer by autoplastic scleral transplantation.** Brit. J. Ophth. 32:54-57, Jan., 1948.

Soon after successful removal of a retrobular hemangioma in a seven-year-old child a severe corneal ulcer developed because of lagophthalmos. Despite all routine treatment, and four attempts to cover it with a conjunctival flap, the ulcer persisted, became larger and developed a large descemetocele. A scleral button was removed by means of an ordinary punch, the ulcer edges were excised, the button placed in the opening and a conjunctival flap covered over it. The result was very satisfactory; the button remained in place, the ulcer remained closed, the flap persisted and the vision improved from 0.2 to 0.5.

Morris Kaplan.

Magitot, A. **The transparency of corneal grafts.** Ann. d'ocul. 180:619-628, Oct., 1947.

Corneal transplantation is not new; in animals, 125 years old; in humans, only 65 years. The results of 100 transplants were reported by Elschnig in 1925, and but few basic improvements have been made since. American exuberance and over-dramatization of keratoplasty, especially in the popular press, was editorially commented upon recently in this journal. Corneal healing and transparency is largely dependent upon the normalcy of the epithelium and the endothelium. Rapid epithelial reproduction is apparently due to an extension of conjunctival proliferation. But little is known concerning the nutrition and replacement of the stromal cells. Although the cornea and sclera are similar anatomically, one is transparent but the other is opaque. This transparency is largely due to a hydrophile gel which exists both in colloid and crystalline form. The refractive index is of less importance in corneal transparency than the hydrophile gel. Under normal conditions oxygen passes through the cornea into the anterior chamber and carbon dioxide passes in the reverse direction. In the presence of toxic agents, cations are retained in the cornea by both systems, affecting both corneal permeability and transparency. Anaesthetic corneas are predisposed to opaque grafts, which means that nervous regulation is involved. Each epithelial cell is attached to a nerve filament. It has long been known that partial keratectomies with a healthy bed frequently retain their transparency. In pemphigus, however, the stroma remains clear but the epithelium soon becomes opaque. The corneal metabolic rate is high; many wearers of contact glasses observe Fick's phenomenon. Autoplastic grafts are more frequently successful than homoplastic. Of the latter, approximately 20 percent are incompatible with the cornea of the host and therefore doomed. Heteroplastic grafts are almost uniformly unsuccessful in man. Corneas for grafts are best preserved at 4 to 7 degrees C. They may remain vital for fifteen years at this temperature. The best preservative media are hemolized serum and cerebrospinal

fluid. The performance of keratoplasty is not more difficult than cataract extraction, and it must be undertaken with the same sense of its moral and medical responsibility. Chas. A. Bahn.

Michtner, H. **Lesions in corneal epithelium caused by spraying of lacquer.** Proc. Ophth. Soc. Vienna p. 36, Jan. 18, 1943.

Some months after having started working as a lacquer sprayer a man developed pain in both eyes and headache. Slitlamp examination revealed minute whitish opacities in the corneal epithelium which did not impair the vision. After a change of occupation the corneal lesions disappeared completely.

F. Nelson.

Neame, Humphrey. **A rare case of bilateral macular keratitis with cyclitis, affecting all layers of the cornea. Comparisons with corneal lesions present in some virus infections.** Tr. Ophth. Soc. U. Kingdom 65:328-340, 1945.

The eyes of a patient with bilateral macular keratitis, two with nummular keratitis and two with disciform keratitis are described. The opacities were numerous but countable and the depth variable. The size of the spots varied from 0.5 to 1 mm. The disappearance of the spots was complete except in the severe cases of disciform and zoster keratitis.

The author concludes that nummular keratitis lies morphologically between superficial punctate keratitis and disciform keratitis and that the one case he presented forms a link between superficial punctate keratitis and nummular keratitis. (5 figures.)

Beulah Cushman.

Nizetic, Z. **Visual results after corneal grafts.** Ann. d'ocul. 180:596-603, Oct., 1947.

After a brief review of the subject one sees this statement: good vision in one eye usually means that keratoplasty is superfluous on the other. Twelve personal cases of operation performed during a period of fifteen years are reported with observation from six months to eleven years afterward. The keratoplasties were necessitated by trachoma, serpentic ulcer and parenchymatous keratitis. Vision ranged from 0.1 to 1. Chas. A. Bahn.

Offret, G. **The biologic problems of keratoplasty.** Ann. d'ocul. 180:613-618, Oct., 1947.

The successes reported in homografts range from 40 to 85 percent. Preservation of the cornea at 4°C. preserves sufficient vitality for replacement surgery. Corneal transplantation somewhat resembles tendon transplantation. Both are essentially mesodermal and their basic structures are not replaced after transplantation. The epithelium and endothelium are of vital importance in maintaining transparency in keratoplastic grafts. Allergy and immunity play a more important part in success than has been realized. Allergic toxic reactions of the donor implant to bacterial and other toxins of the host are relatively frequent. Keratoblasts in the donor cornea succumb within three days and are replaced by those of the recipient cornea, which possibly arise from epithelial cells. Cicatricial tissue and new blood vessels interfere most with the vitality of the graft. In some types of hereditary dystrophies the donor graft is not poisoned by the cornea of the host. The early life of the graft depends largely upon the diastatic activity of the stromal cells. Keratoplasty has been used therapeutically in some acute corneal diseases.

Chas. A. Bahn.

Paufique, L. **Defense of non-perforating corneal grafts.** Ann. d'ocul. 180:587-595, Oct., 1947.

This type of operation is advisable largely in corneal opacities, especially bilateral, which cause practical blindness. These include: 1. inflammatory diseases such as tuberculosis, syphilis, rosacea, trachoma, severe thermal and chemical burns; 2. degenerative diseases, especially severe keratoconus, recurrent progressive pterygium, and severe dystrophies. Optical iridectomy may be a preliminary or subsequent adjunct. The underlying opaque corneal tissue forms a protective wall for the intraocular contents and does not reduce vision as much as is generally supposed. Obviously the results are not brilliant. The 60 cases reported were unfavorable surgical risks. Patients must be carefully selected for this type of surgery which must be expertly performed. Chas. A. Bahn.

Somerset, E. J. and Sen, K. **Intra-ocular foreign bodies. An account of military cases from the Burma-Assam front.** Brit. J. Ophth. 32:13-23, Jan., 1948.

Techniques and results of care in 29 selected cases of intraocular foreign body are presented. (These cases were evacuated by air personally by the abstractor from the Burma front into India). Each patient selected had a retained foreign body within the eyeball and each retained fair light perception. Most patients were seen several weks after the injury and most had received routine administration of sulpha drugs by mouth when first injured. Fifteen were British and 14 were Indian and the latter tended to react much less to surgery or injury than the former. There were no cases of serious infection and no cases of sympathetic ophthalmia. Morris Kaplan.

Sourdille, G. P. **Perforating partial grafts of the cornea: their technique and results.** Ann. d'ocul. 180:604-612, Oct., 1947.

The donor eye after enucleation is placed in paraffin oil, kept at a temperature of 4°C. and finally washed with serum. Two sized trephines are used: in the donor eye, 5.1 mm.; in the recipient eye, 5 mm. Descemet's membrane should not be traumatized. A lid suture is used, the eye is bandaged 17 days, and examined after five days.

The success of the transplant depends partly on the normality of the donor cornea and especially the uveal tract. Centrally located opacities with sharply limited margins in the recipient eye are a good omen. Increased intraocular tension following the operation as well as vascularization are bad omens, as are also slight vitreous loss, mobility of the graft adhesions between cornea and iris, and lowered vitality of the surrounding cornea, as in severe alkaline burns. In one case sympathetic ophthalmia was observed. Chas. A. Bahn.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Barany, E. H. **The mode of entrance of sodium into the aqueous humour.** Acta Physiol. Scandinav. 13:55-61, 1947.

Radio-active sodium chloride in solution was injected intraperitoneally into anesthetized rabbits. Studies of aspirated aqueous were made on animals whose bloodpressure in the ophthalmic and retinal artery was lowered by carotid clamping and on control animals whose arteries were not clamped.,

Those with obstructed carotids should have shown a lowering of the accumulation of sodium in the chamber if ultrafiltration affected the dynamics of passage of the sodium. Since the rate accumulation of sodium was not greatly affected by the clamping and the subsequent lowering of arterial pressure, the author believes that the process involved

in the passage of the sodium was not one of filtration but of secretion.

Francis M. Crage.

Barany, E. H. **The relative importance of ultrafiltration and secretion in the formation of aqueous humour as revealed by the influence of arterial blood pressure on the osmotic pressure of the aqueous.** Acta Physiol. Scandinav. 13:81-86, 1947.

It has been shown that clamping the carotid artery reduces the rate of ultrafiltration by reducing the filtering pressure in an eye. If untrafiltration played an important role in the formation of the aqueous humour then one should expect that clamping a carotid would influence the osmotic pressure of the aqueous.

Osmotic pressure studies were made on aqueous aspirated from each of the two eyes of rabbits in which one carotid was clamped off. After the blood pressure of the eye on the clamped side had been kept at 30 mm. Hg below normal for one and one-half to two hours no significant difference in osmotic pressure of the aqueous was detected between the two eyes. The amount of filtered aqueous therefore could not be considerable. This favors the theory of secretory production of the aqueous humor.

Francis M. Crage.

Laval, Joseph. **Hyaline membrane of the iris. Report of two cases.** Am. J. Ophth. 31:461-463, April, 1948. (5 figures.)

Lowenstein, Arnold. **The sympathizing eye.** Tr. Ophth. Soc. U. Kingdom 65:219-231, 1945.

The author presents the findings in the exciting and sympathizing eyes in two cases. He stressed the findings of corneal epithelial edema, the digestive power of granulomatous tissue towards the glass membranes, the existence of huge macrophages filled with lens matter in the anterior chamber and the great mass of eosinophiles, the granulomatous tissue in the vitreous with epithelioid and giant cells especially in the pre-retinal region. The huge perivascular retinal infiltrates contained many plasma cells and plasma cell rows lined the internal limiting membrane. The histologic findings refute the allergic theory of sympathetic ophthalmia. The provoked allergic uveitis resembled endopthalmitis and not sympathetic ophthalmia.

The saprophytic virus of the conjunctiva may be transferred by a perforating wound into the contents of the globe. If the strain is neurotropic the alleged virus creeps along the ciliary or optic nerve to the brain. In cases of sympathetic ophthalmia it migrates along the nerves to the other eye. The infection of the other eye is patch-like. The repeated reabsorption of the virus creates allergy with release of an H-substance where the nerve endings enter the tissue of the second eye.

This assumption would explain: 1. the multiplicity of independent foci of inflammation, 2. the predominant impairment of the outer layers of the eye and relatively inconsiderable retinal disease, 3. the histamine-like reaction in the epithelium of the conjunctiva and cornea, 4. the tuberculous structure, typical of allergic tissue reaction, 5. the presence of eosinophile cells found frequently in allergic tissue, 6. the negative bacteriological findings, 7. that the disease of the second eye is prevented when the whole source of infection is removed in time, and that excision of the exciting eye is ineffective when the second eye is diseased, 8. sympathetic ophthalmia in cases of evisceration of the exciting eye, 9. meningeal involvement, deafness and bleaching of eyelashes by migration of the virus into other nerve trunks at the base of the brain. Beulah Cushman.

Samuels, Bernard. **The problem of sympathetic Ophthalmia.** Am. J. Ophth. 31: 397-410, April, 1948. (10 figures.)

Whittington, T. H. **Leucosarcoma of iris.** Pro. Roy. Soc. Med. 65:65-66, Jan., 1948.

A hemorrhagic yellowish lobed nodule was found protruding from the anterior surface of the iris in a 64-year-old woman. It was not cystic and not transluminable. The tumor was removed by iridectomy and found to be malignant melanoma.

GLAUCOMA AND OCULAR TENSION

Barkan, O. **The technique of goniotomy for congenital glaucoma.** Tr. Am. Acad. Ophth. pp. 210-223, Jan.-Feb., 1948.

The author's streamlining of the older de Vincentii's operation has found its most successful use in some types of congenital glaucoma. Of 76 such operations performed, 66 are reported as having tension normalized, and 10 unsuccessful. The effectiveness of the stripping of the iris from the cornea where it is adherent because of persistent embryonic tissues, depends on several factors. Schlemm's canal must be patent; the cornea must not be so degenerated structurally or functionally that a return to normal is prevented, and the uveal and retinal tissue must not be too badly degenerated to prevent a reasonable return of vision. If the cornea is sufficiently transparent, goniotomy is performed by direct vision under a prismatic contact glass. If not, the operation is performed without a contact glass but with preliminary canthotomy. One-fourth or more of the adherent iris is stripped at one operation which may be repeated, usually without increasing risks. Air or physiological salt solution may be used to further deepen the anterior chamber. This operation, if indicated, should be performed before degenerative changes in the eye doom it to partial or complete failure. Meticulous attention to the numerous details that make goniotomy successful in infantile glaucoma is imperative. Any attempt to abstract these details would be unfair to the author and to the patients. These should be read in the original article by those who are sufficiently deft and understanding to successfully perform this operation.

Chas. A. Bahn.

Cristini, Giuseppe. **Operative results, mechanism of action, and indications for cyclodiathermy in glaucoma.** Giorn. ital. di oftal. 1:1-13, Jan.-Feb., 1948.

The records of thirty-seven patients operated on by the method of Weekers are reviewed with reference to vision, ocular tension and visual fields (primary glaucoma 18, aphakic glaucoma 3, secondary glaucoma 10, hydrophthalmos 6). In five cases, histopathologic examinations were made of the globes enucleated at varying intervals following the cyclodiathermy.

The change in pressure is attributed by the author to changes in the vascular hydrostatic pressure and of the osmotic pressure and not to variations in the balance between absorption and secretion of the aqueous. The author feels that the Weekers method should not be used in eyes which can be treated by the classic decompression procedures.

Francis P. Guida.

Friede, R. **Treatment of chronic hypotonia bulbi. Wien. klin. Wchnschr. 59:752-754, Nov. 14, 1947.**

The author is interested in attempting to raise the intraocular pressure temporarily (days or weeks) in cases of hypotonia bulbi so that what little vision remains may be preserved and possibly increased and feels that he has succeeded.

He suggests two ways of increasing the intravitreal tension. First, he has the patient drink two or three liters of water for days; and second, he tenotomizes the four recti muscles because he believes the tension at their insertion over the ciliary body tends to decrease the secretion of intraocular fluids by the ciliary body. When the bulb has more tonus he reattaches the muscles. He believes that in early cases of uveitis with hyptotony, the latter may be arrested by his treatment.

Theodore M. Shapira.

Heinz, K. **Retinal detachment following a Lindner bulbus fistula and Elliot trephining.** Proc. Soc. Vienna p. 41, Feb. 22, 1943.

In a man whose left eye had been blind from glaucoma for a long time instillation of homatropine solution into his apparently normal right eye was followed by a severe attack of glaucoma. A Lindner fistula was made and the large quantities of vitreous that appeared were cut off. After 10 days the eye tension was again normal and an Elliot trephining was performed. Four days later the lower half of the retina was found detached but the eye recovered completely after it had been operated upon for this condition.

F. Nelson.

Longhena, Luisa. **Considerations of glaucoma secondary to cataract surgery.** Riv. di oftal. 2:125-144, March-April, 1947. 1947.

After reviewing the literature the author reports 12 cases of glaucoma following cataract operation. She feels that the glaucoma which follows cataract extraction is not a secondary glaucoma but a primary type, since sooner or later glaucoma appears in the unoperated eye. Repeated tonometric measurements preceding surgery can bring to light this latent glaucoma and help to avoid acute attacks by proper treatment during surgery and post-operatively. Once manifest, glaucoma following cataract surgery must be treated as in a non-aphakic eye. However, the prognosis is poor and frequently in spite of surgical and medical treatment, there is total loss of vision and finally of the eye.

Francis P. Guida.

Matteucci, P. **The transmission of humoral nervous impulses in primary chronic glaucoma.** Ann. d'ocul. 180:671-680, Nov., 1947.

Quantitatively and qualitatively the aqueous comes from the blood, which in the glaucomatous differs chemically from that of normal eyes. The existence of a central vasomotor disequilibruim in the glaucomatous has been experimentally proven and is becoming more widely accepted. Involved in this disequilibrium is the sympathetic-parasympathetic mechanism. This affects capillary permeability (vasomotor phenomena), also photomotor reactions, and in the glaucomatous may cause a descending optic atrophy. The author's experiments in determining the cholinase and the amino-oxidase in the aqueous and in the blood of normal and glaucomatous patients support the concept that a deficient parasympathetic and/or over-active sympathetic mechanism and reaction exist in the uveal tract of the glaucomatous. For a statistical study of 12 glaucomatous patients and 5 non-glaucomatous patients, the aqueous was obtained at the time of operation for glaucoma or cataract extraction. The data show that the amino-oxidase of normal compared with glaucomatous eyes is higher in the glaucomatous than in the normal eye and also that the cholesterinase in both the serum and aqueous humor is definitely higher in the glaucomatous. Biologic investigators of glaucoma should read this article in the original.

PAN-AMERICAN NOTES

Edited by M. URIBE TRONCOSO, M.D.
500 West End Avenue, New York 24

Communications should reach the editor by the 12th of the month

PAN-AMERICAN OFFICERS

At the III Pan-American Congress of Ophthalmology, the following officers were elected to serve from 1948 to 1952: President, Dr. Conrad Berens; vice-presidents: Argentina, Dr. Esteban Adrogué; Bolivia, Dr. Aniceto Solares; Brazil, Prof. Ivo Correa Meyer; Canada, Dr. John MacMillan; Chile, Dr. Santiago Barrenechea; Colombia, Dr. Francisco Vernaza; Costa Rica, Dr. Alexis Aguero; Cuba, Dr. Miguel Branly; Ecuador, Dr. Varas Samaniego; Guatemala, Dr. Miguel Medrano; United States, Dr. Frederick C. Cordes and Dr. William L. Benedict. Secretary for north of Panama, Dr. Thomas D. Allen; secretary for south of Panama, Dr. Moacyr E. Alvaro; assistant secretaries for Latin America, Dr. Jorge Balza and Dr. Manoel Silva; assistant secretary for the United States, Dr. Brittain F. Payne; assistant secretary for Central America, Dr. Palomino Dena.

COMMITTEES APPOINTED

It was decided at the council meeting and ratified by the general assembly that the following permanent committees should be appointed:

Interamerican Federation of Ophthalmologic Societies. President, Dr. William Benedict (United States); Members: Dr. Jorge Malbran (Argentina), Dr. Aniceto Solares (Bolivia), Dr. Sylvio Abreu Fialho (Brazil), Dr. Italo Martini (Chile), Dr. Carlos Mena (Costa Rica), and Dr. Jorge Suarez Hoyos (Colombia).

Committee on Lighting and Optics. President, Dr. Magin Diez (Argentina); Members: Dr. J. Pascal (United States), Dr. Roque Bellido Tagle (Perú), Dr. J. M. Penichet (Cuba), Dr. Rivas Cherif (Mexico), Dr. A. Cowan (United States), Dr. Caretti (Argentina), and Mr. Tolman (New York).

Committee on Glaucoma. President, Dr. Antonio Torres Estrada (Mexico); Members: Dr. Peter Kronfeld (United States), Dr. Julio Raffo (Perú), Dr. Hilton Rocha (Brazil), Dr. Baudilio Courtis (Argentina), Dr. Esteban Adrogué (Argentina).

Committee for the Encouragement of Research in Ophthalmology. President, Dr. Edwin Dunphy (United States); Members: Dr. Phillips Thygeson (United States), Dr. Esteban Adrogué (Argentina), Dr. Paulo Filho (Brazil), Dr. Lech Junior (Brazil).

Committee on Pharmaceutics. President, Dr. Parker Heath (United States); Members: Dr. Roberto Pereira (Argentina), Dr. K. Swan (United States), Dr. W. Hughes (United States).

Society of "Amigos." Honorary President, Dr. Francisco Belgeri (Argentina). President, Dr. Paulo Cesar Pimentel (Brazil); Members: Dr. William Crisp (United States), Dr. Shaler Richardson (United States), Dr. Magin Diez (Argentina), Dr. Santiago Barrenechea (Chile), Dr. Abelardo Zertuche (Mexico).

Committee on Establishment and Guidance of Ophthalmologic Societies. President: Dr. Jesus Rhode (Venezuela); Members: Dr. Frederick Cordes (United States), Dr. Durval Prado (Brazil), Dr. Roberto Pereira (Argentina), Dr. Oscar Horstmann (Cuba).

Committee on Legal and Industrial Ophthalmology. President, Dr. Jorge Diaz Guerrero (Colombia); Members: Dr. Ralph Lloyd (United States), Dr. Alberto Urrets Zavalia (Argentina), Dr. Santiago Barrenechea (Chile), Dr. J. M. Espino (Venezuela), Dr. Morris Davidson (United States), Dr. José A. Senà (Argentina), Dr. Thomas R. Yanes (Cuba), Dr. Eduardo Arce (Bolivia), Dr. Colombo Spinola (Brazil).

Committee on Standardization of Ophthalmic Hospitals and Clinics. President, Dr. J. H. Dunnington (United States); Members: Dr. Magin Diez (Argentina), Dr. Ivo Correa Meyer (Brazil), Dr. J. M. Penichet (Cuba).

Committee on Interamerican Medical Relationships. President, Dr. R. Pacheco Luna (Guatemala); Members: Dr. Daniel Kirby (United States), Dr. Derrick Vail (United States), Dr. Palomino Dena (Mexico), Dr. Sylvio Abreu Fialho (Brazil), Dr. Georgiana Theobald (United States), Dr. Olga Ferrer (Cuba).

Committee of Purchasing Section. President, Dr. Rene Contardo (Chile); Members: Dr. Paiva Gonçalves (Brazil), Dr. Luis E. de Mora (Perú), Dr. Jorge Malbran (Argentina), Dr. Roberto Vazquez Barriere (Uruguay).

Contact Lens Center Committee. President, Dr. Baudilio Courtis (Argentina); Members: Dr. Arno Town (United States), Dr. Enrique Bertotto (Argentina), Dr. Daniel Silva (Mexico), Dr. J. Pascal (United States).

Committee on Orthoptics. President, Dr. Avery Prangen (United States); Members: Dr. Jorge Malbran (Argentina), Dr. Cesar Rodriguez (Perú), Dr. Raimundo Tartari (Argentina), Dr. J. Mendonça de Barros (Brazil).

Committee on Scientific Cinematography. President, Dr. Hilton Rocha (Brazil); Members: Dr. Gilberto Cepero (Cuba), Dr. A. Bedell (United States), Dr. Magin Puig Solanes (Mexico), Dr. Caretti (Argentina).

Committee on Trachoma. President, Prof. Cesario de Andrade (Brazil); Members: Dr. José R. Toja (Argentina), Dr. Roque Bellido Tagle (Perú), Dr. Paula Santos (Brazil), Dr. Phillips Thygeson (United States).

Bureau of Professors. President, Dr. Jorge Valdeavellano (Perú); Members: Dr. Derrick

Vail (United States), Dr. R. Rodriguez Barrios (Uruguay), Dr. Miguel A. Branly (Cuba), Dr. Alberto Urrets Zavalia (Argentina).

Committee for the Prevention of Blindness. President, Dr. Alberto Vazquez Barriere (Uruguay); Members: Dr. Tomás R. Yanes (Cuba), Dr. Sanchez Bulnes (Mexico), Dr. Natalicio de Farias (Brazil), Dr. Magin Diez (Argentina), Dr. C. Espildora Luque (Chile), Dr. Franklin Foote (United States).

Committee on Statutes. Dr. Tomás R. Yanes, Dr. Moacyr E. Alvaro, Dr. Conrad Berens, Dr. Alberto Vazquez Barriere, Dr. Thomas D. Allen, Dr. Santiago Barrenechea.

Board of Censors. President, Dr. Tomás R. Yanes (Cuba); Members: Dr. Alberto Vazquez Barriere (Uruguay), Dr. Esteban Adrogué (Argentina), Dr. Enrique Cipriani (Perú), Dr. Derrick Vail (United States), Dr. Rene Contardo (Chile), Dr. Paulo C. Pimentel (Brazil), Dr. Luis Sanchez Bulnes (Mexico), Dr. Constantino Herdocia (Costa Rica).

Committee on Neuro-Ophthalmology. President, Dr. Alejandro Posada (Colombia); Members: Dr. Pedro Falcão (Brazil), Dr. Jorge Malbran (Argentina), Dr. Esteban Adrogué (Argentina), Dr. Frank Walsh (United States), Dr. Alfred Kestenbaum (United States).

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the 12th of the month

DEATHS

Dr. Archibald Alexander MacLachlan, Pittsburgh, Pennsylvania, died December 2, 1947, aged 73 years.

Dr. Hamilton Stillson, Seattle, Washington, died January 11, 1948, aged 90 years.

Dr. George A. Morley, Crookston, Minnesota, died recently, aged 79 years.

MISCELLANEOUS

REPORT OF EYE-BANK

The Stanford Eye Bank has reported that it provided 33 corneas for eye-graft operations during its first year of operation. All qualified eye surgeons on the Pacific coast are invited to make use of the facilities of the bank. Corneas collected and preserved by the Eye-Bank are distributed without cost to either patient or surgeon, except for a small service fee. Information on the correct procedure for registration of donors can be obtained by writing to the Stanford Eye Bank, 2398 Sacramento Street, San Francisco.

RECOGNITION DINNER HELD

On April 22, 1948, a recognition dinner was held at Talladega, Alabama, following the inauguration earlier this year of the assumption by the Department of Ophthalmology, Medical College of Alabama, of the full ophthalmic responsibility for the Alabama Institute for the Deaf and Blind. Representative officials of the state and of the university were present. There are 209 blind or partially blind children at the institute and much investigation and therapeusis are planned, particularly with reference to those children with progressive ocular disease. A resident in ophthalmology spends two days each week at the institute (50 miles from Birmingham) and the rest of his time at the Medical College and the Thigpen-Cater Eye Hospital. Dr. Arthur Steinmetz, Hayward, California, is the present resident.

SOCIETIES

The Milwaukee Oto-Ophthalmic Society held its regular meeting on April 27th at the Milwaukee Children's Hospital. The scientific program included: "Surgery of strabismus with special reference to the oblique muscles," Dr. Beulah Cushman, Northwestern University, Chicago; and "Treatment of acute laryngo-tracheo-bronchitis," Dr. Howard High, Milwaukee.

PENNSYLVANIA ACADEMY MEETS

The Pennsylvania Academy of Ophthalmology and Otolaryngology met on April 23rd, 24th, and 25th at the Penn-Harris Hotel, Harrisburg. Dr. Gabriel Tucker was the guest of honor.

Of particular interest to eye physicians were the following papers: "The surgery of the extraocular muscles," Dr. Glen Gregory Gibson, Philadelphia; "Retinal detachment," Dr. John H. Dunnington, New York; "Surgery of the lids and conjunctiva," and " External ocular diseases and their treatment," Dr. Raymond Emory Meek, New York; "Integrated implants and the presentation of a new type universal implant," Dr. Norman L. Cutler, Wilmington, Delaware; "General anesthesia for operations on the eye, ear, nose, and throat," Dr. Philip D. Woodbridge, Reading, Pennsylvania; and "Pitfalls in cataract surgery," Dr. Carroll R. Mullen, Philadelphia.

Two splendid motion pictures of ophthalmic interest were shown. They were "Keratoplasty," and "Cataract extraction—Extracapsular, intracapsular with forceps, intracapsular by suction." Both were made by Dr. Ramon Castroviejo, New York.

AMERICAN JOURNAL OF OPHTHALMOLOGY

VOLUME 31 JULY, 1948 NUMBER 7

DACRYOCYSTITIS OF INFANCY*

J. V. CASSADY, M.D.
South Bend, Indiana

The treatment of dacryocystitis of infancy is still a controversial subject. The majority of the literature on this subject advocates conservative treatment and is opposed to early probing of the nasolacrimal duct. The tear-sac infection in infants is due to an imperforate lumen of the lacrimal duct with a retention of infected tears in the sac. Many ophthalmologists believe that a long period of irrigation with massage of the sac should be employed because of some bad effects that might ensue from early probing of the duct. One hundred cases that I treated by early probing of the duct cleared up promptly without incident or bad effects from such management.

REVIEW OF THE LITERATURE

In a recent review of the literature I found 15 papers recommending early probing of the duct to clear up the dacryocystitis of infancy and 18 that decried manipulation of the duct, the latter favoring conservative management with local antiseptics and sac massage for a period varying from 2 to 24 months. Among those favoring early probing were Weeks, Zentmayer, Ollendorf, Green, Nagel, Meller, Ferrer, Pesne, Berens, Sanford Gifford, Becker, Wiener and Alvis, Walker, and Judge. Those opposed to probing and advocating a prolonged period of conservative treatment were Posey, Klinedinst, Edward Jackson, Roy, Curdy, McMurray, Crigler, Rollet, Campbell, Botteri, Busacca, Meek, Hardesty, Moret, Arruga, Harold Gifford, and Guerry.

Several members of the Chicago Ophthalmological Society have contributed to the literature on this subject. The two papers that I wish to review are those of H. W. Woodruff and of Roy Riser. Dr. Woodruff, in 1931, pointed out that the majority of these infants come to the ophthalmologists at about six months of age. Some only require sac irrigation, while others need to have their nasolacrimal ducts probed. In some instances, he found it necessary to pass a second probe into the nose rubbing the two instruments together to break through the mucosa and establish a lumen from the duct into the nose.

Riser, in 1935, reported 44 instances of dacryocystitis of infancy, most of which were seen at about six months of age. Conservative treatment for 2½ months resulted in subsidence of the symptoms in 21 cases. Only 50 percent, however, were relieved by conservative treatment. Nine cases were probed and their symptoms subsided promptly.

EMBRYOLOGY AND DEVELOPMENTAL ANATOMY

To understand the pathogenesis of dacryocystitis of infancy better, the works of J. Parsons Schaeffer and of M. Schwartz of Tubingen should be considered. These two authors have made such valuable contributions to the embryology and developmental

* Read before the Chicago Ophthalmological Society, October 6, 1947. The author gratefully acknowledges the assistance given by the staff of the South Bend Medical Foundation, Inc., in the preparation of the embryology and the illustrations.

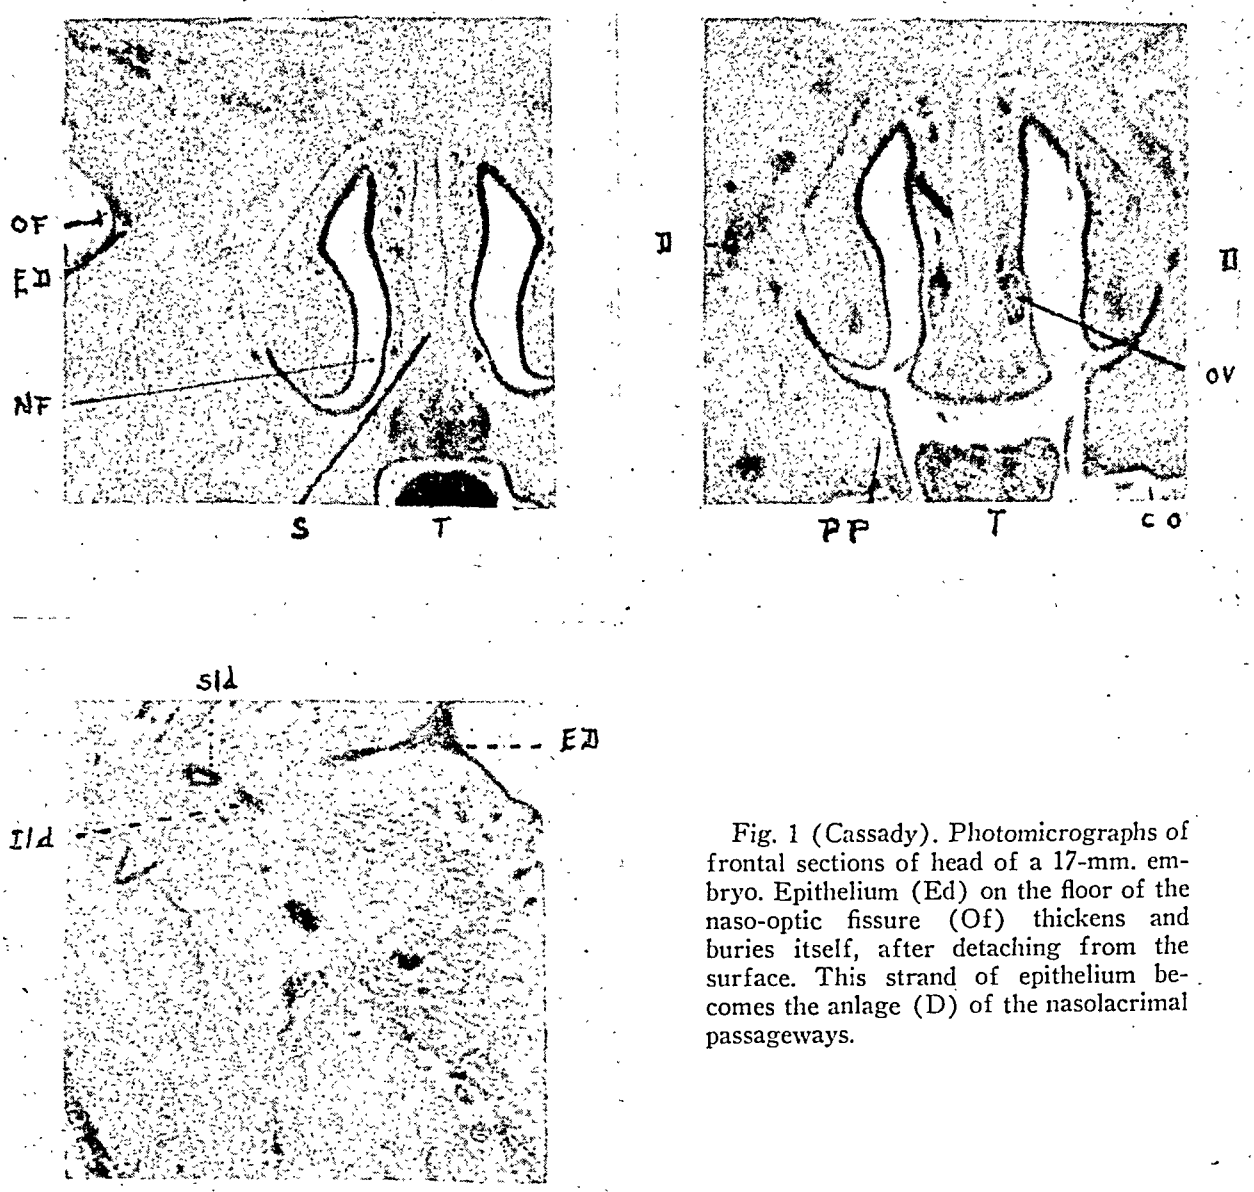

Fig. 1 (Cassady). Photomicrographs of frontal sections of head of a 17-mm. embryo. Epithelium (Ed) on the floor of the naso-optic fissure (Of) thickens and buries itself, after detaching from the surface. This strand of epithelium becomes the anlage (D) of the nasolacrimal passageways.

anatomy of the nasolacrimal duct that, in spite of your familiarity with their work, I would like to review it.

"The nasolacrimal duct starts in the 12-mm. embryo from a thickening of epidermal cells which grows down into the mesenchymal tissue and detaches itself from the surface ectoderm. This epithelial cord begins to develop a lumen by the third month: sections through 100-day embryos show that the superior and inferior canalicular cords have extended to the free margin of the eyelids and that the nasal end of the mother cord of cells has reached the nasal mucous membrane. The ocular end establishes a lumen long before the nasal end and the latter is delayed approximately until birth or a little later. The last portion to become patent is the site of coalescence between the nasal sprout of the mother cord and the nasal mucous membrane. The position of the ostium, whether

at the highest point of the inferior meatus or at some lower site on the lateral nasal wall, and the shape of the ostium, whether large, wide open, or more or less guarded by folds of mucosa, depend upon the point

tact, (2) be of microscopic size and inadequate for normal function, (3) be buried in mucosa of the lateral wall of the inferior meatus and guarded by a valvelike fold of mucous membrane, (4) be wide open and

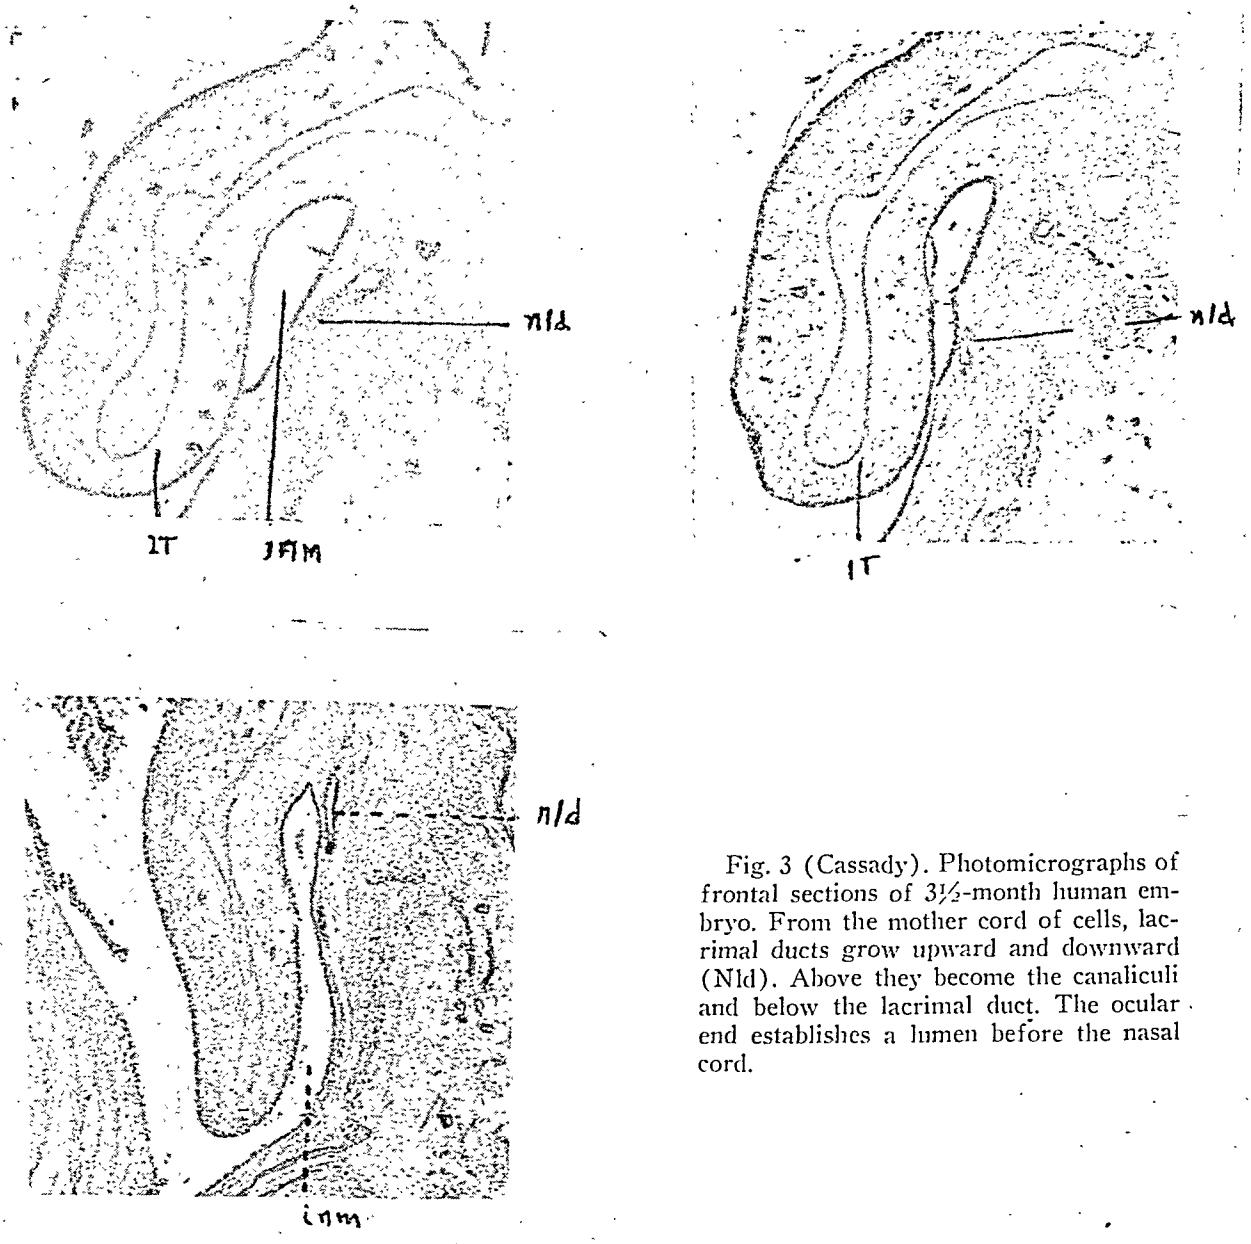

Fig. 3 (Cassady). Photomicrographs of frontal sections of 3½-month human embryo. From the mother cord of cells, lacrimal ducts grow upward and downward (Nld). Above they become the canaliculi and below the lacrimal duct. The ocular end establishes a lumen before the nasal cord.

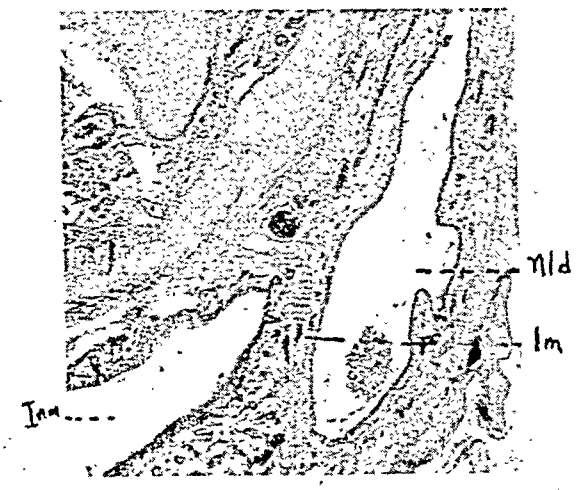
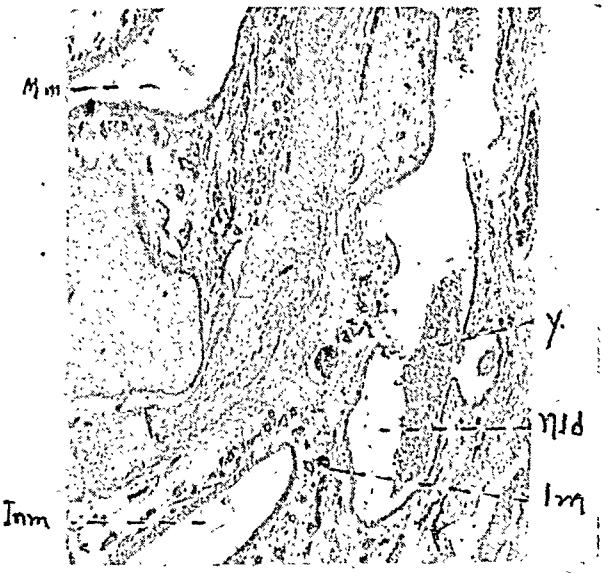
and extent of coalescence between the nasal end of the mother cord and the nasal mucosa." This description is that of J. Parsons Schaeffer. He further goes on to say, "The nasal ostium of the duct may (1) fail of canalization, and its membrane remain in-



adequate." (See Figures 1, 2, 3, 4, 5, 6, and 7.)



Schwartz, in 1935, after examining 207 nasolacrimal ducts in fetuses in the 8th, 9th, and 10th fetal months, found 35 percent had atresia or an imperforate lumen of the nasal

ostium. Some of these were associated with a terminal cyst or bulla and were ruptured by the trauma incident to delivery. The closed lumen was present in the stillborn in about the same proportion as in the older fetuses.

brane separating its lumen from the nasal cavity, indicate that passing a probe through into the nose should be the preferred method of treatment.

Prolonged conservative treatment, with

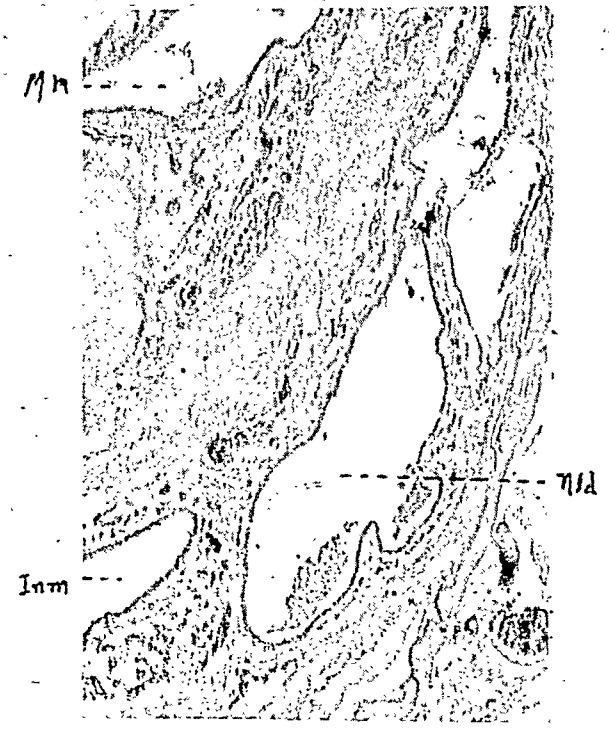


Fig. 4 (Cassady). Photomicrographs of section of the nasal end of the lacrimal passages in a full term, stillborn infant. A septum (Lm) separates the unruptured duct and the inferior meatus. The entire thickness of the nasal mucosa and that of the lacrimonasal duct abut against one another to occlude the lumen of the duct. Detritus (Y) is seen within the lumen of the duct.

The delayed development of the nasal ostium of the nasolacrimal duct, its failure to open at or near birth, the high incident of atresia of the duct, yet its practically complete lumen except for the imperforate mem-

its resultant sac distention, trauma, and infection of the passage, is likely to result in permanent distention and loss of elasticity, as well as endangering the eye from a purulent dacryocystitis. Several instances of loss

of an eye from dacryocystitis in infancy are reported in the literature (Granstrom, 1938).

"Atresia in the newborn is due to an unruptured lacrimal nasal membrane and in these surgical intervention may be necessary (Schaeffer)." Schaeffer, in a personal communication, is of the opinion that Schwartz's figure of 35 percent imperforate nasolacrimal ducts at birth is a conservative one.

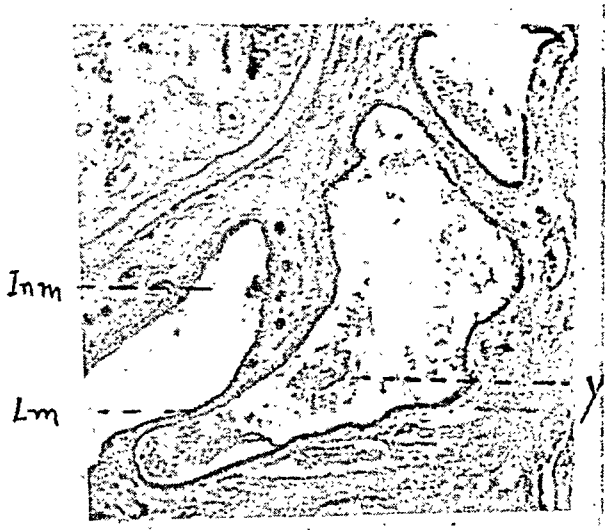

Fig. 5 (Cassady). Photomicrographs of section of the lower end of the nasolacrimal duct of a stillborn infant. The nasolacrimal membrane (Lm) separating the lower end of the duct from the inferior meatus (Inm) is very thin, but unruptured. Detritus (Y) is in the dilated lumen of the duct.

Incidence of dacryocystitis

A large percentage of nasolacrimal membranes are not ruptured at birth. The incidence of dacryocystitis of infancy has been reported as 1.75 percent in some 1,500 infants. In a local series of 279 infants, dacryocystitis occurred in 14 instances or 5 percent. This latter figure probably is higher than usual because special inquiry was made by pediatricians and careful examination for dacryocystitis was done in each of the 279 infants.

The reason why infection of the nasolacrimal sac is not seen more often is probably due to the fact that, although a patent lumen may not exist at birth, tears do not form at once and the need for patency of the duct does not occur until later. There are no definite figures in the literature as to just how early tears occur in infants. In an investigation of this subject in newborns and infants by our local pediatricians, the same 279 infants were investigated by asking their parents to note when they first cried tears. The time at which tears appeared varied from 1 to 12 weeks. The average time at which tears first appeared was at 3⅓ weeks.

Although the lacrimal passages may not be patent at or near birth, it is probable that they become patent within the first week or two after birth, before tears start. If dacryocystitis develops, it may resolve spontaneously as soon as the patency of the duct is established. This may occur without probing the duct if prolonged conservative treatment and watchful waiting are employed. If, however, the duct is not patent by 2 or 2½ months, or when these patients appear in the ophthalmologist's office for advice, it is unlikely that the membrane will rupture spontaneously.

Method of treatment

In 100 cases of dacryocystitis in infancy that I have seen and treated, so-called radical treatment was used; the duct was probed open at once without a trial period of conservative treatment. In almost all of these cases, an attempt to wash the sac with a lacrimal syringe showed the duct impatent and the solution would not go through into the nose. Only after the nasal duct was probed and its patency established would the solution go through. In other words, there is a membrane separating the nasal from the lacrimal duct mucosa. This obstructs the lower end of the nasolacrimal duct and its rupture is essential to establish free passage through the duct. As long as obstruction or an imperforate lumen exists into the nose, dacryocystitis persists. Local treat-

ment of the dacryocystitis with antiseptics or antibiotics may clear up the infection in the sac, but the sac will not remain clear and function properly until the lumen is open into the nose. Treatment which does not establish a lumen is too conservative and results in prolonged sac distention with more trouble than from radical treatment.

In my cases, the dacryocystitis subsided promptly with 1 or 2 treatments and in three fourths of the instances subsided within a few days to a week after probing. In other words, although there was a dacryocystitis of 2½ to 3 months' duration before probing was done, one office treatment was all that was necessary to cure the disease.

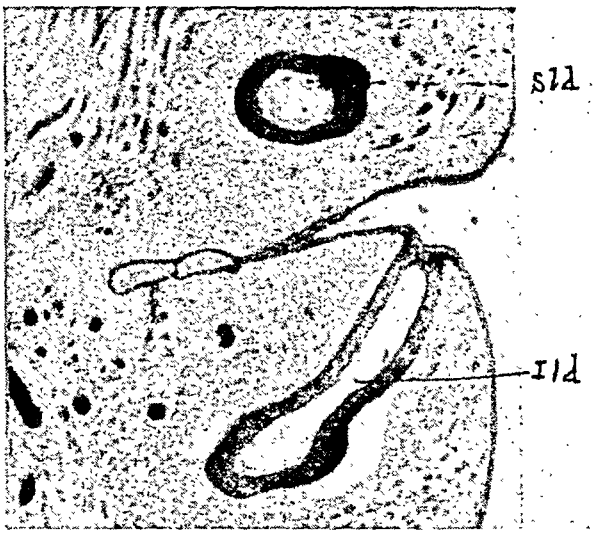

Fig. 7 (Cassady). Photomicrograph of section showing the upper and lower canaliculi, the lower at its vertical portion, the upper at its horizontal portion with patent lumen.

Technique of probing

Topical local anesthesia was used along with restraint of the child. The child was tightly swathed with the arms extended at the sides. The shoulders and head were held by the nurse. Pontocaine or butyn conjunctival instillations were used, and the duct was probed. The operator sat at the head of the table looking down toward the lower canaliculus, the illumination behind him directed at the punctum.

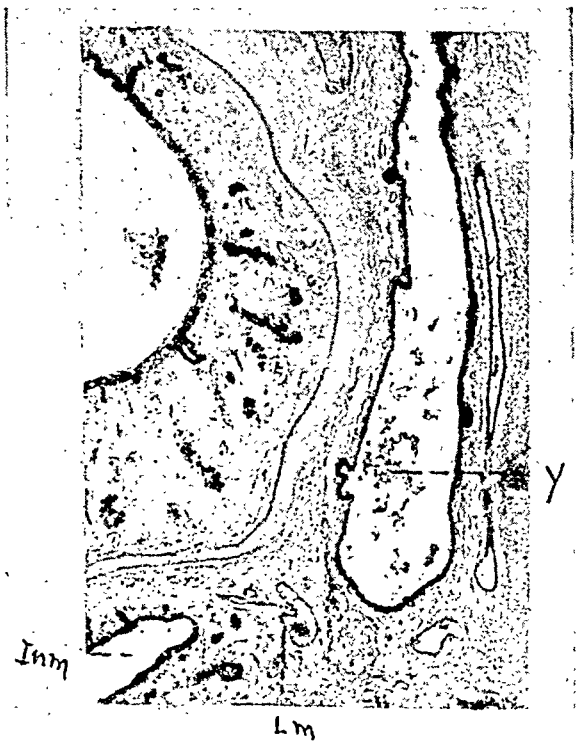

Fig. 6 (Cassady). Photomicrograph of section of the nasal end of a nasolacrimal duct in a stillborn full term infant. Although serial sections were used to find a thin lacrimal nasal membrane (Lm), no thinner could be found.

A conical punctum dilator was used to allow the introduction of a 23-gauge, 1-inch lacrimal cannula attached to a 2-cc. syringe containing normal saline. As soon as the cannula entered it, the sac was irrigated. As the cannula struck the osseous wall, it was turned from the horizontal to the vertical position where it passed easily down through the duct. Resistance of the membrane at its lower end is felt just before the cannula enters the nasal cavity. Perforation of this membrane is assured when the saline solution is injected and the infant swallows solution as it runs back into its throat.

The cannula attached to the syringe is used instead of a Bowman probe to simplify the procedure so that the irrigation and the probing can be accomplished with one probing of the duct.

A solution of penicillin, 2,500 units per cc., is prescribed as instillation drops for use at home for a few days after the office

treatment. If pus is still present in the sac at the next visit, the probing and irrigation are repeated. It is then possible to determine with the cannula whether or not the duct is patent. If it is plugged, the solution cannot be irrigated through into the nose until the canal is again probed.

Results

If carefully done, there is no danger from this type of treatment. In 100 cases, only one instance of a false passage occurred. This ballooned the tissue outside the lumen of the duct with saline. In this instance, the probe was withdrawn, reintroduced into the upper puctum and canaliculus, and the patency of the duct was established without untoward effect. The subcutaneous edema promptly disappeared, and the dacryocystitis had entirely cleared up within a week. The best security against creating a false passage is adequate immobilization of the child and careful, gentle handling of the cannula.

The average length of treatment using this method was between 10 days and 2 weeks. Some sac infections which had persisted for several months did not clear up with a single probing. The sac was distended and stretched with an infected mucosa for such a period of time that it had lost its elasticity and recuperative ability. When probing is delayed until the infant is six months of age, the ducts may not, in fact very often do not, clear up with one probing. If the duct is probed at the first visit to the eye physician, usually by 2 or 3 months of age, the infection clears up quite promptly and there are no untoward persisting symptoms.

Conclusions

A review of the developmental anatomy of the nasolacrimal duct shows that frequently the lumen of the duct is not patent at birth. About one third of newborn infants have a membrane over the lower end of the duct separating it from the nasal cavity. This is a common developmental defect which may or may not rupture before the passages are needed for tears. Tears first appear on an average at about 3½ weeks of age. The lumen is usually established by rupture of this membrane before tears start but if it is not, the sac distends, becomes infected, and dacryocystitis of infancy occurs. The incidence of this disease varies from 1.75 to 5 percent. Sometimes it will resolve spontaneously if the membrane ruptures but, in most instances, probing the duct is necessary to rupture the membrane mechanically.

The majority of articles in both the ophthalmic and pediatric literature advocate a long period of conservative treatment of dacryocystitis of infancy. The writers warn against early probing of the duct as being dangerous and radical and an unjustified method of treatment. In my own series of cases and also in those cases, reported in the literature, which did not respond to prolonged conservative management, the dacryocystitis subsided as soon as the duct was opened. (See Figures 4, 5, and 6.)

Summary

1. Tears start to form and appear at about 3½ weeks of age.

2. The incidence of dacryocystitis in infancy is somewhere between 1.75 and 5 percent.

3. Prompt subsidence of dacryocystitis can be obtained as soon as the lumen of the duct is adequately patent.

4. Early probing of the duct produces no untoward injury providing it is carefully and gently done.

5. Early probing of the nasolacrimal duct in infants is the method of choice for prompt subsidence of symptoms.

ANATOMIC FACTORS IN THE ETIOLOGY OF HETEROTROPIA*

RICHARD G. SCOBEE, M.D.
St. Louis, Missouri

The present status of our knowledge of the etiology of heterotropia leaves much to be desired. There are almost as many classifications of heterotropia as there are ophthalmologists to enumerate them. One finds much overlapping in the various existing classifications and often there is frank disagreement. It has been said that when there are many treatments for any disease, their very multiplicity is excellent evidence that no single treatment is satisfactory; just so the many existing classifications of heterotropia make them all suspect to a certain degree. It is the purpose of this paper to present a rearrangement of the usual classification of the types of heterotropia based upon factual evidence and to suggest an outline of treatment based upon this classification.

CLASSIFICATION OF TYPES OF HETEROTROPIA

Most classifications have at least three main categories: (1) anatomic, (2) innervational, and (3) paretic. Under *anatomic,* there are listed such things as "muscles too large or too small," "unusual attachments of muscles," and, rarely, "complete absence of a muscle."

In the *innervational* group are lumped all heterotropias which seem to be on a basis of refractive error, all of those with an anomaly of either convergence or divergence, those with "a weak fusion faculty," those without obvious cause, and all cases wherein fusion is impossible by virtue of some organic obstacle such as cataract, retinal detachment, hole in the macula, unilateral optic atrophy, congenital amblyopia, and so forth.

The *paretic* group contains those patients with heterotropia due either to trauma or noxae or those with congenital paresis.

The conscientious ophthalmologist must sooner or later become dissatisfied with such a classification because he will encounter some cases that are "neither fish nor fowl." A closer study of these particular cases makes one suspect that many of them may be partly innervational, partly paretic, and partly something else. While all writers faithfully include the *anatomic* category, few cases are ever actually reported as belonging to this group and the average clinician seldom even considers it in making a diagnosis. The few cases which have appeared in the literature as belonging in this group were rarely if ever diagnosed before the patient was on the operating table and the diagnosis was often a subject of some consternation to the surgeon.

Chavasse[1] made an admirable attempt to explain the heterotropia associated with accommodative effort or the lack of it, yet one often sees patients that will not fit into his classification. Chavasse was, of course, fully aware of these misfits and said of them that they were patients in whom ". . . there is a lag in the development of the reflex which settles the rival claims of accommodation and convergence." What he neglected to say was that the foregoing comment might be made about almost any patient with heterotropia and can neither be proved nor disproved.

Having made these prefatory remarks, a statement can be made that will undoubtedly be considered rash. *Ninety percent of all cases of heterotropia appearing in the first six years of life have some underlying ana-*

tomic cause for the deviation. Is this heresy? It will seem so to many. A consideration of the evidence is in order.

Anatomic factors

The anatomic factors playing an important role in the etiology of heterotropia are three in number: (1) Abnormal check ligaments, (2) abnormal muscle slips, and (3) abnormal insertions. They will be considered in that order.

The check ligaments

The check ligaments of the oculorotary muscles are familiar, at least by name, to every student of ophthalmology. They are one of the subdivisions of the fascia of Tenon and arise from the sheath of each of the oculorotary muscles. They are faithfully mentioned in all texts on anatomy and carefully depicted, with those of the medial and lateral rectus usually being chosen for the illustration. The picture—always diagrammatic—suggests that each oculorotary muscle has a check ligament and this ligament is shown arising perpendicular to the muscle from its sheath and running a course parallel to the line of pull of the muscle. The check ligaments, however, are not as simple as the usual description implies, nor may they be dismissed with no more than a mere mention if one is truly interested in the etiology of heterotropia and of heterophoria.

These ligaments arise from the muscle sheaths and are inserted, for the most part, into the orbital wall—really into the periorbita. Parts of the check ligaments on the medical and lateral rectus are inserted into the medial and lateral palpebral ligaments and into the medial and lateral conjunctival fornices respectively. The ligament of the medial rectus is also inserted into the lacrimal caruncle. Whitnall[2] wrote that ". . . these expansions of the sheaths draw the fornices of the conjunctiva backwards, exactly as muscle fibers adjacent to joint capsules draw the slack of synovial membranes out of the way in extension, but a more important function is that by their fixation to the orbital walls they anchor the whole fascial apparatus of the globe in position."

Appropriately named *check* ligaments, their primary function is quite obviously one of preventing or checking excessive excursions of the globe which would be produced by the oculorotary muscle from whose sheath the ligaments in question arose. For example, the check ligaments of the medial rectus prevent excessive adduction of the globe, while those of the lateral rectus prevent excessive abduction. This fact is as obvious as it is well known.

What is not so well known is the fact that the check ligaments may serve to check movement *in two directions.* Not only may they serve to prevent any excessive rotation which might be produced by the muscle from whose sheath they arise, but they may also prevent effective relaxation of that same muscle when its antagonist is contracting if they are abnormally developed. A muscle that is constantly prevented from attaining full relaxation when its antagonist contracts becomes at first a tonically contracted muscle and later a moderately fibrotic one with a consequent loss in elasticity—a tremendously important fact in patients with heterotropia.

One need not necessarily go to the dissecting room to study the check ligaments. The ophthalmic surgeon in the course of an operation for heterotropia is presented with an unexcelled opportunity to study these ligaments if he cares to do so. And he has the advantage over the cadaver anatomist in that he is working with fresh, living, normally colored tissues.

The medial rectus is probably attacked by the surgeon more frequently than any of the other oculorotary muscles and its check ligaments offer more variation than those of any other muscle. They cannot be adequately and properly inspected and studied until the insertion of the medial rectus has been severed from the globe.

The medial rectus always has one check ligament running in the horizontal plane of the globe and this is the one so carefully depicted in all textbooks. It arises from the sheath just as does the dorsal fin of a fish at a point between 6 and 8 mm. posterior to the insertion of the muscle itself into the sclera. Even in the nonheterotropic patient

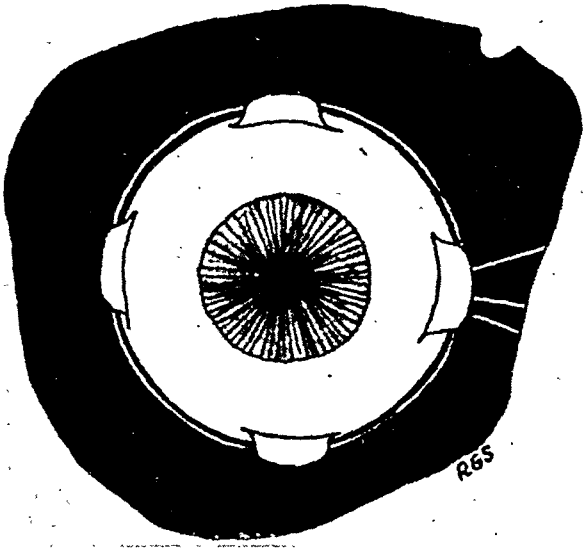

Fig. 1 (Scobee). Schematic diagram of the right eye viewed from the front showing the normal check ligaments on the medial rectus muscle. The intermuscular membrane is also shown as a thin white line running between all of the rectus muscles.

it is moderately thick and can be nicely visualized when put on a stretch by pulling the severed end of the medial rectus forward and toward the center of the cornea. Occasionally two very thin additional check ligaments are found in the normal person, one above and one below the main horizontal one. All three ligaments are shown in Figure 1.

In the patient with esotropia, several variations from the normal may be found, either separately or in combination. There may be any or all of the following: (1) Extra and thickened check ligaments, (2) fused check ligaments, and (3) posterior check ligaments.

(1) *Extra and thickened check ligaments.* A frequent finding is that of additional,

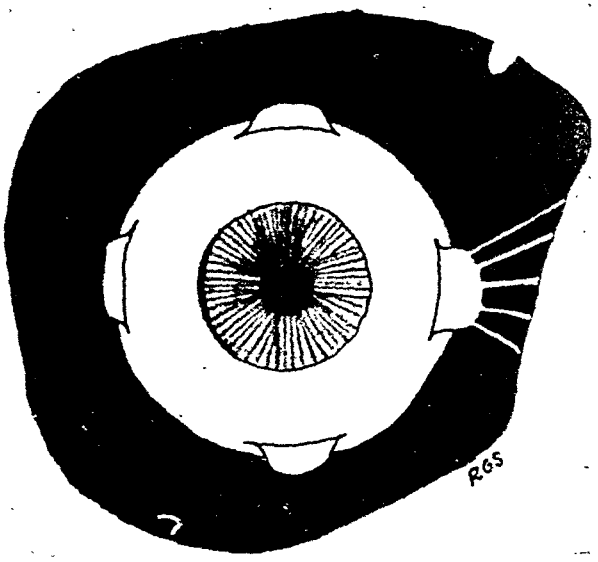

Fig. 2 (Scobee). Schematic diagram of the right eye showing extra and thickened check ligaments which are abnormal. The intermuscular membrane is not shown.

thickened check ligaments. The normal main horizontal ligament is present and quite obviously thickened and somewhat contracted. Extra check ligaments arise from a line paralleling the origin of the main ligament and either just above or just below it, as shown in Figure 2. They lie in planes which are oblique to the horizontal, in such a way that when put on a stretch they seem to fan out like the pages of a book from its binding when the covers of the book are purposely held wide open.

(2) *Fused check ligaments.* If the esotropia has been present from birth, it is not at all unusual to find that the 3 or 5 ligaments shown in Figure 2 are apparently fused together into a thick solid mass running from the muscle sheath to the orbital wall as in Figure 3. Such a mass is a dense ligamentous anchor which not only prevents excessive adduction by the medial rectus but it also prevents a normal excursion of the globe in abduction as well. Patients with esotropia and the fused type of check ligaments on the medial rectus will show:

(a) Definite although perhaps slight limitation of abduction of that eye in preoperative examinations.

(b) An absence of divergence of the

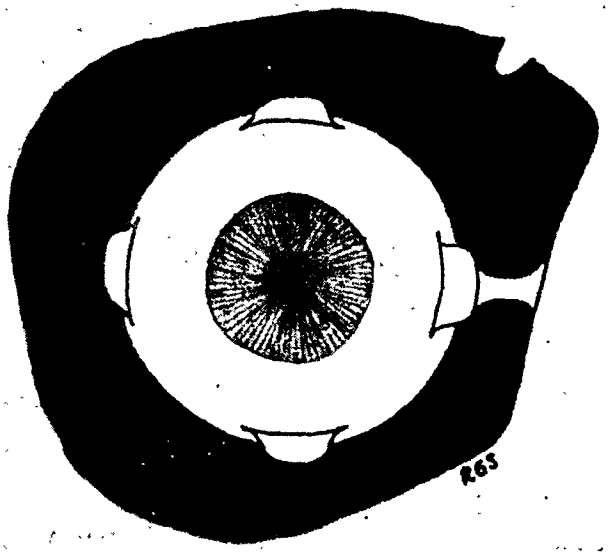

Fig. 3 (Scobee). Schematic diagram of the right eye showing a fused type of check ligament. It is quite thick and seems to be the product of fusion of several smaller ligaments. The intermuscular membrane is not shown.

eyes under general anesthesia, the esotropia either remaining constant in degree or decreasing only slightly.

(c) If, under general anesthesia, a muscle hook is placed in the lateral conjunctival fornix and depressed, this attempt to abduct the eye forcibly will result in a definite feeling of resistance to the abduction, and if abduction is forced by this method, the globe can easily be seen to retract.

(3) *Posterior check ligaments.* A final variation from the normal in the check ligaments of the medial rectus muscle in the esotropic patient is what could probably best be called a posterior check ligament. The normal check ligament arises from the muscle sheath just posterior to the level of the equator of the globe and when the ligaments are divided this far back, the external surface of the medial rectus is normally freed. A posterior check ligament, however, arises from the muscle sheath far back in the orbit and runs just as far anteriorly, inserting into the medial orbital wall along its entire course as shown in Figure 4. In order to section such a posterior ligament, one must often invade the orbit for a distance of perhaps 5 mm. past the level of the posterior pole of the eyeball. Until such posterior check ligaments are cut, the medial rectus will not stretch freely nor retract properly and the globe will not abduct as freely as it normally should.

Three variations from the normal check ligaments on the medial rectus muscle in patients with esotropia have been described:

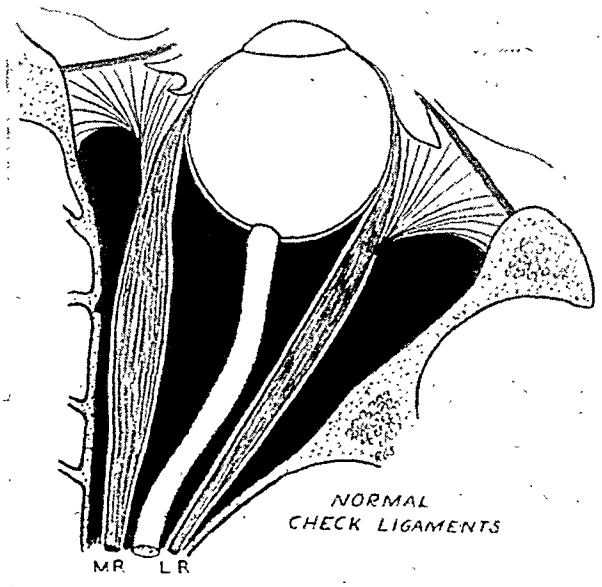

Fig. 4a (Scobee). Schematic diagram of the check ligaments of the horizontal muscles of the right eye as viewed from above.

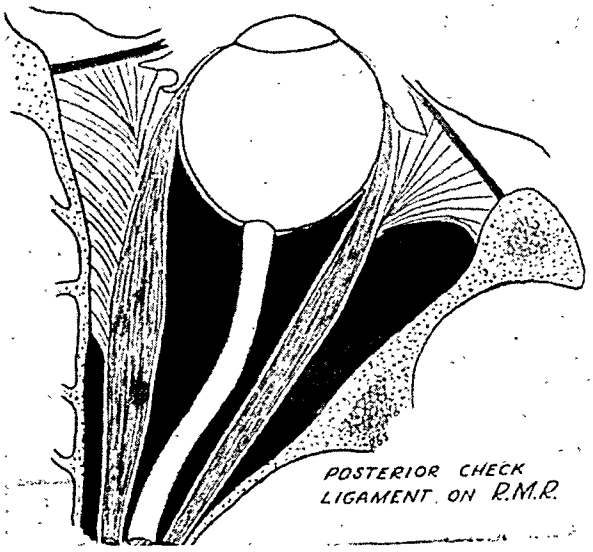

Fig. 4b (Scobee). The same as Figure 4a except that a posterior check ligament is present on the right medial rectus, and this is a definite anatomic anomaly.

(1) Extra and thickened check ligaments, (2) fused check ligaments, and (3) posterior check ligaments. The existence of any one or of all three together will prevent proper abduction of the globe with a muscle hook under general anesthesia, and may cause retraction of the eyeball if abduction is forced. The conscientious surgeon can, therefore, predict an abnormal check ligament or some other anatomic abnormality before he ever makes any incision at all.

free and unattached to retract indefinitely back into the orbit. On the contrary, the cut tendon retracts only from 3 to 5 mm. or even less because the capsule of Tenon which envelops the muscle is attached to the sclera at about the same distance from the cornea as the tendon insertion, and its connection with the muscle is sufficiently firm and intimate to serve as a secondary attachment for the muscle."

This structure running between the rec-

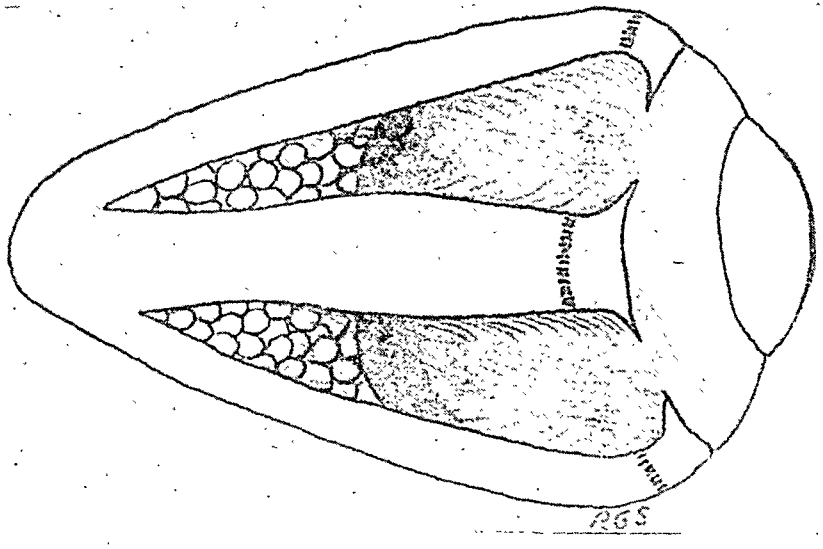

Fig. 5 (Scobee). View of the left eye from the medial surface to show the intermuscular membrane. The superior, medial, and inferior rectus are shown; running between them is the intermuscular membrane which is fairly dense anteriorly and thins perceptibly as it is traced posteriorly.

Two other check ligaments are invariably found on all of the rectus muscles, although they have not been called by that name. Lancaster[3] described them as follows: "The rectus muscles are inserted into the sclera by tendons the length of which is about half the diameter of the cornea. The width of the insertion is about equal to the diameter of the cornea. But these tendons and insertions do not represent the whole method of attachment of the muscles to the eyeball. Both surfaces of each muscle are covered with a thin layer of connective tissue which is the capsule of Tenon. These layers blend or unite at the edge of the muscle and continue as a single layer to the edge of the next muscle where it splits to cover both surfaces of this muscle, and so on around the eyeball. When the tendon is cut at its insertion into the sclera, the muscle and tendon are not left

tus muscles has been called the *intermuscular membrane* and it is shown in Figure 5. The check ligaments are fascial extensions of the muscle sheaths. The intermuscular membrane is an extension of the muscle sheaths. The check ligaments insert primarily into the periorbita while the intermuscular membrane inserts into the sclera. Both the check ligaments and the intermuscular membrane serve as secondary attachments of the muscles, both are subdivisions of the fascia of Tenon, and both may exert a checking action on excursions of the globe. Jameson[4] described the checking action of the intermuscular membrane and this will be considered in some detail in a subsequent paragraph. Suffice it to say that both the check ligaments and the intermuscular membrane can be considered as *check ligaments.*

There are three points about the check

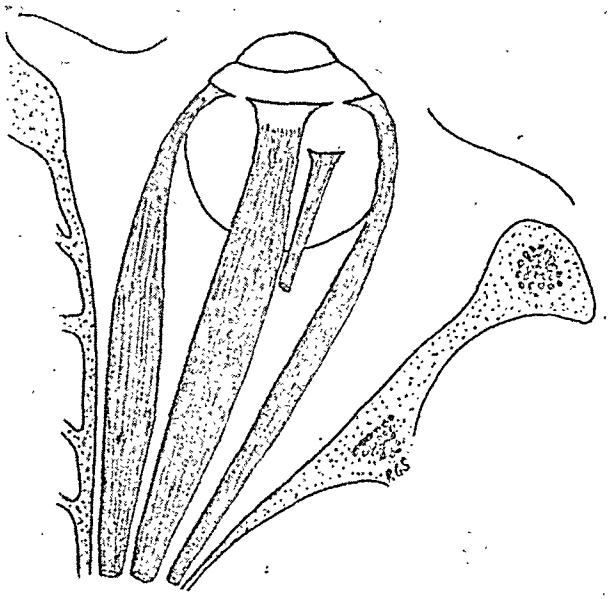

Fig. 6 (Scobee). Schematic diagram of the right eye as viewed from above showing the insertion of an abnormal muscle slip laterally and somewhat posteriorly. The slip appears to have arisen back in the orbit from the superior rectus but, since this is not certain, no definite origin is shown. A similar situation was found on the left eye of the patient mentioned in the text.

ligaments in heterotropia which must be emphasized:

(1) All anatomists have implied that any fascial expansion of the muscle sheaths are check ligaments. Therefore, the intermuscular membrane is a check ligament.

(2) The externally directed check ligaments, that is, those running to the orbital walls, are not a single fascial plane in the patient with heterotropia, but there may instead be several fanning out from each muscle sheath and running to the periorbita. In the case of esotropia, they fan out from the sheath of the medial rectus muscle.

(3) With but a single exception, all writers have pointed out that the check ligaments check *over-action* of the muscle from whose sheath they arise, but the fact that they may also *prevent adequate relaxation* when the antagonist of that same muscle contracts does not seem to be generally recognized at all.

Abnormal muscle slips

Abnormal muscle slips may either arise well back in the orbit and diverge slightly from the course of the rectus muscle which is their apparent source to become inserted into the globe at a point somewhat behind and to one side of the insertion of their parent muscle, or an abnormally large collection of muscle fibers will be found in the intermuscular membrane. The latter condition is by far the more common of the two. Abnormal muscle slips appear in association with the rectus muscles in the following order of frequency: (1) Superior rectus, (2) lateral rectus, (3) medial rectus, and (4) inferior rectus.

As an example of the first type—the abnormal slip inserted posterior to and to one side of the apparent muscle of origin—a 15-year-old girl with intermittent left hypertropia was subjected to two operations. At the first operation, the left superior rectus was receded to the equator. At the second operation, the left inferior rectus was resected some 4 mm. Neither procedure seemed to have any effect on the left hypertropia which became particularly evident in levoversion with the right eye fixing. At a third operation, the left superior rectus was severed from the globe and a muscle hook passed over the entire upper surface of the eyeball.

A muscle slip was hooked in this maneuver which seemed to arise from the superior rectus about half-way back in the orbit; it ran forward and slightly laterally to become inserted into the globe about 4-mm. lateral to the course of the left superior rectus and about 2-mm. anterior to the equator as shown in Figure 6. When the slip was sectioned and the left superior rectus reinserted in its receded position, the left hypertropia disappeared entirely.

A similar case was that of a 5-year-old boy with marked esotropia which appeared, according to the history, at about the age of one year. A slip which appeared to arise from the inferior border of the medial rectus was found and it was inserted below and about 4 mm. behind the normal inser-

tion of that muscle. Section of this slip corrected the deviation entirely and nothing was done to the medial rectus.

The second type of abnormal muscle slip —collections of muscle fibers running in the intermuscular membrane—is encountered much more frequently than the first type. The intermuscular membrane is normally thickest between the superior rectus and the lateral rectus. Not infrequently, patients with an apparent paresis of an inferior rectus and a consequent hypertropia on the same side are encountered. When the forced duction test is applied, definite resistance to infraduction is found in the eye in question. Surgical exploration will usually reveal what appears to be an abnormal and asymmetric insertion of the superior rectus; actually, the superior rectus has a normal insertion but a thick band of muscle fibers runs in the intermuscular membrane toward the lateral rectus and these fibers have a curving insertion into the sclera which extends laterally from the insertion of the superior rectus as shown in Figure 7. A small recession of the superior rectus plus sectioning of this lateral extension of the normal insertion is usually sufficient to correct the hypertropia entirely. Postoperatively, it is obvious that the inferior rectus was never paretic at all but that the abnormal muscle slip associated with the superior rectus prevented adequate relaxation of that muscle when its antagonist was contracting; naturally, the conclusion preoperatively was one of paresis of the inferior rectus.

In exotropia, it is not at all unusual to find an abnormally thick intermuscular membrane running between the lateral rectus and the inferior rectus and it often will contain abnormal bands of muscle fibers. Recession of the lateral rectus plus section of these fibers in their membrane is almost invariably sufficient to correct the deviation. And these abnormal bands, or merely the thickened intermuscular membrane without them, is sufficient to produce a definite feeling of resistance preoperatively when the forced duction test is applied. No resection or advancement of the medial rectus is necessary or even indicated in such cases, and yet they are often mistaken for paresis of a medial rectus and a so-called strengthening operation is performed on that muscle.

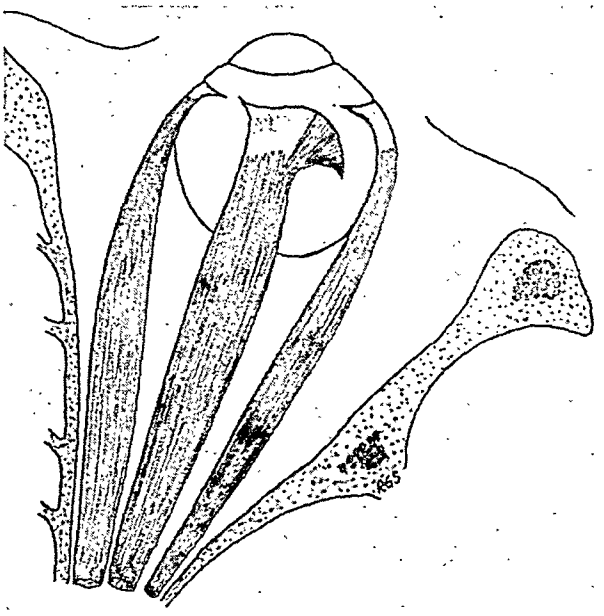

Fig. 7 (Scobee). Schematic diagram of the right eye as viewed from above and showing an abnormal insertion of the right superior rectus. The usual insertion is extended laterally and posteriorly in a curve and the extra insertion contains muscle fibers. Such an insertion is fairly common in patients with hypertropia with a preoperative diagnosis of paresis of an inferior rectus.

Abnormal insertions

At first glance, this category might seem to be an overlapping of the previous one. It is not, however, because what is meant by an abnormal insertion is a foot-plate type of insertion. The insertion line of the muscle at the usual distance from the limbus appears to be normal both in length and in direction. The intermuscular membrane is of normal thickness and contains no bands of muscle fibers. The check ligaments may appear to be perfectly normal.

When the linear insertion of the muscle is severed, however, the muscle will be found to be solidly attached to the globe backward from its linear insertion for a distance varying anywhere from 2 to 7 mm. This large,

broad insertion is solid—in short, a foot-plate—and is depicted in Figure 8.

Prior to surgery, the heterotropia in these cases is often erroneously attributed to paresis of, for example, a lateral rectus because esotropia is present, abduction of the eye is definitely limited, and fixation with that eye results in greater esotropia than fixation with the opposite eye. The latter point is strongly suggestive, of course, of

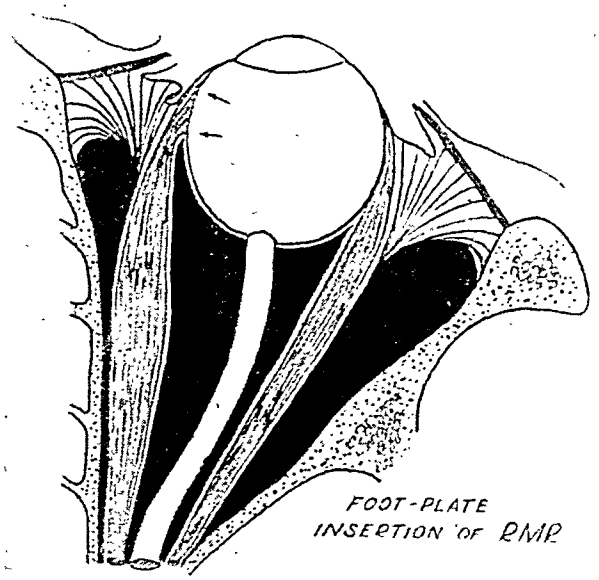

Fig. 8 (Scobee). Diagram of the right eye viewed from above and showing a foot-plate insertion of the right medial rectus. The right lateral rectus has a normal insertion. This solid insertion extends backward about 6 mm. from the normal linear insertion.

primary and secondary deviation following paresis. Indeed it is primary and secondary deviation although it is doubtful that paresis, at least in the usual sense of the word, had anything to do with the origin of the deviation. A muscle that is so attached is usually normal in size and elasticity.

Occasionally one finds such a muscle that has lost some of its elasticity and has apparently become contracted or perhaps even slightly fibrotic; this could well be due to its inability to relax properly over a long period of time when its antagonist contracted. After all, when an agonist is paretic, it is a commonly accepted idea that its antagonist may become contracted and even fibrotic for these same reasons. The presence of such a broad foot-plate insertion is invariably revealed preoperatively in the form of resistance to free rotation of the globe in the forced duction test applied under general anesthesia.

The forced duction test

When the patient with heterotropia is placed under general anesthesia, the tonus of all of the voluntary musculature of the body is markedly reduced. With respect to the oculorotary muscles, this means that they should all relax to the point where forced rotation of the globe in any direction, produced by placing a muscle hook in the conjunctival fornix and depressing it, should be free and easy. In at least 90 percent of all patients with heterotropia which became evident before the age of six years, forced ductions are not free and easy in all directions.

If a patient has esotropia, for example, and under general anesthesia the surgeon forcibly rotates first one and then the other eye outward (in forced abduction) by depressing the lateral conjunctival fornix with a muscle hook, unequal or at least increased resistance of the forced duction will be encountered on the two sides in 90 percent of the patients whose deviation appeared before the age of six years. In addition, the eye offering the greatest resistance to this forced abduction will also often be noted to retract.

When one explores the check ligaments and other attachments of the medial rectus of that eye, almost invariably the cause of the resistance to forced abduction and frequent retraction of the eye will be found. It seems obvious that the retraction is the same, at least on mechanical grounds, as that seen in Duane's retraction syndrome, and is indicative of inability of the medial rectus muscle of that eye to relax adequately

for one reason or another when its antagonist contracts.

O'Connor[5] is certain that the antagonist of a paretic muscle will become contracted before the expiration of the usual one-year waiting period following development of the paresis. He employs a procedure somewhat similar to the forced duction test but with the object of determining whether or not contracture has developed in the antagonist of a paretic muscle. His plan, however, is that of grasping the tendon of the suspected muscle through the conjunctiva with a fixation forceps, the eye having been anesthetized, and exerting traction. If either undue resistance is felt or the eye cannot be rotated through a normal excursion, O'Connor quite justifiably assumes that contracture is present. If one judges correctly from his papers on the subject, he only applies this test to patients with relatively recent paresis and then only in an attempt to determine the time of onset of contracture of the antagonist in order to select the proper time for surgical interference.

The forced duction test can be quickly and easily carried out prior to the beginning of an operation and will yield invaluable information. Its practical application will perhaps be more evident if a few illustrative and typical cases are cited.

A 4-year-old boy who had developed marked alternating esotropia at the age of three had no difference in the angle of deviation with either eye fixing. All available tests indicated what appeared to be a truly concomitant heterotropia. The angle of the deviation measured 25 degrees. Under general anesthesia, marked resistance to abduction was encountered in the left eye with the forced duction test. Surgical exploration of the left medial rectus revealed a fused type of check ligament. This was sectioned and the muscle receded to the equators. The result was 25 degrees of correction and the patient had good second-degree fusion within four months following the operation.

Another patient was a 5½-year-old girl with right esotropia which had become apparent at about three years of age. The deviation measured 32 degrees without her glasses and decreased to 20 degrees with glasses. Her correcting lenses were: +4.0D. sph. ⊃ +0.50D. cyl. ax. 90° in each eye. Voluntary abduction of the right eye was subnormal. The preoperative diagnosis was one of mild paresis of the right lateral rectus. Forced duction tests under general anesthesia elicited definite resistance of the right eye to abduction. The right medial rectus was explored and found to have five large check ligaments fanning out from the muscle sheath to the periorbita. These were sectioned and the muscle was found to be of normal size and elasticity; the muscle was receded 4 mm. The result was 22 degrees of correction. The plus spheres were slightly weakened and the patient soon developed fusion.

Patients with intermittent heterotropia have been the most difficult and unsatisfactory to classify in the past. These are the patients who have relatively high degrees of heterophoria and who lapse into heterotropia with fatigue or any undue usage of the eyes. The patient with between 20 and 30 prism diopters of exophoria who goes into frank exotropia with fatigue is a good example. Careful examination reveals only what appears to be convergence insufficiency or "divergence excess." The deviation, when elicited, is the same with either eye fixing. And yet forced ductions will almost invariably reveal increased resistance to adduction in both eyes, often unequal on the two sides. Surgical exploration of the lateral recti will usually reveal large check ligaments, particularly in that portion of the intermuscular membrane running downward to the inferior rectus. Often enough, this thickened membrane between lateral and inferior rectus will contain a band of muscle fibers. These abnormal bands have already been discussed as abnormal muscle slips. Section of all check ligaments and bands and

recession of the muscle are all that is needed if the deviation be not too great. If it is great, both lateral recti must be receded.

Dealing with anatomic factors

One might inquire as to why simple division of the abnormal attachments previously described should not be enough to correct the deviation, provided they were responsible for the deviation originally. In the first place, check ligaments acting in two directions can prevent adequate relaxation as well as over-contraction and thus lead to some degree of loss of elasticity, even to contracture and fibrosis in a muscle. Certainly it is not reasonable to expect that correction of the anatomic anomaly alone will correct the heterotropia in the face of the subsequent changes—that is, loss of elasticity, contracture, and fibrosis—which have occurred. In the second place, there may have been other etiologic factors in addition to the anatomic one.

Consider the patient with esotropia which appeared at about the age of three years. The eyes and the orbits are markedly divergent before birth, become less so at birth, and as the skull and its contained structures grow in infancy and childhood, the tension on the anatomic anomaly in the attachment of the medial rectus increases. This would mean that the position of rest in such a patient would be one of less-than-normal divergence at birth and one of decreasing divergence as growth proceeded. Meanwhile the growing child is discovering his developing powers of visual acuity and of accommodation. As he begins to see objects more clearly, he begins to attempt and to succeed in exerting more and more accommodation with its associated convergence. We have seen how the position of rest in such a patient instead of being one of frank divergence is one of little or no divergence—almost parallelism; furthermore, full abduction is impossible because of the anchoring effect of the anatomic anomaly on the medial rectus. The exercise of accommodation and convergence, when beginning from a position of rest of near-parallelism, is sufficient to produce frank esotropia. And this would be true *irrespective of the refractive error of the individual,* as long as anatomic anomalies were present either in the check ligaments, the muscle insertions, and so forth.

Hypermetropia is considered by many as a developmental anomaly in that the hypermetropic eye is usually a small eye, presumably one whose growth was arrested before attaining emmetropia. Abnormal anatomic attachments of the muscles are certainly developmental anomalies. The finding of one anomaly frequently means that others are present. This, then, is a possible explanation for the frequent association of hypermetropia with esotropia. However, the refractive error need make no difference, and esotropia in the myopic infant can also be explained on the basis of an anatomic anomaly; the same is true for anisometropia.

It does not seem likely that the majority of anatomic anomalies described in the muscle attachments could be sufficient in themselves alone to produce heterotropia except in such rare instances as strabismus fixus. However, the addition of the accommodation-convergence relationship, for one thing, can act as a precipitating factor in producing the deviation. Thus it is that a majority of cases of heterotropia have a definite and demonstrable accommodative element but almost invariably there can be demonstrated some underlying anatomic defect; otherwise the eyes would never have deviated in the first place except in a few instances.

When one operates on patients with paretic heterotropia of recent origin, these anatomic anomalies—that is, abnormal check ligament, abnormal muscle slips, abnormal insertions—are not found. And when one dissects the nonheterotropic cadaver orbit, these anatomic anomalies are not commonly found. They occur only in patients with heterotropia or with marked degrees of heterophoria. Surely their almost invariable

presence in patients with heterotropia and their invariable absence in patients without heterotropia is significant.

It does not seem likely that the existence of heterotropia could result in changes in the fascia of the check ligaments, and certainly it could not cause the development of abnormal muscle slips and abnormal insertions. Such an idea has been considered before, however, because Jameson[4] wrote:

"I think that it is not exceeding rational reasoning to consider that any eye deflected for many years acquires fascial contractions conforming to the fixed position of the globe in which the capsule (he refers to the intermuscular membrane) is an important part, and it is still within reason that a check ligament not called on to perform its function of a shock deterrent on the opposing side for a number of years may lose some of its elasticity and capability of stretching and assuming contractility, and may act as a deterrent to outward rotation."

One cannot disagree with Jameson on factual grounds about the patient who has had esotropia for 20 years; definite argument can be raised, however, about the child patient whose esotropia did not appear until the age of three years and who is subjected to surgery within 3 or 4 months after the deviation appeared because the same anatomic anomalies are found in the 3½-year-old child as in the 23-year-old adult patient.

The conclusion is therefore thrust upon us that the anatomic abnormalities preceded the heterotropia in point of time and that the heterotropia is at least partly due to these anatomic findings which have been described.

Method of inspection

The technique of searching for the anomalies described is simplicity itself and yet is followed by only a few. The muscle toward which suspicion is directed by the forced duction test, as well as by examinations preoperatively, is exposed on a muscle hook. A double-armed suture is placed through the tendon as close to the insertion as possible, the suture locked, and the tendon then severed from its insertion. Traction is made on the severed muscle by means of the double-armed suture and the muscle is pulled first away from the globe. This maneuver enables the operator to see whether or not a foot-plate type of insertion is present; if found, it may be divided.

The muscle is next pulled forward and toward the globe and the lips of the conjunctival incision are held apart by an assistant using forceps; the external check ligaments are thus put on a stretch and may not only be visualized but sectioned with scissors. It is to be emphasized that this is not a procedure of stripping the muscle of its sheath (to which there are serious and valid objections) but merely one of cutting the fascial extensions from the muscle sheath; no bare muscle is exposed. The check ligaments should be sectioned as far posteriorly as they may extend. If visibility is not good as one goes backward into the orbit with the inspection, a muscle hook can be passed gently backward along the orbital or external surface of the muscle. The check ligaments are not properly severed until this hook can be passed well beyond the posterior pole of the globe without encountering resistance.

Finally, in the case of the medial rectus, the muscle is pulled first upward and then downward in order that the intermuscular membrane can be inspected for thickness and the presence of abnormal muscle slips; the membrane should then be sectioned parallel to the borders of the muscle and a millimeter or so away from it, as shown in Figures 9 and 10.

When all anatomic anomalies of attachment are properly and completely sectioned, the muscle will usually retract promptly out of sight into the orbit when the tension on the muscle suture previously placed in the tendon is released. Once the muscle is thus freed, one may estimate its elasticity because this has an important bearing upon the amount of recession to be performed. As

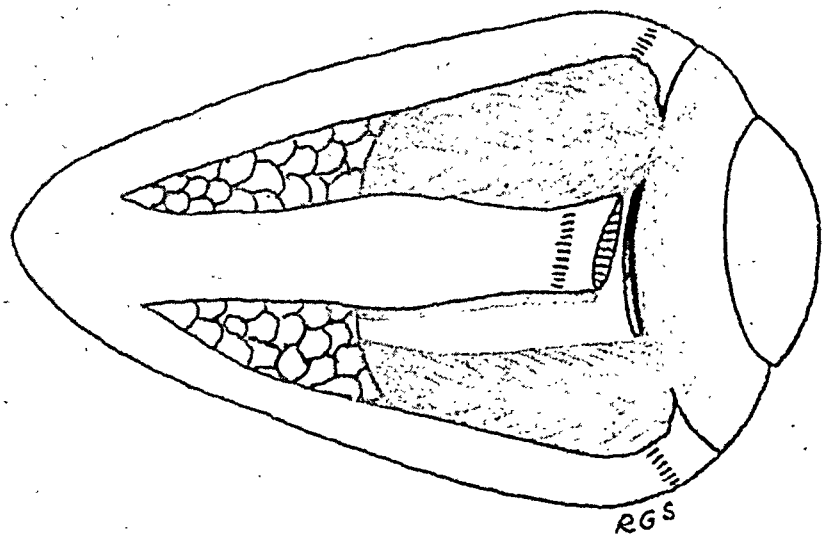

Fig. 9 (Scobee). View of the left eye from the medial surface showing the left medial rectus severed from the globe and the intermuscular membrane sectioned parallel to the lower margin of the muscle. Sclera is visible where the muscle has retracted and the intermuscular membrane pulled aside.

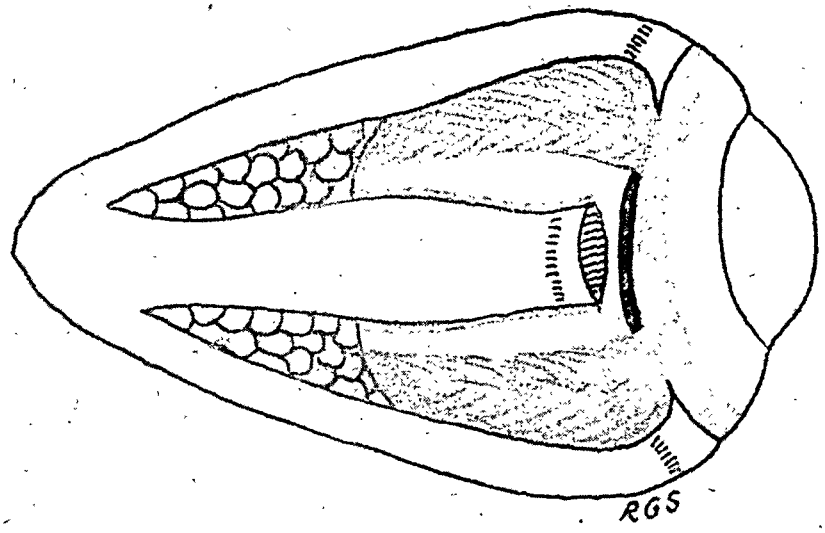

Fig. 10 (Scobee). The procedure of sectioning the intermuscular membrane (begun in Figure 9) has been completed. The muscle is now freed completely both superiorly and inferiorly. The other check ligaments are not shown.

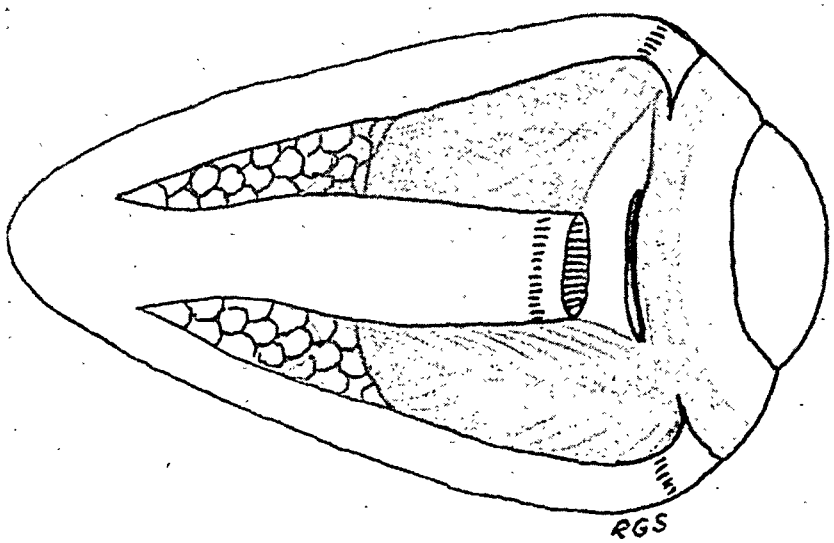

Fig. 11 (Scobee). The left eye viewed from the medial surface and illustrating Jameson's method of cutting the intermuscular membrane vertically. The left medial rectus has been severed from its insertion and a vertical cut started in the intermuscular membrane running upward toward the superior rectus. Jameson advised making a similar cut below toward the inferior rectus.

a final step, a muscle hook should be swept over the portion of the globe involved in a search for any abnormal muscle slips attached behind and to one side of the muscle under inspection.

The check ligaments should always be divided by sharp dissection, that is, with scissors, and never by blunt dissection as by tearing them with a muscle hook forced along the muscle edges because the latter procedure rarely severs all of the check ligaments, often tears the sheath from the muscle leaving bare fibers exposed, and almost invariably leads to the formation of troublesome adhesions which may partially negate the effect of the operation. When the muscle is properly freed, it may then be reinserted at whatever site is desired and the conjunctiva closed.

Objections to sectioning check ligaments

Many surgeons raise objections to any suggestion of cutting the check ligaments in the manner described in previous paragraphs. When pressed for reasons for their objections, a vague reference to retraction of the caruncle is the usual answer. Jameson[4] was one of the most prominent to counsel avoidance of the check ligaments and he, apparently, was also saddled by the bogey of "retraction of the caruncle." In speaking of his recession operation, he wrote ". . . the semilunar conjunctiva is also undermined in the direction of the caruncle, with care not to disturb the fascial trabeculae or areolar tissue on the surface of the muscle." And ". . . the areolar tissue in which the muscle is deeply imbedded in the region of the caruncle should not be sliced. If this is done, the muscle is endangered, the anatomy disarranged, and the reaction will be greater." And yet Jameson was the first exponent of complete division of the intermuscular membrane and he cut it vertically as shown in Figure 11. When first reporting his operation in 1922, he cautiously wrote that ". . . there has been but slight retraction of the caruncle and that difficult to distinguish and of negligible quantity." After 10 years of experience with his operation, he confidently reported in 1931[6] that ". . . it has been most noticeable that no caruncular retraction or inversion has occurred."

It will be recalled that some of the worst instances of retraction of the caruncle followed free tenotomy of the medial rectus. When one considers the anatomy, the reason is obvious. The medial rectus is attached by means of its check ligaments to the caruncle. When a free tenotomy is done, the muscle naturally retracts somewhat, tensing its check ligaments, and retracting the caruncle. On theoretic grounds, one would expect less retraction of the caruncle when the check ligaments are severed than when a recession is done and they are left intact. This is adequately borne out in a series of over 120 patients in whom the check ligaments of the medial rectus were completely divided by the technique previously described and not a single patient had a retracted caruncle.

It is difficult to see how Jameson could claim that sectioning the check ligaments would "disarrange the anatomy" any more than his free vertical sectioning of the intermuscular membrane. And he would have come much closer to the truth, perhaps, if he had not avoided them. He wrote[6] that ". . . even after this vertical capsulotomy is accomplished, forcible traction meets with obstruction to rotation in a few cases. The reasons are hard to fathom when both muscle and capsule are freed." The reasons would not have been difficult to fathom if he had not so religiously avoided the check ligaments!

One cannot admire Jameson enough for his forthright and scientific studies of the role of the intermuscular membrane in the etiology of heterotropia. He was one of the first to make the point that no final decision as to what surgery should be done could be made until the muscles were exposed at the time of operation. He wrote that ". . . when

exposure yields information that runs counter to the preoperative computation, one can close the wound and proceed on the opposing side." He was among the first to point out that a muscle might appear to be paretic when actually the true situation was anatomic abnormalities on the direct antagonist; section of these abnormal attachments, of course, led to complete "restoration" of function in the "paretic" muscle.

Esotropia, being more common than exotropia in young patients, will yield to recession of one or both medial recti in the majority of cases, *provided one carefully sections all abnormal attachments of the medial recti* and provided the medial recti are not too inelastic as a result of their inability to relax adequately; if they are inelastic, a shortening procedure may be necessary on one or both lateral recti in addition to recession of both medial recti. A deviation of 20 degrees in one patient and of 30 degrees in another may yield to recession of a single medial rectus *if* that muscle's abnormal attachments are severed. This is far more correction than might be expected with mathematical computation but is easily explainable in view of the anatomic anomalies encountered.

The writer does not ask the reader to accept without question these ideas which are presented, and indeed there will probably be few who will be so inclined. If the reader will, however, apply the forced duction test prior to operation and then carry out a search for anatomic anomalies as described, it is believed that the results will speak for themselves and that the individual operator will convince himself.

A classification of heterotropia

The statement has been made that 90 percent of all patients with heterotropia which developed before the age of six years have some anatomic anomaly underlying their heterotropia.

If the foregoing views are acceptable, or are found to be so at a later date, one may then elaborate what may perhaps be a more satisfactory classification of heterotropia. There would still be three main categories. (Monocular or alternating—exo-, eso-, hyper-, cyclo-).

A. Anatomic

1. Abnormal origins of muscles
2. Abnormal insertions
3. Abnormal muscle slips
4. Abnormal check ligaments
5. Abiotrophies

B. Innervational

1. Nervous (anomalies of convergence and divergence)*
2. Refractive (accommodative)*
3. Amblyopic (any organic obstacle to fusion)

C. Paretic

1. Toxic
2. Traumatic
3. Congenital

It will be noted that "a weak fusion faculty" or a "defect of the fusion faculty" has been omitted entirely in the classification and this is a radical departure from custom. The fusion mechanism is a well-recognized entity although it has never been demonstrated anatomically. It seems to attain its full development at about the age of six years, on the average. In the opinion of many, the fusion faculty is inherited just as brown eyes are inherited; it is said to be possible for a parent with a "weak fusion faculty" to pass on this defect to his or her offspring, and this is one explanation offered for the definite familial incidence of heterotropia. Chavasse[1] typifies the opposite view when he said ". . . we need no longer vainly gesticulate before the fireless altar of defect of the fusion faculty any more than we need to be content to regard lameness (with which strabismus has so

*This is frequently found superimposed upon some anatomic factor.

much in common) as a defect of the walking faculty."

It is believed that a careful search for anatomic abnormalities in every patient with heterotropia in every case that comes to surgery will soon convince the surgeon that Chavasse was right. Truly the role of anatomic abnormalities in heterotropia makes that entity very similar to lameness which is usually due to organic causes. One wonders if we have not been mentally lazy in the past and willing to speak of many cases as being due to a defect of the fusion faculty when a more thorough search would have revealed a more easily demonstrable and hence more acceptable cause for the deviation.

It is much easier to accept the idea of the inheritance of some anatomic abnormality from the parents, a common and well-recognized occurrence, rather than the inheritance of a weak fusion faculty. Anatomic abnormalities can be demonstrated in both parent and child while a defect of the fusion faculty is a nebulous entity whose existence can be shown only by inference.

In conclusion, one might well ask the value of such a classification to the clinician, even if he is willing to accept it. The answer is that it will lead to a far more successful therapy of heterotropia. The so-called "strengthening" operations alone will have nothing to recommend them except as they are used in conjunction with the recession. Cases of esotropia in children, for example, which appear to be due to a unilateral or a bilateral paresis of the sixth cranial nerve, may well be found to be due to abnormal check ligaments on the medial rectus muscles instead (as indeed so many of them are) which prevent adequate abduction of the eyes. The futility of trying to "strengthen" an apparently paretic lateral rectus when in reality the difficulty lies in a group of abnormal check ligaments or some other anatomic anomaly on the direct antagonist, that is, the medial rectus, should be obvious. One might as well double or triple the number of tugs used in an attempt to move the *Queen Mary* away from the dock when her anchoring shore-lines have never been cast off.

Lancaster[3] wrote that ". . . the two things for which we strive in operating are a position of orthophoria since, other things being equal, the nearer the eyes to a position of orthophoria, the less the task of the neuromuscular mechanism in maintaining binocular vision. Second, an effective range of fusion, this being, if possible, even more important than the former. A neuromuscular mechanism which, because of defective working of the controls, produces an exophoria, for example, may be made to produce an orthophoria by so shifting the position of the eyes in the orbit that approximately the same working of the controls will now result in orthophoria because the eyes start from a position nearer to the ideal one. *The idea that the purpose of operating on the ocular muscles is to weaken or strengthen some muscle which is too strong or too weak is unsound physiologically* (italics my own)."

REVIEW OF 100 CASES OF RETINAL DETACHMENT*

RUTH APPLEBY, M.D.
Los Angeles, California

AND

D. K. PISCHEL, M.D.
San Francisco, California

This paper is an analysis of 100 consecutive cases of idiopathic retinal detachment examined between January, 1945, and October, 1946, operated on with the electrodiathermy technique, and subsequently followed by us. Excluded in this series were 3 Linder underminings, 4 scleral resections done on aphakics, and 6 scleral resections done as a primary procedure by us on patients who had had previous diathermy operations. With the realization that 100 cases is an insufficient number on which to base any definite statistical conclusions, the figures herein presented serve to emphasize certain important features of retinal-detachment work. Inasmuch as the adverse outcome of an untreated case is well known, surgery was not denied anyone if they wished it, regardless of the appearance, duration, or apparent hopelessness of the case.

INITIAL EXAMINATION

Initial examination included vision tests, external examination, measurement of tension with the Schiøtz tonometer, slitlamp observation with dilated pupil, and inspection of the vitreous with the contact lens and slitlamp (Linder's offset corneal microscope). Perimetric fields were done with the smallest isotope visible to the patient.

Extremely careful fundus study and search for a retinal tear or tears was made with a sketch of the fundus diagraming the extent and elevation of the detachment. We have frequently found that, while tracing the retinal vessels and their branches, a tear may be located which has escaped notice in an overall fundus examination. The careful search for and localization of retinal tears cannot be overemphasized, since successful reattachment depends on closure or sealing of these tears.

FINDING TEARS

In regard to finding tears it must be remembered that a tear is not necessarily in the area of greatest detachment especially in those cases where the separation begins superiorly. Here the subretinal fluid gravitates inferiorly, and the tear may be found in a flat or apparently attached area of the retina. If a tear is not found at the first examination it may be hidden by an overhanging edge of the retina or in a deep fold, but when the retina settles back toward normal position following bed rest with binocular bandages, the tear may be revealed. Contradictorily, when the retina settles back the tears previously seen are often difficult to see because they become displaced far into the periphery or may not stand out because of the lack of color contrast.

When no tear has been found and the detachment settles out after several days of bed rest, the patient may be allowed to get up or to wear peephole glasses. Repeated examination may then show where the detachment reappears giving either a clue as to the location of the tear or the actual finding of it. A clue may also be obtained from the history as to where the detachment has commenced, and hence where the tear exists, if the patient noticed the location of the appearing shadow or curtain.

The tears are localized carefully with the hand perimeter as to arc and meridian. An arc of 50 degrees is considered to be 15 mm.

* From the Division of Ophthalmology, Stanford University School of Medicine, San Francisco.

posterior to the limbus, and each 5 degrees of arc is equal to approximately one millimeter.

Surgical management

Surgical management has been conducted in a similar way in these 100 cases. Preoperatively both eyes are bandaged, and the patient put at absolute bed rest in a position so that the retinal tear is in the most dependent part of the eye. In approximately half the cases, the retina had settled back markedly after this period of four or five days rest. No change was noted in 15 cases, and there were three cases in which the detachment increased in extent.

Surgery was done under local or combined local and avertin anesthesia. The horizontal meridian of the eye was marked at the limbus prior to the retrobulbar injection. The conjunctiva was incised 8 mm. from the limbus and, with Tenon's capsule, was separated from the sclera posteriorly.

Traction sutures were placed in the conjunctiva, and sling sutures through the muscle insertions to obtain better rotation. There was no hesitation in tenotomizing one or even two muscles to assure adequate exposure. The cornea was kept moist with normal saline, but covering it with the lid into which a traction suture had been placed was found to keep the cornea clearer than saline, glycerine, or other agents that have been recommended for this purpose.

The tear was localized directly with the ophthalmoscope (which is conveniently draped so as to be ready for use at all times), using an Arruga spoon and gentian violet to mark the relative position of the tear as it corresponded to the scleral surface. Rarely did the preoperative localization have to be transferred to the Walker rule and Linder dial for mathematical localization.

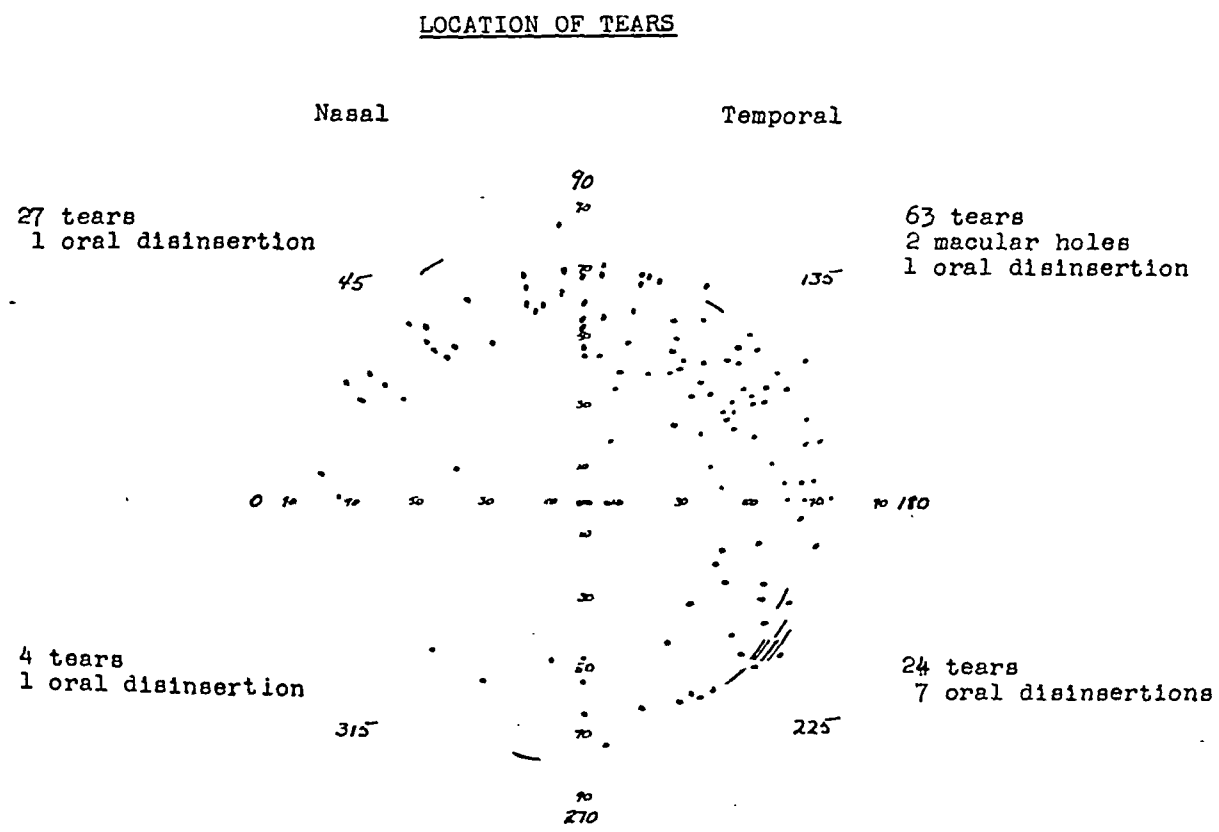

Fig. 1 (Appleby and Pischel). The location of tears in the present study was in agreement with the findings of other authors.

Partial penetrating Pischel electrodes and the Rose Walker diathermy machine were used, employing 50 milliamperes for 2 to 3 seconds. Two or three spots of diathermy were placed 1 to 2 mm. behind the localized tear, and the fundus was examined to see where these were in actual relation to the tear.

These spots usually showed well in the fundus, but if the retina was so elevated that they were not visible, a Pischel pin was inserted over the localized area on the sclera (done in 37 of these cases). This pin was almost invariably easily seen and served as an accurate guide to the location of the diathermy coagulations, assuring complete surrounding of the tear.

A double row of coagulations was placed about the tear coming up to the ora serrata (8 mm. in emmetropes, and 9 mm. in high myopes). Cystic areas were likewise included. Pischel pins (usually 9 to 12 of them) were inserted *within* the loop of diathermy barrage for drainage. Very frequently these pins could be seen to perforate the retina; therefore, it was decided that these newly formed retinal holes should be within the diathermy loop resulting in their being sealed also.

Occasionally, if no drainage was obtained from the pin openings, perforating electrodes or trephine openings were used. Frequently considerable more subretinal fluid could be aspirated from these openings in the sclera. In only 10 cases was air injected into the vitreous chamber to push the retina toward the choroid.

Postoperative care

The patients were kept in bed with binocular bandages for two weeks. The first of daily dressings was done on the second postoperative day, and stitches were removed the 7th to 10th day. The fundus was not examined until the 7th to 10th day. After 14 days, peephole glasses were substituted for bandages, and these were worn for an additional six weeks, with the patients' activities limited. During this period, the pupil was kept dilated with atropine or scopolamine.

Statistical analysis

Age and sex

Of the 100 cases analyzed 58 percent occurred in males, and 42 percent in females. Berens'[1] figures, 63 percent and 37 percent respectively, correspond closely to those reported by others, and the predominance shown by men has been explained by their predilection to trauma. In this series, 57 left eyes and 43 right eyes were affected, and in 13 cases both eyes had developed detachments; the time interval of involvement of the second eye varied between 5 months and 18 years. The maximum number of detachments occurred in patients aged between 60 and 65 years, but the average age for the entire series of cases was 49.5 years.

Refractive error

Myopia existed in 56 percent (31 cases 0.0D to −3.0D., 13 cases −3.0D. to −6.0D., 8 cases −6.0D. to −9.0D., the highest being −17.0D.); while 25 percent occurred in hyperopes (22 cases 0.0D. to +3.0D., the highest being +4.25D.). There was no record on the remaining cases. (Dunnington and Macnie[2] reported myopia existing in 53.8 percent and 66.6 percent of retinal detachments; Berens, in 68 percent; Shapland,[3] in 62.3 percent and Hine,[4] in 40 percent).

Precipitating factors

Of our patients, 43 percent gave a definite history of trauma which was believed to be the precipitating factor in producing the detachment. Seven of these were a direct blow on the eye, the remainder being indirect trauma such as a bump on the head, a hard fall, or heavy lifting. In three cases severe coughing and sneezing were implicated. Thirteen percent of the patients could recall no such trauma, and no history of trauma was recorded in 40 percent of the cases. It is of interest to note the time inter-

val between the so-called trauma and appearance of symptoms, as this is a frequent problem in establishing etiology.

We found it to be as follows:

60-90 days	6 cases
30-59 days	7 cases
14-29 days	2 cases
7-13 days	3 cases
1-6 days	13 cases

Symptoms

The most common presenting symptom was a shadow or curtain coming across the eye. This was noted by 44 patients; black spots or floaters by 31 (these are believed to be caused by slight hemorrhage into the vitreous from a ruptured blood vessel in the region of the retinal tear); flashes of light (resulting from mechanical stimulation of the retina) were noted by 14; and 39 complained only of blurred vision. Eight cases had been previously diagnosed as vitreous hemorrhage.

Parenthetically, it should be emphasized that all patients complaining of the sudden appearance of black spots before their eyes should be carefully examined for the presence of a retinal tear. Peripheral fields must be done and the examination repeated if nothing is found at the first examination. Arruga has 47 cases of retinal holes without detachment, and it is probably true that many more exist in those who do not consult a physician because of passing photopsia or black spots.

In this series, only one patient who had previously had a detachment in one eye noted black spots and flashes in the other. Several small holes were found in the periphery but no detachment developed (followed 10 months).

Retinal tears

Retinal tears were found in 88 percent of the cases, while in the remaining 12 percent no tear could be found. This is considerably higher than reported by others (Berens, 29 percent; Dunnington and Macnie, 56 percent; Shapland, 76.2 percent; and Meyer,[5] 57 percent) with the exception of Hine who in 120 cases found no retinal tear in only six cases. As Meyer pointed out, tears can usually be found if the ophthalmologist exercises sufficient care in his examination. We do not agree with those who believe that the finding of a retinal tear is unimportant in obtaining a reattachment. The mechanism of a detachment need only be considered to realize the necessity of finding and sealing off the tear in the retina to assure success.

The horseshoe-shaped tear was most common, occurring in 58 percent of the cases. Round holes were found in 33 percent, macular holes in 2 percent, linear and oval holes, each 7 percent, irregular rents in 5 percent, crescent shaped in 3 percent, and oral disinsertions in 10 percent. Multiple holes were found in 27 percent (2 to 8 tears). The location of tears can be seen in Figure 1 and is in agreement with the finding of others. Tremendous tears or large multiple tears decrease the chance of successful reattachment, but beyond this there was no relation to the type of tear and cures.

Type of detachments

We found that 35 percent of the detachments were classified as bullous in type, 33 percent as flat, and 32 percent as combined bullous and flat. A total detachment existed in 21 of the cases, 15 of which were cured despite the general opinion that these cases are hopeless. In 5 cases over three fourths of the retina was detached; in 12, three fourths was involved; in 36, one half; in 21, one fourth; and in 6 cases, the extent of the detachment involved less than one fourth of the retina, or was limited to the area of the tear. Comparison of the above findings with final results shows that the chance of surgical success is greater, the less the extent of the detachment. How-

ever, a detachment of total or marked extent should certainly not be disregarded nor considered hopeless.

Duration of detachment

The duration of a retinal detachment is difficult to determine and, in this series, was based only on the time of onset of symptoms regardless of the appearance of the retina. In this series, this time varied between one day and 11 years (the latter diagnosed by two ophthalmologists). The duration of the detachment is of importance in prognosis for anatomic and functional success. From Table 1 it may be seen that if the detachment had existed less than two months the chance of success was definitely enhanced. If the duration of the detachment was two months or over, the number of unsuccessful cases markedly increased. This bears out the necessity of treating cases of retinal detachment as emergencies, hospitalizing them immediately, and operating as soon as the retina has settled back toward normal position. This was usually found to be accomplished with 4 to 5 days of bed rest with binocular bandages.

TABLE 1

Duration of detachment

Duration in Months	Number of Cases	Number of Cases Unsuccessful
0 to 1	47	3 or 6.38%
1 to 2	11	1 or 9.09%
2 to 3	9	3 or 33.3 %
Over 3	23	5 or 21.7 %

Incidence of vitreous detachment

In 35 cases a posterior vitreous detachment was discerned with the contact lens and slitlamp, using Linder's offset corneal microscope; and in 6 cases no detachment was found; while in 9, the vitreous was noted as completely disorganized. Of the remaining 50 cases, there was no note of vitreous detachment. In this respect it must be remembered that no group of normal eyes was examined for comparison.

Complications

Out of the 100 patients, 6 had complications attributable to the retinal detachment. Four of these had iridocyclitis (2 inactive), and two had a tension of 40 mm. Hg (Schiøtz). One of the cases of increased ocular tension was controlled by eserine and pilocarpine in three days, following which mydriasis did not result in any elevation. In the other case a cyclodialysis was necessary to control the tension.

Criterion for success

The criterion for success in these 100 cases was based only upon permanent reattachment of the retina, regardless of the resultant visual acuity or peripheral field. With this as a basis, 86 percent of the cases were cured. It should again be mentioned that this series is not large, and that it was perhaps fortunate that we saw few bad cases in the time interval considered. With the inclusion of all detachment cases operated on by us during the period under consideration (Linder underminings, and scleral resections), 80.5 percent were cured.

A second diathermy operation to obtain reattachment was done on 15 eyes, 10 of which were successful. Two of the successes were on eyes that developed a second retinal tear and detachment completely isolated from the first. Six patients had been operated by diathermy elsewhere, two of whom had undergone two operations. These two and three of the others were cured.

In successful cases, an apparent reattachment is the usual finding at the time of discharge from the hospital. However, in five cases the detachment of the retina was still present at this time, only to become reattached within 4 to 6 weeks. Of those apparently successful, one became detached in the operated area after six months following a severe coughing and sneezing spell. This was an 83-year-old patient who refused fur-

ther surgery, and is listed as a failure. One other retina remained attached 1½ months and at the time, due to an unexplained cause suffered a practically complete detachment which increased in extent in spite of bed rest with binocular bandages. The two other cases of redetachment occurred after two months and 2½ weeks and were cured by reoperation.

Postoperative complications

Postoperative complications were minimal. One patient had a severe iridocyclitis which cleared with typhoid-fever therapy; another one had a hyphemia, while a 44-year-old woman became hysterical and had to be transferred to the psychiatric service (all failures).

One patient became so disoriented that she was allowed up with peephole glasses for the first three postoperative days, after which the routine was carried out in full (cure). Two others had small vitreous hemorrhages immediately following surgery (cures).

In no cured case was any change noted in the lens. It has been stated above that recti muscles were tenotomized without hesitation to assure adequate exposure. In those cases where the horizontal muscles were cut from their insertions, no important change in muscle balance has been noted. Of the vertical muscles tenotomized 9 cases showed a hypophoria, with 3 requiring prismatic correction for comfort. A hyperphoria resulted in 24 cases, requiring prism correction in 5; while 7 had orthophoria. In 12 cases, muscle balance was impossible to obtain, and in 7 none was recorded. In those cases where the muscle had not been cut, equal degrees of hypophoria and hyperphoria resulted, but in no case was it sufficient to be annoying to the patient.

In 49 cases, the retina was seen to recede toward the choroid to a considerable extent after drainage of subretinal fluid; moderately in 17; slight in 19; and no change was noted in 15. This had no apparent effect on the final outcome. Air was injected in 10 cases, and trephine openings were made in six.

Perimetric fields

Perimetric fields are taken at each postoperative visit at one-third meter distance with a 1-mm. test object (rarely 3 mm.). The immediate result in those cured cases was a return to a normal, or an almost normal, peripheral field, except in 13 cases. Twelve cases showed a constriction corresponding to the area of operation, and two were concentrically constricted. The only cases showing any gradual improvement of field were those five mentioned previously in which the retina became reattached over a period of time. Late loss of field was noted in four patients. In the first two, the loss was limited to the area of operation after six months and one year had elapsed, respectively. The third showed a shrinkage of field similar to that prior to surgery, and the fourth developed a concentric constriction of 20 degrees in five months. There was no relation between the duration of the detachment and the maintenance of peripheral vision or the late loss of it.

Visual results

The overall visual results may be seen in Table 2. In our 100 cases the visual

TABLE 2

Visual Results

Vision	Number of Cases	
	Preoperative	Postoperative
HM ½–6′	14	
CF 3–8′	13	
CF 1–3′	19	
20/400	7	3
20/300	3	
20/200	5	15
20/100	4	4
20/80	1	
20/70	1	3
20/60		4
20/50	3	11
20/40	2	8
20/30	4	10
20/25	2	4
20/20	8	22

acuity was found to be maximal after sufficient time had elapsed to allow for vitreous clearing. In no cases did improvement of vision continue over several months as has been noted by Kronfeld[6] and Sallman.[7]

Over a postoperative period varying between 2½ months and one year, five patients were found to have lost vision over that originally regained. In one, a definite macular cyst could be seen. In the others no definite ophthalmoscopic explanation was found, although the macula had been detached prior to surgery. The visual loss was as follows: 20/20 to 20/30, 20/30 to 20/70, 20/60 to 20/200, 20/50 to 20/100. Reese[8] in his detailed study showed that cystic degeneration occurred first in the macula, attaining its largest size in this area. He attributed this change to altered arterial circulation resulting in stasis of fluids. He also concluded that defective central vision suggests that macular detachment and cystic formation have existed even though not seen clinically. This late visual loss in the above cases may be the result of degenerative changes from circulatory impairment.

In the cases where the macula was not definitely detached, 21 obtained an acuity better than 20/30, one had 20/40, and two had 20/50.

Macular detachments

An attempt was made to study the return of function in those cases where the macula was included in the area of detachment. In 53 percent a total macular detachment existed, being based only on definite ophthalmoscopic findings. Questionable cases, as well as those in which the macular area was invisible due to an overhanging bulla, were not included.

The duration of the detachment was again only estimated according to the time of onset of symptoms. This was, however, believed to be frequently inaccurate as it was perhaps the time that central vision was affected rather than the onset of the original detachment. Kronfeld,[6] in 1933, after a meticulous study of his six cases and those reported in the literature, concluded that in complete macular detachment of not over eight weeks' duration, fair acuity could be expected (0.3 to 0.1), and if over two months functional recovery was rare but did occur. Gradle,[9] in 1943, felt the resulting central acuity was determined by the duration of the detachment and the patient's age, concluding that in cases of macular detachment the chance of functional return was good if the patient was not over 35 to 40 years. Subsequent to this age, he found a high percentage of macular cystic degeneration; and under 25 years, he believes that there is apt to be no degeneration despite the duration of the detachment.

TABLE 3

Macular detachments

Final Vision	Number of Cases	Age	Average Age	Duration of Detachment	Average Duration
20/20	5	14–66	44.4	7 days – 2 months	0.83 month
20/30	6	30–69	51.3	5 days – 1.5 months	0.69 month
20/40	7	42–69	60.0	3.5 weeks – 4 months	1.85 months
20/50	3	54–70	61.4	3 days – 2.5 months	1.60 months
20/60	3	44–68	56.0	10 days – 5 months	1.37 months
20/70	4	46–67	59.3	10 days – 5.5 months	3.38 months
20/100	15	45–76	59.5	9 days – 1 month	1.25 months
20/200	3	16–69	47.2	3 days –11 years	29.2 months
20/400	3	19–55	35.6	1.5 months–11 months	4.8 months

Our 53 percent of macular detachments has been recorded in Table 3 as to the duration of the detachment and the age of the patient related to final acuity. (In Table 4 each case has been tabulated separately.)

From this it can be seen that the return of good central vision is more closely related to the duration of the detachment than to the age of the patient. Although not entirely consistent, if the detachment has existed less than one month, a good visual restoration can be expected (20/30 or better), and if less than two months a fair acuity may result (20/60 or better). However, in cases of long duration one should not hesitate to attempt an operation, since useful vision for practical purposes may be achieved. The two patients with macular holes obtained 20/200 and 20/400 vision.

Unsuccessful cases

In reviewing the 14 unsuccessful cases, the age of the patient varied between 1½ to 83 years, with three in the 55 to 60 age group, and four in the 60 to 65 group. Sex played no role. There was no record of refraction in seven cases, but one was a high myope of −13.0D., and three had between −1.0D. and −2.0D. The duration of the detachment varied between 3 days and 10 months, five existing from 1 to 3 months. In two cases, no retinal tear was found, and of three reoperated cases, two had no visible tear, and one had a small secondary hole. Among these 14 cases there were four horseshoe-shaped rents (two very extensive), a very large oval tear, one round hole present between the macula and disc, and six in which multiple tears occurred. These varied from 2 to 6 in number.

Six cases had total detachments, while in three the detachment involved three fourths of the eyeball, and in the remaining five only one half of the retina was detached. Three of the detachments had stiff white folds agglutinated together by vitreous strands. Prior to surgery following bed rest with binocular bandages, the retina receded markedly in three cases, slightly in four, with no changes noted in four. In three cases, the detachment progressed despite bed rest.

The surgery on all these cases was performed in the usual manner. It was uneventful with the exception of one instance when the electrode perforated an old diathermy spot resulting in vitreous loss. Drainage was good in all cases, although in two cases, trephine openings had to be made to obtain adequate release of subretinal fluid. In seven

cases 1½ cc. of air were injected into the vitreous chamber in an attempt to approximate the retina and choroid. In two cases, scleral resections were done following unsuccessful diathermy operations without further improvement.

Postoperative complications have been included in those above.

In one case the extensive horseshoe tear was seen to be still open at one small area, but reoperation was refused by the patient. In two others the tears were not closed at all.

PROBLEMS IN RESEARCH IN ORTHOPTICS*

F. ELIZABETH JACKSON, M.A.
Erie, Pennsylvania

Orthoptics is a comparatively new field of science. It has not yet evolved from the "trial and error" stage which is typical of all beginnings. If orthoptics is to continue its present rapid growth and to reach maturity with universal application as well as acceptance of its principles and methods, research is imperative to improve the results of our "trials" and to eliminate the wasted time and effort that constitute the bulk of "errors." We need to be able to give specific answers to specific questions, and these answers need to be substantiated by accurate data in order to gain the respect and confidence of the ophthalmologist and of the parent whose complete coöperation with the technician is so essential for worthwhile results.

The dictionary defines research as "the effort to find new information by experiment or by thorough investigation of sources; a careful inquiry or diligent investigation to discover facts by study." The key words in these definitions are: *new information, facts*—these are our immediate goal; *experiment, investigation of sources, inquiry, study*—these are the methods.

INFORMATION AND FACTS

If one applies this definition to orthoptics and considers what new information and facts would make the daily routine of treatment more effective, he realizes that the field for research is wide and its possibilities manifold. One does not have to search for a suitable topic for study, for every day some problem arises for which there is no satisfactory solution to be found in current orthoptic literature.

Motivation for research is not a basic problem. One does not have to be inspired with lofty ideals of service or with a consuming ambition for fame and recognition. The common sense that inspired the adage, "build a better mouse-trap," is sufficient. The answer to our daily problem makes our task easier and more pleasant and helps us to avoid the tedium of purely mechanical repetition.

You may say, "But I have had no training, no experience in research methods. Where shall I begin?"

Begin thinking about that daily problem. Method will evolve from trial and error, if necessary, and "know-how" will come with momentum.

COLLECTING OF SOURCE MATERIAL

The first step in any research problem is the collecting of source material. One usually thinks of source material as all printed matter pertaining to his subject. Extensive reading is required and is greatly facilitated if one is acquainted with available library resources. Find out how you may obtain library privileges, inquire into procedures for using or borrowing books, learn the arrangement of periodicals, general reference books, dictionaries, and textbooks so that it is a quick and easy matter to find any specific reference. Some cities have a Union Catalogue Service which one may call to find out in which library any book is obtainable.

Since most articles on orthoptics and many on strabismus have been written in recent years and published in current periodicals, they can easily be found by consulting the *Index Medicus,* a reference book published twice yearly which lists all articles published in medical journals during the six months' period. The articles are listed both by author and by subject. Subheadings give the full title. There are often cross refer-

* From the Orthoptic Clinic, St. Vincent's Hospital, Erie, Pennsylvania. Read before the sixth annual meeting of the American Association of Orthoptic Technicians, Chicago, Illinois, October 12, 1947.

ences to a specific topic which might be listed under two general subject headings. Unfortunately, there is no such listing for books. One usually can obtain all important references by consulting the bibliography given at the end of articles published in periodicals. Textbooks often give excellent bibliographies at the ends of chapters on the specific material in that chapter. It is advisable to start with the latest publications and work back, as older articles may be made obsolete by more recent discoveries and study.

Studying periodicals

It is an excellent idea to keep up one's background reading as articles are published. Certainly the *American Journal of Ophthalmology* and the *Archives of Ophthalmology* are available to all of us. The *British Journal of Ophthalmology* has excellent articles. If one abstracts an article as he reads it, he has a permanent record of its usefulness available at any time. The length of the abstract and the amount of information in it may vary according to the value of the article for one's particular needs. It may be only a notation, such as good bibliography, or it may be a fairly complete summary of the entire paper. Frequently it may consist of the conclusions drawn at the end of the article. It is sometimes valuable to note for future reading references given to some other Journal not immediately available. I formed the habit of filing abstracts on white cards by general subject, such as diagnosis, treatment, statistics, tests, and so forth with author, title, periodical at the top of the card, so that they are immediately accessible. The abstracts compiled in the past two years by the American Association of Orthoptic Technicians are complete and most helpful.

Analysis of cases

Our second consideration is analysis of cases. This forms the bulk of orthoptic research. The patient is our first-hand material, and the study of his condition, reactions, and progress constitutes our original contribution in the field of research.

In everyday planning for clinic efficiency, preparation for case analysis can be started. Infinite time will be saved if records of diagnosis and daily treatment are complete, uniform, and well arranged. To illustrate, measurements by various methods should be in one space where they are easily compared. Tests for correspondence should be listed together. Printed forms which can be filled in save time and are clearer. A definite system of follow-up for discharged patients is valuable for comparative data.

Another time-saving device is a diagnostic file. When the diagnosis of each case is complete, that record should be classified under headings of possible investigation; for instance, causal factor, correspondence, amblyopia, phorias, hyperphoria, and so forth. There is no regulation set of headings. Individual interest and needs dictate one's grouping. When one wants to make a study of any of these topics, he has at hand a list of all pertinent cases and is not faced by the laborious task of going over all his records. Such a file is of value also in quick compilation of data for reports.

Perhaps procedures in case analysis will be clearer if we take a hypothetical research project and trace our steps one by one. Let us take retinal correspondence to see what is its relationship to other factors present in convergent squint, and whether type of correspondence is conditioned by any one of these factors to the exclusion of the others. The following series of topics is complete for our purpose:

1. Causal factor
2. Angle of deviation
3. Age of onset
4. Years of duration
5. Amblyopia
6. Alternation

One finds in reviewing current literature that the last four topics have been consid-

ered by various authors to be determining factors in the type of correspondence found in any case.

Selection of cases for study. The first step is selection of cases for the study. Data on every case included must be standardized and complete. Standard data in the series above would involve: (1) The same test or tests for diagnosis of correspondence, (2) definite specifications for classification into any causal category, (3) uniform method of measuring the deviation, (4) reliability of history in age of onset and duration, (5) standard system of classifying degree of amblyopia, (6) specifications for differentiation between monoculars and alternators. Any history which does not have all the above information must be discarded. Ideally, in a study of this sort, all cases of convergent squint which come into the office or clinic should be usable to give a true overall picture and the most accurate results possible. One cannot attain such uniformity, but he should attempt to keep the cases he selects representative of the whole group.

Charting of cases is the second step. A chart on which all necessary material can be listed makes it possible to collect all data on one work sheet. Large sheets of cardboard or even a roll of white wrapping paper may suffice. A usable chart for our sample project might have the following headings (adequately spaced and reading from left to right): History number, correspondence (subdivided into two columns for normal and anomalous), causal factor, angle of deviation, age of onset, years of duration, amblyopia, alternation (with three columns for monoculars, borderline cases, and alternators).

Once this information is transferred from the case histories to the chart, we are ready to get percentages.

First comes number of cases of normal and of anomalous correspondence and the percentage of their occurrence. Next, the number of cases according to cause and the percentage of their distribution. Then comes correlation of causal factor and correspondence which shows the number of normal and of anomalous correspondence cases in each causal factor category. Two sets of percentages can now be obtained: (1) For distribution of each type of correspondence through the various causal groups; that is, what percentage of cases with anomalous and what

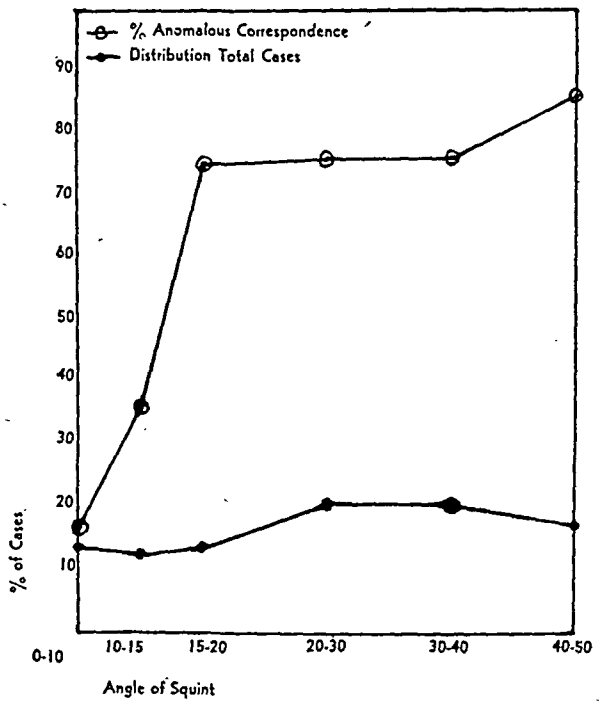

Fig. 1 (Jackson). In a graph, percentage of total cases will be the vertical component; the comparison factor, the lateral. A connected line or curve, or solid blocks may be used to show their changing relationship. A second curve or set of blocks may be used to show the incidence of anomalous or normal correspondence. When two lines or sets of blocks are used, they must have individual markings recorded in the graph key. The line or curve graph is used where the steps of the lateral factor are interrelated or show continuity. The block graph is clearer if the lateral factor is comprised of separate entities in order to emphasize comparison between them. To illustrate, a line graph works out very nicely in charting distribution of total cases and/or percentage of anomalous correspondence by angle of squint, since there is continuity in gradation of squint angle.

percentage of those with normal correspondence are accommodative, paralytic, and so forth, and (2) comparative percentages of the occurrence of both types of correspondence in each causal group, or what

percentage of cases of each of these groups have anomalous and what percentage have normal correspondence.

Our next column, angle of deviation, gives us figures on the size of the squint in our cases, and again, correlation with correspondence shows distribution of normal

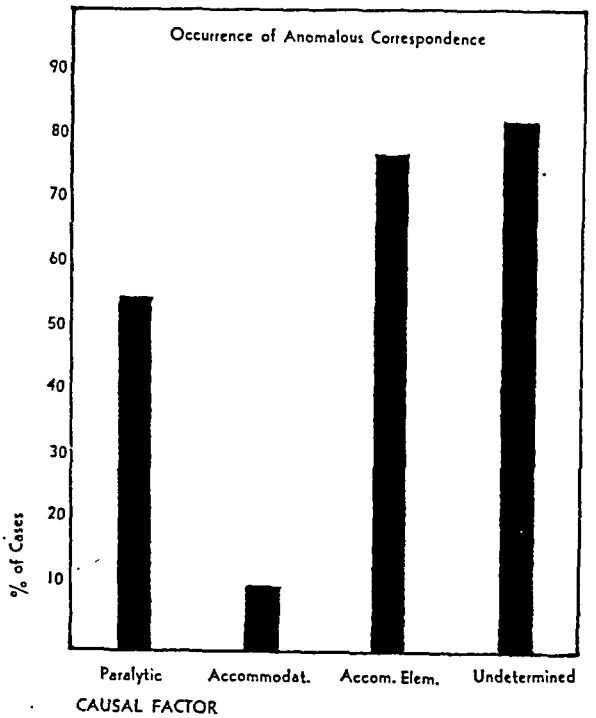

Fig. 2 (Jackson). A block graph shows distribution of total cases or percentage of anomalous correspondence according to causal factor more clearly since the entities listed are different, and we want to compare rather than to connect them.

and anomalous in varying amounts of deviation. Similarly with the other headings on our chart.

As figures are obtained for each column, they should be set down in percentage tables with headings across the page showing total cases and their distribution according to correspondence (table 1), the first column from top to bottom showing the related factor (angle of squint, age of onset, and so forth). It is a good idea to draw a graph of these figures in order to show their relationship more clearly (fig. 1).

We now have statistics on each entity and its relation to correspondence, but in order to evaluate these figures properly and to eliminate, if possible, 5 of the 6 factors, we must have relationships between the factors (disregarding correspondence for the time-being); that is, angle of deviation and causal factor, angle of deviation and alternation, causal factor and alternation and so forth.

Correlation of Facts

The material is now analyzed, and the next step is synthesis or correlation of the facts so far obtained. These isolated figures are like pieces of a jig-saw puzzle which must be put together to form a meaningful picture.

Conclusions must be based on careful evaluation, comparison, checking and re-checking to make certain that no item which might alter the results has been overlooked. If statistics are accurate, certain facts become apparent, and definite conclusions can be drawn.

The principal value of a statistical survey

TABLE 1

Cases and their distribution according to correspondence*

* Figures for percentage table and graphs taken from a study of 175 cases of convergent squint by Adler and Jackson: *Correlations Between the Sensory and Motor Disturbances in Convergent Squint.* Arch. Ophth., **38**: 289 (Sept.) 1947.

of this sort is elimination of extraneous factors. By clarifying the basic problem, it leads the way to further study without waste of time or effort.

The worth of any large study lies in the elimination of variables. There are always three variables in orthoptics—the child, the

methods and tools, and the technician. By standardizing diagnostic or treatment methods in the cases reported, we have eliminated one variable. We can never totally eliminate the individual factor in the other two variables. However, the more cases studied, the more are the individual differences of the child minimized. If coöperative comparative analysis could be made at various clinics, and the results pooled and evaluated as a whole, the technician variable would be reduced.

Comparison study

Another type of research project of great value in the field of orthoptics is the comparison study. Evaluation of treatment method and results would come under this heading. By comparison, one method will prove itself best, and other less efficient treatments can be discarded. In a study of this sort, it is essential to have a control group, that is, a series of cases to which cases under analysis can be compared. For instance, in evaluation of results of orthoptic treatment, we should have a group of patients who have had no treatment to give us a basis for claiming the value of orthoptic procedure. Here again, the larger the series of cases studied, the less will individual variation in cases affect the final figures.

Report of individual cases, or small series, is another method of research. Its aim and value lie in pointing out some particular phenomenon or in suggesting some form of therapy, in calling attention to some important factor not stressed by previous authors. As a classic example, I refer you to Dr. Kenneth Swan's article on "Esotropia Following Occlusion" (Arch. Ophth., 37: 444 (April) 1947). It has aroused great interest and stimulated better therapeutics generally, besides pointing out the one factor which is basic in a condition sufficiently unusual to be puzzling when it occurs.

Writing reports

A few practical suggestions for the actual writing of papers and reports may be useful.

1. Standards of analysis must be given, so that the reader has some measure by which to evaluate the findings reported.

2. Any quotation or information from another source which you may use must be acknowledged, and the author, book or article title, periodical or publisher given in a footnote reference. Medical publications have a standard method of footnote reference which you can check on in the *American Journal of Ophthalmology* or the *Archives of Ophthalmology*. If your paper consists largely in compilation and reorganization of reading material, a complete bibliography of material referred to should be given at the end of the paper.

3. Only pertinent information must be included. Extraneous material, although interesting, detracts from the point in question. Choose a title to fit the purpose of the paper. Study your findings, and once having decided what you are trying to prove, outline the steps by which your material will build up to the final conclusion logically. Relate the introduction to the conclusions.

4. Evaluate your reader's background for the information you have to offer. You will have done extensive reading in your subject. Has this material been easily accessible to your anticipated readers? What do textbooks give on your subject? They are a good key to your reader's mind-set. Does textbook terminology coincide with yours, or will you have to simplify and explain the terms used. Consider how much background material will be necessary for your reader's understanding. It is a safe rule to err on the side of simplicity.

Topics for consideration

The problems of research are synonymous with the problems of orthoptics. The solving of individual problems carries with it a solution to basic but less specific inadequacies of the profession.

To offer a few topics for consideration:

1. There is a great need for clarification of orthoptic terms on the basis of ophthalmic terminology. Many ophthalmologists think of sensory phenomena in the terms of Worth. Since his time, the major amblyoscope has provided an entirely different group of findings. The use of Worth's terminology as applied to present-day orthoptic methods has resulted in a state of confusion which makes coöperation with the ophthalmologist difficult for lack of common understanding.

2. Comparative evaluation of method. A statistical survey of results would not only improve results but would give much needed standards for their evaluation.

3. A study of the basic principles of child psychology as they apply to orthoptics would give knowledge of what can be expected of the child at various age levels and of how to motivate the tasks which are set for him, thus helping to eliminate age and coöperation variables.

4. The collection and analysis of sensory data is needed to stimulate and direct further ophthalmological study into etiology, manifestations, and over-all treatment of squint. Further analysis of retinal correspondence and divergent squint come to mind as examples.

One of the outstanding values to be gained from research is a truer perspective of the whole field of binocular training. Faced by the constant variability of our daily cases, we are too prone "not to see the woods for the trees."

Summary

Much time and preliminary effort involved in research can be minimized by (1) a definite system in keeping records of diagnosis, treatment, and follow-up cases, (2) abstract file of current publications, (3) diagnostic file of case histories.

Analysis of cases represents the bulk of orthoptic research. Results of such analysis can be presented in three ways: statistical survey, comparison study, and report of individual cases.

Five benefits are to be derived from research in orthoptics.

1. Clarification of orthoptic terminology
2. Standardization for evaluation of results
3. Elimination of variable factors
4. Collection of sensory data
5. A better sense of perspective for routine treatment

St. Vincent's Hospital.

AGNOSTIC ALEXIA WITHOUT AGRAPHIA FOLLOWING TRAUMA*

HAROLD H. JOY, M.D.
Syracuse, New York

Agnostic alexia is an infrequent form of aphasia and is a variety of visual agnosia (mind blindness).[1] It is a disturbance of language function consisting of failure of recognition of the conventional meaning of graphic symbols, and may include inability to read letters, syllables, words, musical notes, and mathematical figures.

The terms alexia and word blindness, which are most frequently used for this condition, are somewhat objectionable in that inability to read may depend on many different focal cerebral defects. Agnostic alexia is more specific for it is used in contradistinction to aphasic alexia and semantic alexia.[2] In aphasic alexia there is loss of ability to comprehend statements of a simple character, the words being properly recognized. In semantic alexia the patient is unable to comprehend complicated statements while retaining the ability to grasp simple ones.

The act of seeing is a highly complicated procedure requiring the integrity of the optic apparatus and a considerable part of the cerebral cortex. Much of the mechanism of how it is accomplished is conjectural and controversial, and its study involves the fields of anatomy, physiology, and psychology.

Experimental and clinical investigations have proved that the calcarine area (area 17 of Brodmann) of the occipital lobe is the site of the primary cortical termination of the visual impulse.[3] Neurons from the retina maintain a precise spatial organization in their course to the external geniculate body and thence to the calcarine cortex, thereby producing point to point retinal representation throughout the radiation and calcarine area.[4, 5] Decussation of the nasal half of the optic-nerve fibers results in cortical representation of the nasal half of the contralateral retina and of the temporal half of the homolateral retina.

The question of the physiologic relationships concerned with the higher visual areas is far from settled. Many ingenious schemata of brain localizations have been worked out, based partly on experimental and clinical data and partly on psychologic premises. This has led one school of thought to accept more or less rigid conceptions of various centers and tracts. On the other hand, many neurologists believe that our knowledge of the various sensory centers and association tracts is not yet sufficiently accurate to warrant such concepts of localization.[6–13]

It is quite generally agreed that the occipital lobe is primarily concerned with vision, and that area 18 of Brodmann which surrounds area 17 (the calcarine cortex), and area 19 which surrounds area 18 are concerned with visual association and organization[6] (fig. 1). There is less agreement regarding other salient features. Definite proof of the specific functions of areas 18 and 19 is lacking. Area 18, receiving impulses from area 17 only, is believed to be the center for recognition of objects and probably of colors.[2, 14] Area 19, which receives impulses from all parts of the cortex, serves as a center for coördinating visual and other reflexes.[6] Its chief function seems to be that of revisualization.[15] Area 37 and the region immediately anterior to it is believed by many neurologists to form a field in which language is formulated.[2]

Ferrier,[16] in 1875, concluded that the area of cortex chiefly concerned with recognition of written or printed words was the dominant angular gyrus (area 39). This opinion

* Presented at the 83rd annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June, 1947. From the Department of Ophthalmology, Syracuse University College of Medicine.

was not generally accepted for a long time and is not universally accepted even now. However, most neurologists, due to the investigations of Dejerine, Henschen, Pötzl, Hinshelwood, Nielsen, and others, maintain that the angular gyrus and the area immediately beneath it are essential for the visual recognition of letters, words, and musical notes. The center for mathematical figures is believed to be closely adjacent in the parieto-occipital region, and according to Henschen[17] is situated about the borders of the interparietal sulcus.

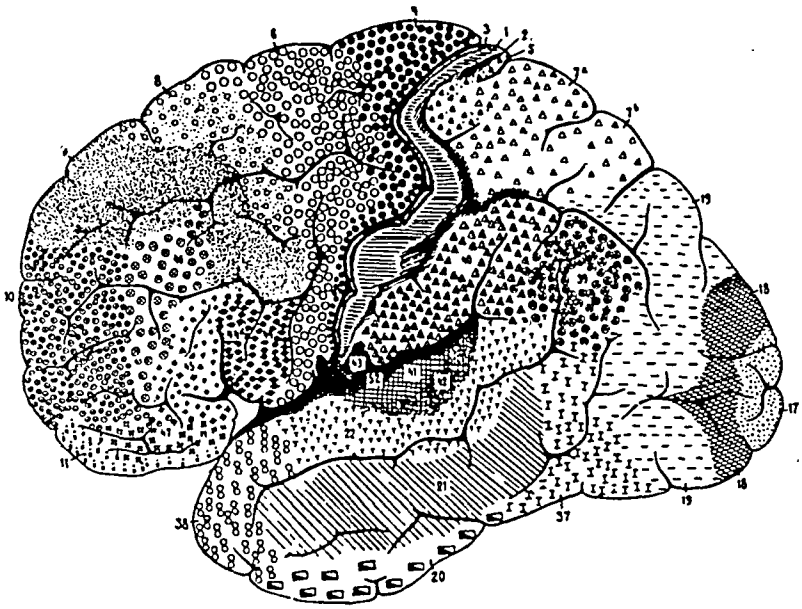

Fig. 1 (Joy). Brodmann's architectonic chart of the cerebral cortex. Lateral aspect. A large part of area 4 actually lies within the fissure of Rolando and areas 41, 42, 43, and 52 lie within the fissure of Sylvius. (From: Ford, F. R.: *Diseases of the Nervous System in Infancy, Childhood, and Adolescence.*)

The angular gyrus apparently has two functions, one for recognition and the other for the revisualization of the written or printed word symbol.[2] In this cortical zone the optic images of words are thought to become integrated with the corresponding representatives of the other sense organs, and only when such integration takes place does a word take significance.[18]

Symbols are in the sphere of language and unilateral dominance is much more pronounced in all language functions than in recognition of objects in general; thus, the major or dominant angular gyrus is essential to reading function.[7] The minor angular gyrus in most instances has its engrams so crudely made that it functions poorly unless forced to do so by lesions on the dominant side.[19] Even then, except in the very young, it usually takes years to function well.

The various subdivisions of the higher cortical visual field have more or less intimate association with each other in accordance with the degree of association between their functions. The angular gyri of the two hemispheres seem to be connected with each other, with the primary cortical areas of vision in both hemispheres, with the optic thalamus, and with other special sense centers, including Wernicke's auditory-word center and Broca's motor-speech center.[20] It apparently has numerous associating tracts with other centers contributary or coördinate in function, like those for object seeing and for stereognostic function.[21] It is also believed to be connected with the language formulation area whose chief function is the association of names with objects, concepts of which are obtained from the special senses.[21]

The functional relationship of the angular gyrus to Wernicke's center in most individuals and to Broca's center in some individuals is particularly close. In childhood word impressions are first received through the auditory mechanism, and the word is thus interpreted as it is heard. In most instances this habit continues throughout life. However, so-called sight readers, who are strongly visually minded, learn in time to read without reliving the sound-memories of each word and acquire independence from Wernicke's center.[2]

Also in childhood, word impressions are closely associated with the motor-speech center. As the child learns to read he enunciates, and as a result the printed image of the word becomes intimately tied up with the sound of the word. If his training in reading doesn't advance beyond the point of enunciating, this close association persists throughout life. However, most educated individuals develop silent reading ability and ultimate independence from Broca's center.[2]

Thus, the perfect functioning of the visual word center presupposes the integrity of the center, of all of its association tracts and of the other special sense areas.

Agnostic alexia

The most frequent type of agnostic alexia is blindness for letters and words.[21] Although letter blindness may appear without word blindness and word blindness without letter blindness, the two are usually associated and are almost always accompanied by inability to read musical notes, and much less frequently by blindness for mathematical figures.[2] The degree of alexia may vary considerably; some patients are able to recognize one or two or several symbols, while others exhibit complete loss of identification.[21]

Several bizarre types of alexia have been recorded; for example, in bilingual individuals there may be blindness for one language while ability to read another with similar characters is retained.[22] It has been assumed that such cases indicate that the engrams of different languages are laid down in separate areas.[21,22] However, the more modern conception is that such cases represent incomplete alexia. It is believed that in the disorganization that takes place in alexia the more complex and more recently acquired language functions are lost first.[2, 18] Thus, a foreign language is lost before the native language, and words are lost before letters. This order also holds true in the return of function in favorable cases, the more simple and basic functions returning first.

The faculty of reading is not only confined to letters and words but also applies to mathematical figures. The relatively infrequent occurrence of numeral alexia has received much comment in the literature. In the classic picture of pure alexia described by Dejerine,[23] and in a great many cases recorded since, the reading of figures and the ability to calculate were entirely conserved. This frequent sparing of mathematical figure language in agnostic alexia has led to the assumption that numbers and calculations are functions independent of letter and word language, and that they have their own cortical center and connecting pathways, which, although independent of each other, lie in the same vicinity.[2, 17, 21, 23, 24]

On the other hand, many neurologists consider it unlikely that the various symptoms of optic agnosia have a separate localizing significance. A. Adler[9] expressed the belief that agnostic patients recognize numbers more easily than letters because there are only 10 numbers and it is comparatively easy to recognize them by a few characteristics.

Agnostic alexia in itself is not pathognomonic of a lesion in a certain cerebral area, for language is a very intricate function requiring for its use the entire brain.[1] A lesion in any one area may so affect the mechanism as to interfere with activities other than those mediated directly by the involved area.[25] Moreover, when language function is disturbed mental functions may

also be affected and they, in turn, influence the language disturbance.[18] Therefore, to determine the site of the lesion producing alexia other factors must be taken into consideration.

Because of the fact that agnostic alexia is a disturbance of language function the lesion producing it is almost always in the dominant or major hemisphere (left in right-handed individuals). Atypical cases in which necropsy has revealed a right-sided lesion in right-handed individuals have been explained on the basis of unrecognized left-handedness, an unrecognized lesion of the left cerebrum, or ipsilateral cerebral dominance.[2] Chesher has shown that in about 6 percent of persons the major hemisphere in language is ipsilateral to the major hand.[1]

All lesions within the secondary visual area produce impairment of visual memory.[20] These disabilities represent the loss of previously acquired engrams of memory and concepts in which visual memory was a component. Cortical lesions which destroy engrams of visual memory cause a loss of both recognition and revisualization, but subcortical lesions which interrupt connections between these areas and the calcarine fissure of both occipital lobes cause only loss of recognition.[23]

On this premise destruction of the dominant angular gyrus destroys both recognition and revisualization of letters and words resulting in inability to either read or write: cortical agnostic alexia. On the other hand, if the association tracts connecting the angular gyrus with both calcarine areas are interrupted, only recognition is lost. The individual, although unable to read, can write to dictation and usually spontaneously, for revisualization is not affected. However, as recognition is lost, he is unable to read what he himself has written. This condition, the pure word blindness of Dejerine, is produced by a subcortical lesion in the dominant occipital lobe, which, due to its anatomic location, almost always impinges upon the optic radiation.[24] As a rule the affected fibers are destroyed, resulting in a permanent congruous contralateral homonymous field defect. In most cases there is complete hemianopia, but if only part of the fibers are affected a quadrantic defect may occur.[28-31]

Quadrant defects are produced by lesions affecting the upper or lower contralateral quadrantic fibers of the optic radiation or the upper or lower lip of the calcarine fissure. The field defect is usually bounded by vertical and horizontal radii in lesions of the radiation, and the temporal lobe is more frequently affected than is the occipital lobe.[32] Holmes[5] explains the reason for the contour of the field in quadrantanopia by assuming that the fibers corresponding to the upper and lower quadrants may be separated by an anatomic interval, an opinion that has also been expressed by other authors.

Inferior-quadrant defects occur much more frequently than do superior defects, except in lesions of the temporal lobe. In these cases the resultant field defects are characterized by their incongruity and their tendency to be right angled. On the other hand, occipital lobe lesions produce defects which are always congruous with angles of variable degree.[32]

In cortical lesions there is no anatomic reason why a quadrant defect should have a clean-cut horizontal boundary. Consequently, homonymous quadrantanopias with irregular outlines and steep edges are characteristic of affections of the calcarine fissure.[32]

All cases of agnostic alexia are not caused by cortical or subcortical lesions of the angular gyrus. Due to the close relation between the auditory function and reading in most individuals, and between motor-speech and reading in some, agnostic alexia may also occur in such patients in lesions of Wernicke's center or Broca's convolution, or in the connecting tracts.[33] Thus, in a given case one cannot tell by alexia alone where the lesion is.

The presence of pure word blindness without other aphasic symptoms or general cerebral disturbances is quite uncommon, for

anatomically it presupposes a highly restricted nonexpanding lesion.[26, 27] Such a lesion would have to miss the numerous other association tracts in the occipital lobe and the adjacent visual language areas. Moreover, the picture of any particular aphasia may change, depending on the nature of the lesion producing it, on cerebral substitution, and on reëducation.[18]

The relation between visual verbal alexia and numerical alexia has already been discussed. The presence of the latter, which is usually accompanied by impairment in calculation, may be explained on the same basis as that of verbal alexia; namely, interruption of the association tracts connecting the calcarine areas with the numeral center.[2] However, it is possible that the retention of ability to read numbers in cases of word blindness represents incomplete alexia.[9]

In the presence of subcortical lesions of the angular gyrus, agnosia may occur not only for symbols, but for objects (amnesic aphasia) and colors (color amnesia).[25, 34] In these disabilities, which are in the zone of language the patient may be unable to call an animate or inanimate object or a color by name even though he recognizes and comprehends it. Amnesic aphasia alone is of little localizing value, for it has been described in lesions of the frontal, parietal, and temporal lobes; in cases with no demonstrable pathology; and in toxic states, dementia, senile involution, and other conditions. It most commonly results from lesions in the language formulation area (area 37) or the temporal isthmus.[2] Due to the close proximity of the isthmus to the angular gyrus, Nielsen[2] expressed the belief that lesions in this locality which cause amnesic aphasia are responsible for angular and adjacent parietal lobe defects. Color amnesia is thought to be due to an occipital lesion affecting area 18.[2]

Westphal,[21] over 75 years ago, recorded the first case of alexia without agraphia. However, Dejerine,[23] in 1892, gave the first complete and detailed physiologic and anatomic description of the differentiation of the subcortical from the cortical type. Within the next few years Dejerine's and Serièux's interpretation was confirmed by Bastian, Broadbent, Hinshelwood, and others.[24, 27]

Although ophthalmic literature has shown little evidence that such a condition existed, cases of subcortical agnostic alexia have appeared in the neurologic literature during the past 50 odd years with sufficient frequency to indicate that the condition is not particularly uncommon. However, this is not true of those cases following cranial trauma, for they are very rare.[30]

Although basically a neurologic problem, some of its most important features embrace the field of the ophthalmologist who, on occasion, may be the first physician consulted by the patient. Therefore, it is important that he be familiar with all of its aspects.

It is for this reason, as well as for the infrequent occurrence of the condition following trauma, that this case is reported.

Case report

History

Mr. C. S., a locomotive engineer, aged 62 years, was seen for the first time on October 1, 1946, 10 days after an apparently slight head injury.

On the evening of September 21st, while returning home from work as a passenger in the front seat of an automobile, he struck his head against the sun visor in a minor collision. Immediately after the accident he got out of the car by himself and stood upon his feet without any apparent difficulty. However, he appeared quite dazed, did not recognize people and complained of foggy vision. Full consciousness of his surroundings did not return until his arrival at St. Joseph's Hospital about one hour later. Examination at that institution revealed no evidence of injury except a deep laceration of the skin of the right forehead. Immediately after the wound was sutured, the patient returned home and was placed under

the care of his private physician, Dr. F. I. Bishop. Aside from some mental confusion, he felt no ill effects from the injury and noted nothing unusual until the following morning, when upon picking up the newspaper, he discovered to his astonishment that he was unable to read.

Physical examination

Dr. Bishop examined the patient on September 22nd. His report follows: A rugged muscular male with no apparent defect except a 7-cm. transverse irregular sutured wound across the right forehead. No evidence of vascular disease: blood pressure 134/78 mm. Hg; pulse ranges from 70 to 80. Urine negative. Wassermann reaction negative. No paralysis or anesthesia excepting for numbness about the wound. No headache or vomiting since accident. He denies serious illnesses and previous injuries. As an employee of the railroad he has been examined periodically at two-year intervals for many years. His general physical condition is unchanged since the last previous examination less than one year ago.

Ophthalmological examination

The patient was still unable to read 10 days after the accident and was referred for ophthalmic consultation, a procedure which extended over a period of three successive days. As he entered the office, his gait appeared normal and he exhibited no difficulty in following directions as to where he was to sit. In taking his history he proved intelligent, coöperative, and mentally alert. He seemed to understand all that was said to him, and spoke fluently and without hesitation. He did not appear apprehensive or depressed and was not unduly alarmed. His only complaint was inability to read, and he was confident that new glasses were all that he needed. There was no apparent disorientation of any kind: he had had no difficulty in finding his way about since the accident and readily distinguished right from left. He stated that he had always been right handed, as were his four children and that, so far as he knew, so were all of his forebears.

The visual test revealed that, although he could not distinguish letters, words, or numbers irrespective of size, uncorrected vision of 20/25 was obtained in either eye with the illiterate chart. Vision was correctable to 20/20 and the illiterate equivalent of J1 with glasses. Externally his eyes appeared normal. There was no derangement of the extraocular muscles, nor was nystagmus present. The pupils were equal in size and their reaction prompt. The lenses were only moderately sclerosed and the media were clear. Examination of the fundi revealed normal optic discs and very early senile sclerosis of the retinal vessels compatible with his age. The central fields were normal but the peripheral fields showed a right, homonymous, congruous, irregular upper-quadrant defect with sharply demarked edges (fig. 2).

He was able to write spontaneously and to dictation with promptness, but in no instance could he read a single letter, word, or number that he had written unless he traced the symbols with his finger. Even then, he did so in a stumbling, halting, and incomplete manner. Also, he could do none but the simplest calculations, being almost totally unable to add or subtract beyond two digits or to multiply beyond one digit. There was no evidence of geometric object agnosia; he copied squares, circles, and triangles correctly and also drew them spontaneously. As he had had no musical training, he was not tested for musical notes.

During the examination, it soon became apparent that the patient could not call by name even familiar objects although he knew what the objects were. He knew that a knife was used for cutting, a pen for writing, and a watch for telling time, but he could not call them by name, even though he handled them and listened to the watch.

He had similar difficulty in naming colors, although his color discrimination proved

normal with the Ishihara, American Optical pseudoisochromatic, and Holmgren yarn tests. While he showed no amnesia for animate objects, upon specific questioning he stated that for the first day or two following the accident he could not even call the members of his own family by name although he recognized them perfectly.

NEUROLOGIC EXAMINATION

On October 4th, Mr. S. entered Syracuse University Hospital for neurologic study by Dr. Wardner D. Ayer, the chief points of whose report follow:

The patient appears well orientated and coördination is excellent, but he shows definite anomia and complains of inability to recognize the printed word. He is right handed.

Cranial nerves are negative except for the field defect. In hearing tests, his tuning-fork responses are excellent and normal in both ears. There is no nystagmus nor vertigo. Facial movements are symmetrical. No facial anesthesia is present except that about the wound. Pharynx is normal. There is good gag reflex. The patient swallows normally. The tongue is in mid line. There is no dysarthria; good enunciation; no aphonia. The neck shows no rigidity.

The extremities show normal motor, reflex, and sensory status.

Careful studies for a right hemianesthesia show none. On testing for astereognosis, he apparently recognizes the objects and claims they feel the same in the two hands but he cannot name them. No pathologic reflexes are present. Abdominal and cremasteric reflexes are active and equal. Gait and station are normal.

Lumbar puncture: 5 cc. of very slightly xanthochromic (light picric-acid hue) spinal fluid were removed under no increase in pressure; cell count, 3 white cells, few red cells (actual count not made); protein, 33 mg. Wassermann reaction was negative. X-ray studies of the skull showed no fracture or other abnormality.

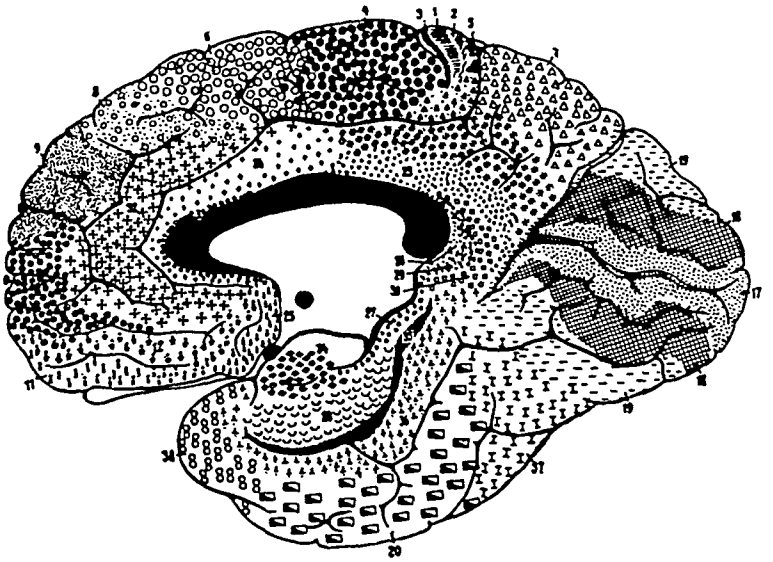

Fig. 2 (Joy). Brodmann's architectonic chart of the cerebral cortex. Mesial aspect. (From: Ford, F. R.: *Diseases of the Nervous System in Infancy, Childhood, and Adolescence.*)

For the three days in the hospital, the patient seemed very comfortable. On one observation the right pupil was larger than the left, but otherwise they were normal. His aphasia continued but seemed somewhat less marked on his discharge.

CLINICAL COURSE

This patient has been under observation over a period of eight months and is now apparently as well as ever except for persistence of the field defect which has re-

mained unchanged. During the first month, all aphasic symptoms subsided appreciably and, by the end of the month, there was only occasional difficulty in naming objects and colors. Ability to identify symbols returned more slowly, but by this time he was able to read fairly well and seemed to understand the meaning of the printed text. However, he missed many multiple syllable words, became fatigued after reading a few sentences, and was consistently confused by certain letters, particularly C & G, b & d, F & E, Y & X, y & x. Numbers caused him less trouble but he had difficulty in differentiating 3 from 8, and 6 from 9. Simple addition, subtraction, and multiplication were accomplished with few mistakes.

By the end of the second month there was no evidence of amnesic aphasia or color amnesia. He was now able to read the newspapers a little, but stated that he had to give up after 2 or 3 paragraphs because of fatigue. A reading test demonstrated frequent hesitation while he spelled out the longer words and he still confused b & d.

There was gradual improvement in the next two months and by the end of the fourth month he felt that he could read as well as ever and without fatigue. He stated that he had never been good at figures but believed he could calculate now as well as before the injury. All confusion of symbols had disappeared.

On January 14, 1947, he was referred to Dr. W. M. Cruickshank of the Psychological Services Center of Syracuse University for complete psychologic investigation. An epitome of the report follows:

On the Wechsler-Bellevue Intelligence Scale the subject received a verbal I.Q. of 97, a performance I.Q. of 94, and a total I.Q. of 97. This places him in the normal group intellectually.

In the advanced progressive reading tests covering seven areas, involving vocabulary and comprehension, and including mathematics, science, and literature, results correlating favorably with the subject's educational background and intelligence level were obtained. These tests showed no concrete evidence of anomia, and there is no evidence of the presence of any form of aphasia.

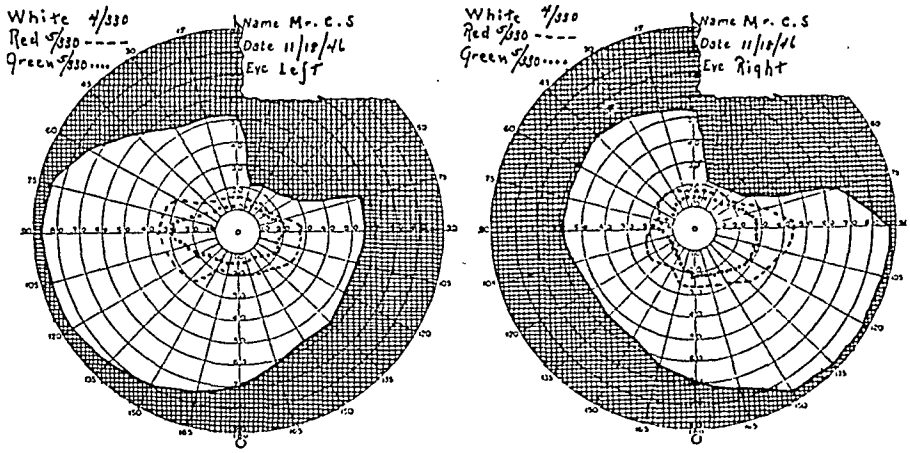

Fig. 3 (Joy). White 2/330 and 1/330 equal the same boundary in defect.

On March 17, 1947, six months after injury, Mr. S. resumed his occupation as a locomotive engineer, his employer feeling that the field defect was not a sufficient handicap to force his retirement. He has carried on to date (May 29, 1947) without incident or accident and feels as well as ever in every way. However, the field defect remains unchanged.

Discussion and Summary

In this case we are dealing with an apparently previously healthy individual who, following a seemingly minor head injury,

suddenly developed aphasic symptoms consisting of visual agnosia for symbols without agraphia, acalculia, amnesic aphasia, and color amnesia, along with right homonymous upper congruous irregular quadrantanopia. All aphasic symptoms disappeared within four months, but the field defect has persisted.

There was no paralysis or anesthesia, intelligence was not affected, and orientation was not disturbed. Motor speech was not involved and spoken words were perfectly understood.

The history of injury, the sudden onset of symptoms, the presence of blood in the spinal fluid, the limited disturbance of the lesion, and the rapid recovery without development of further symptoms all indicate a vascular lesion, probably hemorrhagic in character, with adjacent edema.

The disturbance was primarily that of language on the receptive side without involvement of the auditory or motor-speech mechanisms. Although the absence of a necropsy prevents positive proof of the site of the lesion or lesions producing the symptoms, there is sufficient clinical evidence to indicate with reasonable certainty that it was situated in the left parieto-occipital region.

The reasons for this assumption are as follows:

1. In almost all of the recorded cases of the subcortical type of agnostic alexia which have gone to autopsy the causal lesion has involved the occipital lobe, destroying the association fibers connecting the angular gyrus with both calcarine fissures.

2. Color amnesia is generally considered to be due to lesions of the occipital lobe.[2]

3. Although it is true that amnesic aphasia is usually caused by involvement of the temporal lobe, in the presence of subcortical agnostic alexia the lesion is more likely to interrupt the association fibers in the isthmus,[2] and such a lesion may be in the parietal lobe.

4. Homonymous hemianopia, or less frequently quadrantanopia in the lower field, is almost always present in subcortical agnostic alexia, due to impingement of the lesion on the optic radiation. The upper quadrant defect in this case does not necessarily conflict with the evidence at hand. The presence of congruity militates against an affection of the temporal lobe. It was probably caused by a vascular lesion involving the inferior fibers of the posterior segment of the optic radiation. Quadrant hemianopias are characteristic of vascular lesions in this region, since it is here that the upper and lower halves of the radiation are supplied by two different and separate vessels.[35] However, the field defect could have been caused by a traumatic lesion of the inferior lip of the calcarine fissure.

Franceschetti and deMorisier,[30] in discussing their case and that of L'hermitte, deMassary, and Huguenin,[29] in which there was a lower quadrantanopia, theorized that the field defect was caused by contusion of the upper lip of the calcarine fissure. In pondering why the upper lip should be more exposed to injury than the lower lip, they expressed the belief that the superior lip is more vulnerable because it is in contact with the tentorium and so is much less resistant.

Conclusion

As previously indicated, the site of the lesion or lesions in the case herein reported cannot be determined by any aphasic symptom alone or by the field defect alone. However, taking them all together and in association, the most probable site is in the parieto-occipital region of the left hemisphere. Although the presence of multiple lesions cannot be ruled out, it is tempting to speculate whether a single lesion did not cause all of the symptoms. Involvement either of the parieto-occipital branch of the middle cerebral artery, or of the calcarine branch of the posterior cerebral artery, could produce the necessary pathologic changes. It is probable that the lesion consisted of contusion, hemorrhage, and edema.

Recovery from the aphasic symptoms indicates that the cerebral trauma was not severe. In spite of the evidence of a hemorrhagic lesion, it is probable that contusion and edema played an important part, for the relatively rapid subsidence of the symptoms is definite proof that the association tracts were not irrecoverably destroyed. If an anatomic area subserving a functional unit of language is destroyed, it never recovers.[34] In such cases, return of function depends on training of the homologous area of the other hemisphere, which in a man, aged 62 years, would not occur for a long time, if ever.

The persistence of the field defect is not unusual, for the supragenículate visual pathway appears to be more vulnerable to insult than do the association tracts.

WIDENING OF THE ANGIOSCOTOMA IN THE ALARM REACTION*

M. R. CHOLST,† M.D.
Brooklyn, New York

INTRODUCTION

The various symptoms of alarm are well known. These consist of pupillary dilatation, protrusion of the eyeballs, cutaneous vasoconstriction, contraction of the smooth muscles of the skin causing "gooseflesh," the erection of hairs in man, and increased sweating. Another effect, due to psychic influences, as noted by Evans[1] was a widening of the normal angioscotoma.

An opportunity to study alterations in the angioscotoma in three alarmed subjects was afforded, and the findings are herein reported.

METHOD AND MATERIAL

Gradle,[2] in 1916, believed that the blind areas resulting from the large vessels as they pass from the disc on to the perceiving retina were relative and could be traced several centimeters away from the disc. It is felt by Evans[1] that the angioscotoma is a defect in the visual field related in form to the pattern of distribution of the retinal vessel tree. Duke-Elder[3] defines angioscotometry as the tracing out of thin bands of physiologic blindness corresponding to the retinal blood vessels.

TECHNIQUE

Various investigators have mapped out these shadows using different methods. The technique followed in this study was that of Evans.[1, 4] The Evans stereocampimeter and charts were employed and the test object which was used in all cases was 0.4 mm. in size, spherical, and white. The illumination of the test chart was 15 foot-candles, and monocular fixation was employed.

The test object was moved from the seeing to the nonseeing area, and at all times at right angles to the border of the defect. The blindspot was first outlined and then the object was moved around the periphery of the blindspot until the superior arched angioscotoma was located and plotted. When the width of these bands, adjacent to the blindspot, was greater than 1.5 degrees, they were considered to be abnormally widened. This study was limited to the changes that occurred to this band, since the time element in these particular studies did not permit the mapping of the other bands which originate from the blindspot.

SUBJECTS

(a) Selection. Three individuals were studied while in a state of alarm, under the following circumstances, at the Long Island College Hospital.

Case A was one of a group being examined for the action of a certain drug on the angioscotoma. After the normal angioscotoma had been plotted, prior to the introduction of this drug, a nurse entered the examining room and notified the patient that a cablegram was being held for him in the superintendent's office. This subject immediately showed signs of alarm because, as he stated, his wife who lived abroad had recently become ill. It was requested that the cablegram be delivered to the examining room, and in the interim, while in the state of alarm, his angioscotoma was recharted.

Case B and *Case C* were seen simultaneously in the accident room of the hospital, markedly frightened although coherent and well oriented. They had been working on a chemical experiment at a technical school nearby, when a sudden explosion occurred,

TABLE 1

APPEARANCE AND DURATION OF CHANGES IN SCOTOMA. (SUBJECT EXAMINED BEFORE FRIGHT; AFTER FRIGHT; AND AFTER REASSURANCE.)

	Subject A Time	Pupil	Scotoma Units
Physiologic Angioscotoma	8:45	4	42
Immediately after Saline	9:10	4	42
Immediately after Fright	9:32	7	128
Time Patient Reassured	9:33		
	9:35	6	119
	9:45	4	64
	9:53	4	42
	10:00	4	42
	10:15	4	42

shattering most of the glass equipment. Pieces of glass were found imbedded in the skin of the lower part of the face and chest in both subjects. The chief concern of these individuals was whether glass had entered their eyes. Ocular examinations were entirely negative. Without being notified of this fact, angioscotomas were plotted on these patients, while still in a state of fright, 10 to 15 minutes after the explosion had occurred.

(b) History and physical condition. All known causes for alteration of the angioscotoma were ruled out in the three subjects.

Case A, a British seaman, 24 years of age, a patient in the hospital with a diagnosis of fungus infection of the arms and chest, was otherwise in good physical condition. Past history essentially negative.

Case B, a woman school teacher, 26 years of age, in good physical condition. Last menstrual period, two weeks prior to examination.

Case C, a man, an accountant, 31 years of age, in good physical condition.

PROCEDURE

Case A had a normal angioscotoma plotted, and after the psychic disturbance, was immediately reëxamined. The news contained in the cablegram relieved his anxiety and his angioscotoma was again charted and repeated every 10 minutes until no further change was noted after three successive examinations.

The angioscotomas of *Case B* and *Case C* were plotted while they were still frightened. These patients were then reassured that no foreign body was present in their eyes and their angioscotomas were recharted every 10 minutes, until there was no further change in the width of their respective bands.

OBSERVATION

Widening of the angioscotoma was found in all these cases.

In *Case A,* the normal angioscotoma was first plotted and a control secured by instilling into the conjunctival sac several drops of saline. After being subjected to alarm, a marked widening of the angioscotoma was obtained. Immediately after fright had been dispelled the angioscotoma was found to be slightly less widened and gradually returned to normal with each successive reëxamina-

tion. The normal angioscotoma was again plotted *20 minutes* after anxiety had been relieved.

In *Case B* and *Case C*, the subjects were in a state of fright when their respective angioscotomas were first plotted and an abnormally widened band was plotted in each case. After cause for alarm had been dispelled and the patients reassured, a progressive narrowing of the originally widened angioscotomas was obtained with each plotting. No further narrowing in Case B occurred 22 minutes after fright had been dispelled, and in Case C after 12 minutes. (When the same width occurred after three successive plottings, they were regarded as the normal bands for these individuals.)

Comment

In an attempt to explain the origin and characteristic changes of the angioscotoma, it is apparent that one cannot make the simple assumption that the areas mapped are direct projections of the Purkinje vessel shadows. Vascular dilation is probably not the explanation of the widening phenomenon because:

1. A corresponding change in the diame-

ter of the retinal vessel is not noted when studying the fundus with the ophthalmoscope. For example, when pressure is made upon the globe, the retinal vessels narrow, although the angioscotoma widens.

2. The degree of widening of the angioscotoma is often so great and so rapid that a retinal vessel would probably rupture were it dilated correspondingly (since the widening may be 5 or 6 times greater than the normal angioscotoma).

Alteration of the normal angioscotoma, according to many workers, may be influenced by numerous factors, physiologic as well as pathologic. One hypothesis has been presented[1] in an effort to explain the origin of the alteration of any angioscotoma and is known as the angiogenic hypothesis. This states that the synapse is the most easily interrupted point in the neuron chain. It is extremely sensitive to deleterious agents and in this way acts as a sort of fuse to protect the delicate rod and cone layer. Interference with the normal posterior drainage fluid from the eye, via the perineural and perivascular spaces, produces a temporary damming up of the fluid with a consequent edema of the synapse.[5] This results in a loss of response of the rod or cone of the corresponding chain and widening of the angioscotoma results.

Evidence was found in the literature which suggests a possible explanation for the alterations of the angioscotoma in this study.

Cannon,[6] in his classic experiments with the denervated heart, proved that fright, rage, pain, among other things, produced a reflex liberation of an adrenalinlike substance causing an acceleration in the heart rate of about 20 to 40 beats per minute. Removal of the adrenals or their denervation prevented this effect.

According to Burton-Opitz,[7] working with animals, injection of epinephrine into the circulation produced a rise in venous as well as arterial pressure. G. Rosenow[8] also observed this rise in venous pressure in normal men, using hypodermic injections of epinephrine. Clinically, dilation of the veins of the forehead and neck in individuals under psychic tension has been noted. Changes in venous pressures are accompanied by similar changes in the cerebrospinal fluid pressure, state Merritt and Fremont-Smith.[9]

They found that patients who have increased venous pressure, such as accompanies congestive heart failure, frequently show increased cerebrospinal-fluid pressures. In 32 patients with congestive heart failure the cerebrospinal-fluid pressure was found to be elevated. In studying the effect of the administration of drugs on the cerebrospinal-fluid pressure, they noted that adrenalin produces an increase in cerebrospinal-fluid pressure.

Evans believes that increased intracranial pressure produces a mechanical dilatation of the perivascular spaces by obstructing the posterior drainage system of the intraocular-tissue fluid. It is interesting to note that Spaeth[10] reported a patient with an intracranial vascular lesion who had early extensive widening of the angioscotoma.

There is thus ample evidence that an adrenalinlike substance is liberated in psychic disturbances. The explanation for the widening of the angioscotoma in fright could possibly be due to a transient increase in venous blood pressure which, in turn, produces an increased intracranial pressure. This interferes with the normal drainage of the intraocular-tissue fluids posteriorly, causing a dilatation of the perivascular spaces. The back pressure that ensues interrupts the synapse in the underlying retina due to the edema produced, resulting in a widening of the angioscotoma. Thus, the widening of the angioscotoma in acute apprehension could be explained by the angiogenic hypothesis.

The disappearance of the psychic stimulus is followed by a reversal to normal physiology, which can be clinically noted by the normal angioscotoma replotted.

Conclusion

1. This study presented the effect of alarm on the angioscotoma and also the possible physiologic mechanism involved.

2. A widening of the angioscotoma was demonstrated in the three cases studied, which gradually returned to normal shortly after the causes were removed.

3. This effect of fright could perhaps be a source of error in the mapping of the blindspot when routine central scotometry is performed on individuals in an apprehensive state.

THE CHARACTER OF THE NYSTAGMUS INDUCED BY AMYTAL IN CHRONIC ALCOHOLICS*

Morris B. Bender, M.D., and Charles A. Brown, M.D.
New York

Barbiturate drugs are known to influence ocular movements in man and in the experimental animal.[1,2] A common sign of barbiturate intoxication is a slow coarse nystagmus which appears when the eyes are deviated from the mid position.

While studying the effect of this drug on eye movements, it was noted that in chronic alcoholics intravenous injection of sodium amytal produced fine, shimmering nystagmus. This was a conspicuous and consistent finding. The coarse and slow nystagmoid movement which is often seen in barbiturate intoxication was not present. The difference in response to amytal between the alcoholic and normal individual was so prominent that we felt it warranted publication.

*From Bellevue Psychiatric Hospital and the Departments of Neurology and Psychiatry of the New York University College of Medicine.

Material and Method

The ocular statuses of 15 patients with a history of alcoholism were studied before and after intravenous administration of sodium amytal. Those who showed disorders in ocular movements on routine neurologic examination were excluded from the series. A group of 15 psychiatric patients, who manifested no physical or neurologic defects and had no history of alcoholism, served as the control group.

A 5-percent solution of sodium amytal was injected into the antecubital vein at a rate not exceeding 0.1 gm. or 2 cc. per minute. The total dose was never more than 0.5 gm. or 10 cc. During these tests the patients were instructed to fix their gaze on an object away from the central visual axis. Usually the patient was told to maintain his gaze either to the right or to the

left. With the eyes in a deviated position the onset of nystagmus may easily be detected.

Results

(A) Control series

In the control subjects injection of sodium amytal generally produced ocular responses of two types: (1) wide, slow irregular oscillations in which the eyes drifted slowly toward the midline from a point of fixation and returned to the original position with a flick; and (2) coarse, slow rhythmic nystagmus. This nystagmus varied considerably in rate and amplitude but, as a rule, it always remained sufficiently slow so that discreet oscillations of the eyes could be observed.

The following two cases were typical of the control series.

Case 1. D. P., a boy, aged 15½ years, was admitted to the hospital because of a conduct disorder. Physical and neurologic examinations were normal. The eye movements were intact and there was no nystagmus in any position of the eyes.

Sodium amytal, injected into the antecubital vein:

0.1 gm.—produced no nystagmus but as the injection continued coarse nystagmoid jerks were noted.

0.2 gm.—the nystagmoid movements became more prominent.

0.3 gm.—coarse nystagmoid jerks alternated with regular, rhythmic nystagmus of moderate amplitude. This was pronounced on horizontal or lateral deviations. Occasional nystagmoid jerks were also noted on upward gaze.

0.5 gm.—coarse nystagmus present in all directions. In time the coarse nystagmus became evident in all directions. The patient became drowsy five minutes after the injection of the drug and shortly thereafter fell asleep. Usually, when the patient did not fall asleep the nystagmus persisted for over two hours.

Case 2. T. N., a young woman, aged 19 years, was admitted to Bellevue Psychiatric Hospital with the symptoms of a psychic depression.

Sodium amytal was injected intravenously:

0.1 gm.—produced no nystagmus.

0.2 gm.—produced wide nystagmoid jerks on lateral gaze.

0.3 gm.—produced nystagmoid jerks alternating with sequences of coarse nystagmus on right and left lateral gaze. Later there was rhythmic nystagmus of moderate amplitude on right lateral gaze; coarse nystagmus with frequent jerky oscillations on left lateral gaze. In time the difference in the type of nystagmus between the right and left side deviations became reversed. This reversal was found to take place periodically, sometimes at 1- to 2-minute intervals.[1] The patient became drowsy and thick of speech. Her nystagmus lasted for over an hour. The duration of the nystagmus varied with the quantity of the drug injected.

(B) Alcohol group

All the patients in this series showed, on intravenous injection of sodium amytal, a nystagmus which was different from the type observed in the control series. In fact, one patient who denied addiction to alcohol showed fine shimmering nystagmus on injection of this drug. On further investigation it was learned that this patient had previous admissions to this hospital with diagnosis of acute and chronic alcoholism.

Case 3. G. O'C., a woman, aged 53 years, had been drinking for 20 to 25 years and had been admitted to Bellevue Hospital for alcoholism on several occasions. Neurologic examination was essentially negative. There was no spontaneous nystagmus. All eye movements were normal.

Sodium amytal produced, after the injection of:

0.1 gm.—no nystagmus.

0.2 gm.—no nystagmus.
0.3 gm.—rapid, fine "shimmering" nystagmus on lateral gaze.

Further injection, as much as 0.5 gm. of the drug, produced no change in character of the nystagmus. It continued to be fine and rapid. The duration of the nystagmus after injection of the drug was not nearly so long as that observed in the control series.

In most of the alcoholic patients, it was necessary to inject more than 0.3 gm. of sodium amytal before the nystagmus became manifest. It was also observed that the alcoholic suffered less from the narcotic action of the drug than the patient in the control series; the alcoholics were less drowsy than the controls.

Case 4. L. E., a man, aged 56 years, was admitted to Bellevue Psychiatric Hospital with a history that he had been drinking for over 40 years. At one time he was treated for delirium tremens and on two other occasions for alcoholic hallucinosis.

Sodium amytal injected intravenously produced:

0.1 gm.—no nystagmus.
0.2 gm.—inconstant, coarse nystagmoid jerks.
0.3 gm.—inconstant, coarse nystagmoid movements.
0.4 gm.—persistent, coarse, and rapid nystagmoid movements.
0.5 —"shimmering" nystagmus on lateral gaze alternating with coarse nystagmoid jerks.

It was noted that when the nystagmus became persistent it assumed the character of rapidity and shimmering. There were several such instances in the alcoholic series.

Case 5. W. S., a man, aged 32 years, was admitted to the hospital for symptoms of a depression. After a period of observation a diagnosis of "neurotic depression without psychosis" was made. The patient denied alcoholism and claimed that he drank only on occasions. In the course of a psychiatric interview, during which he was under the influence of sodium amytal, "shimmering" nystagmus was observed. This raised the suspicion of alcoholism. While the patient was under the influence of the drug it was learned from him that he had been addicted to alcohol for many years, that he was drunk at least twelve times, and that he was previously admitted to Bellevue Hospital.

Sodium amytal injected on a subsequent occasion disclosed:

0.1 gm.—produced no nystagmus.
0.2 gm.—produced inconstant, coarse nystagmoid jerks alternating with fine "shimmering" nystagmus on lateral gaze.
0.3 gm.—coarse nystagmoid jerks alternating with fine "shimmering" nystagmus on lateral gaze. Later the nystagmus became constantly fine, rapid, and shimmering.

Case 6. J. L., a man, aged 51 years, was not suspected of drinking alcohol. He was originally selected as a control. During the intravenous injection, it was observed that the nystagmus was of the type usually seen when amytal was injected in chronic alcoholics. Further questioning confirmed that he had excessive drinking habits of long standing.

Sodium amytal injected intravenously produced:

0.1 gm.—fine, inconstant nystagmoid jerks on right lateral gaze.
0.2 gm.—fine, inconstant nystagmoid jerks on right lateral gaze.
0.3 gm.—fine, nystagmoid jerks on left lateral gaze. Occasional fine nystagmus on right lateral gaze. The patient's mood changed. He became euphoric and facetious. He claimed he had been drinking for over a year and that he had consumed between 4 and 5 pints of "liquor" a week.
0.4 gm.—rapid almost "shimmering" nystagmus of right lateral gaze. Very fine rapid nystagmus, almost "shimmering," alternating with regular nystagmus of moderate amplitude on left lateral gaze. Very fine nystagmus was noted on up-

ward gaze. The nystagmus in all directions was persistent.

0.5 gm.—"shimmering" nystagmus on right lateral gaze. "Shimmering" nystagmus alternating with fine nystagmoid movements on left lateral gaze. Very fine, almost "shimmering" nystagmus on upward gaze.

Evidently the character of the induced nystagmus helped us to discover that the patient had been an alcoholic.

Discussion

In previous communications the effect of intravenous barbiturates on ocular movements and on various types of nystagmus were discussed. The pharmacologic mechanism for these alterations, however, have not been clearly understood. Spiegel, working with cats, found that amytal produced ocular effects by action on the brain stem as well as on other parts of the brain.

The present observations reveal that alcohol, when imbibed over a long period, alters the function of the nervous system in man. The latter alteration is apparent in reactions of the eyes to intravenous injection of sodium amytal. In the chronic alcoholic there is a shimmering nystagmus rather than the usual coarse rhythmic nystagmus found in the normal individual.* The fine rapid nystagmus is found even months after the patient has stopped drinking. This suggests that alcohol produces more or less of a permanent change in nervous-system function. Whether this change is basically morphologic or chemical is not known. In this connection, we have seen patients with acute and chronic alcoholism who have manifested unmistakable signs of central nervous-system involvement, such as ophthalmoplegias and marked tremors. Yet, on gross and microscopic examination of the nervous system, no definite evidence of a lesion in the brain, or brain-stem, was found. In such cases one was forced to assume that the neurologic signs observed during the period of alcoholic intoxication were due to a chemical (alcohol) which altered nervous-system function, without producing a change in structure, as could be shown by available histologic staining methods.

It would seem probable that the shimmering nystagmus which we find on intravenous sodium amytal in the chronic alcoholic may also be the result of a more or less permanent chemical change in the nervous-system function. This alteration is not necessarily accompanied by a demonstrable lesion in the nervous system. A method which discloses the presence of such an alteration in function is the study of ocular response (nystagmus) to intravenous injection of sodium amytal.

477 First Avenue (16).

* Shimmering nystagmus was also observed in patients with traumatic encephalopathy. However, we have little data to show that intravenous sodium amytal produces an abnormal type of nystagmus in patients with encephalopathies due to causes other than alcohol.

DIATHERMY TREATMENT OF ANGIOMA OF THE RETINA*

PHILIP MERIWETHER LEWIS, M.D.
Memphis, Tennessee

Angiomatosis retinae is a rather rare condition. Nevertheless, it is one of great interest from the standpoint of diagnosis and also of treatment. Diathermy coagulation has been extensively employed in recent years for the control of many ocular conditions. It seems to be particularly suitable for the destruction of retinal angiomas. In a paper on this subject,[1] presented before the American Academy of Ophthalmology and Otolaryngology in 1942, it was pointed out that only about 145 cases of retinal angioma had been reported in the literature. Since then, reports of the condition have been somewhat more common, leading one to conclude that perhaps the disease is not so rare as we have thought. No attempt is made in this paper to review the literature, as it has been adequately reviewed by Bedell,[2], Lloyd,[3] Cordes and Hogan,[4] and others. This paper is presented to promote the treatment of retinal angiomas by diathermy, to give the "follow-up" on a case operated upon in 1941, and to report another case operated upon in 1944.

A description of the usual fundus findings in angiomatosis retinae is unnecessary before this society as you are already familiar with the appearance of the disease. As Bedell[5] has pointed out, the presence in the retina of greatly dilated, parallel blood vessels usually denotes angiomatosis. However, atypical or far-advanced cases have been confused with Coats's disease, retinoblastoma, aneurysm, endophthalmitis, and several other conditions. Secondary glaucoma and hemorrhage may occur and render the diagnosis extremely difficult.

TREATMENT

Before any local treatment is begun, a thorough general and neurologic examination should be made to rule out involvement of the cerebellum or other organs. Radium applications and roentgen-ray therapy have been used with variable results. However, Cordes and Dickson,[6] in 1943, reported two cases treated successfully by X-ray irradiation. Weve,[7] in 1939, was the first to report the use of surface coagulation and punctures with diathermy. Kaye,[8] in 1941, reported two cases successfully treated in London by a combination of katholysis with surface and puncture diathermy. On April 29, 1941, Fralick[9] performed the first diathermy destruction of a retinal angioma in this country. Without knowledge of Fralick's operation, my first case was done on November 7, 1941, with the assistance of Dr. R. O. Rychener. Guyton[10] reported two cases on which he operated in 1942. One of these patients had a single angioma of one eye which was destroyed by diathermy punctures, with the preservation of normal vision. The other eye of the same patient had multiple angiomas with extensive retinal detachment. The angiomas were successfully destroyed, but no vision was restored.

The localization of the angioma may be done by the same methods as are used for the localization of retinal tears. The technique employed in the diathermy destruction of retinal angiomas is essentially the same as used for retinal detachments and was described in a previous paper.[1] Punctures with micropins into and immediately around the angioma are necessary. In addition to this, a moderate degree of surface coagulation of the sclera is advisable.

In view of the satisfactory results obtained by diathermy, it seems to be the method of choice in single and also in multiple angiomas of the retina. In early cases the prognosis is good for the preservation of useful vision. In advanced cases with ex-

* Presented at the 83rd annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June, 1947.

tensive exudation, degeneration, and detachment, the prognosis for restoration of vision is bad, but the operation is justifiable for preservation of the eyeball, although the latter is not always possible. X-ray treatment may, in certain hands, prove just as satisfactory. Reports of a larger number of cases treated by the two methods and observed over several years, with a final careful analysis of end results, will probably settle this question eventually.

Case reports

Case 1

History. The first case has already been reported and will be discussed here only in the following brief résumé to bring the history up to date. A white man, aged 25 years, was seen first in October, 1941, for refraction because of asthenopic symptoms. He had only recently noticed that the vision of his left eye was poor. He was found to have the typical enormously enlarged vessels and a single angioma far forward in the 3:30-o'clock meridian.

Operative procedure. Operation on November 7, 1941, using Walker micropins, as previously described, succeeded in destroying the angioma and the blood vessels. Vision in this case was only 8/200 before operation. This poor vision was due to the very extensive exudates, or deposits of lipoid material in the macula and surrounding retina. Following operation, vision did not improve. It remained the same for about one year, but had gradually become reduced to 2/200, due to extensive degenerative changes and scar tissue formation.

Course. The fundus picture had remained practically unchanged for the past several years. No trace remained of the large artery and vein, but along their former course, in the region of the equator, newly formed blood vessels and fibrous tissue extended forward into the vitreous to a height of about 6 diopters. When last examined (April, 1947), two small spots of hemorrhage were visible in that area, indicating that perhaps a very quiet form of proliferating retinitis was still going on. Dense scar tissue occupied the site of the former angioma. The general condition of the patient had remained excellent. The eye appeared a little smaller than the other and a scarcely noticeable exotropia was present.

Case 2

History. Mrs. M. P., a white woman, aged 34 years, was first seen in August, 1944, on one of the medical wards of the John Gaston Hospital. She had noticed for about two weeks that vision of her left eye was blurred, but she was confined to the Hospital to find the cause of severe headaches which had been present for three days before admission. The patient had been admitted to the Hospital for various ailments over a period of 12 years. Only one of these conditions was of particular interest. In June, 1944, an exploratory laparotomy had been performed. A small cyst of the pancreas was found and removed. It measured 20 by 8 by 2 mm. Microscopic section showed it to consist of a fibrous tissue wall with a low columnar cell lining. It was not an angioma. The family history was also interesting: her father died of a brain tumor (type unknown) at the age of 36 years. Her daughter died of a tumor (cerebellar cyst) at the age of 17 years, and one of her sisters died of a brain tumor. (None verified by autopsy.)

Physical examination. Complete general physical and laboratory examinations were negative and the consulting neurosurgeon found no evidence of cerebellar or other intracranial involvement. The right eye was normal and the vision, 20/20. The left eye was normal except for the fundus findings. The disc was slightly swollen with blurred borders. Below the disc, two very large blood vessels coursed tortuously downward and forward to a tumor mass in the 6-o'clock meridian, between the equator and the ora serrata. The tumor mass was about 1¾ times the size of the optic disc and of a light reddish brown color. There was no

separation of the retina, and none of the degenerative changes which had been so abundant in the first case. Vision was reduced to 20/100.

Operation. On September 6, 1944, operation was performed at the Memphis Eye and Ear Hospital. The procedure used was essentially the same as that used in Case 1. The conjunctiva, Tenon's capsule, and the inferior rectus muscle were separated from the sclera and retracted downward. One Walker micropin was placed on each side of the 6-o'clock meridian just anterior to the equator. Ophthalmoscopic examination showed these pins to be located just at the posterior border of the angioma. Micropins were then placed on either side of the tumor and the entire area between these 4 pins extending forward to the ora serrata was studded with punctures. A total of 15 Walker pins was used with 45 ma. of current. Surface diathermy was not applied in this case. No hemorrhage occurred during the operation.*

Postoperative Course. On the second postoperative day, there was a retinal detachment present. This gradually increased until on the 16th day it covered the entire lower half of the eye and obscured all but the upper border of the disc. In the meantime, numerous hemorrhages had occured into the retina and it was impossible to find any definite tears, but a disinsertion was thought to be present. On the 20th day after the first operation, a second diathermy procedure was performed. A barrage of micropins was inserted to surround the site of the angioma. Surface diathermy was also applied. Sclerotomy with a Graef knife released a considerable amount of clotted blood. Following this procedure, the vitreous was very hazy with blood so that for some time the fundus could not be seen. After another four weeks in bed, the patient was sent home with pinhole spectacles and with a

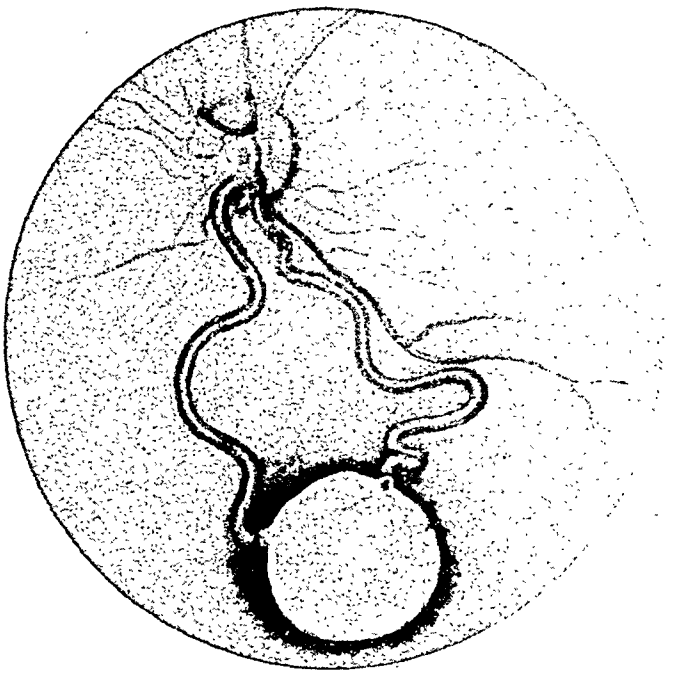

Fig. 1 (Lewis). *Case 2.* Preoperative appearance.

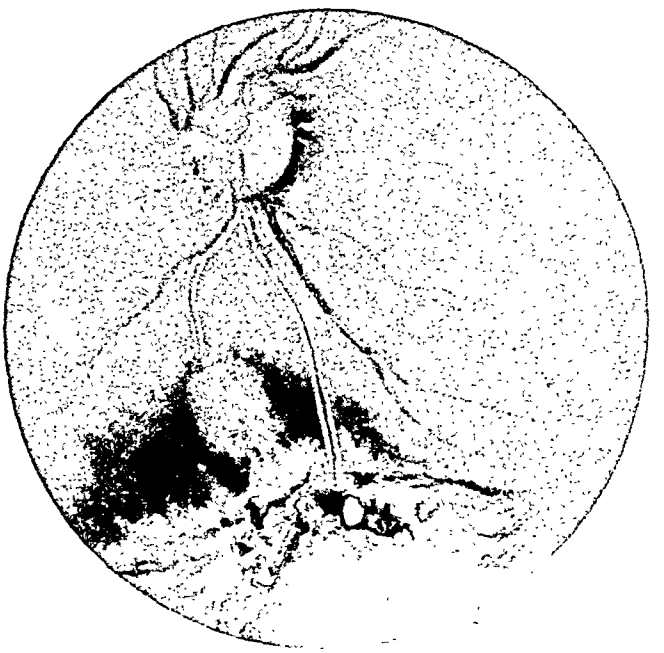

Fig. 2 (Lewis). *Case 2.* Appearance 32 months postoperatively.

* Dr. George Kambara, of Madison, Wisconsin, former resident in the Memphis Eye and Ear Hospital, assisted in the operation and management of Case 2.

rather gloomy prognosis. Iodides given internally, and the passage of time gradually cleared the vitreous. However, it was five months after operation before fundus photographs could be made. Even then they were indistinct. At that time the disc was fairly normal. The vessels were smaller. There was a rather diffuse pigmentation of the retina and the site of the angioma appeared quite red, but no details were visible. Vision was 20/100. The patient was not seen again until July, 1945. Vision was then 20/40 and the fundus could be seen fairly clearly. The angioma seemed to be completely destroyed. Its former site and the entire surrounding retina were pigmented and scarred. The vein appeared as a small column of blood which stopped just anterior to the equator. The artery was rather large and extended from the disc into the scar anteriorly. Both vessels were surrounded by fibrous sheaths. There was no evidence of tumor recurrence, but the patent artery made the final result seem somewhat doubtful.

Outcome. When next seen in February, 1946, vision had improved to 20/30 and J2. White atrophic spots, pigmentation, and very irregular scar tissue occupied the lower anterior one sixth of the fundus. The vessels were slightly smaller. Final examination on April 21, 1947, showed the vision to be 20/30, corrected with a +0.75D. cyl., ax. 90° to 20/20. Near vision was J1 with normal accommodation. The eyes functioned normally and the patient was unaware of a rather large defect present in the upper visual field. There was a definite flattening of the eyeball below, probably due to contraction of the sclera from coagulation. The vitreous was perfectly clear. The fundus was normal except for the extensive irregular scarring and the peculiar vessels. The blood columns were smaller, the fibrous walls thicker and whiter. The vein stopped at the equator, but the artery ran forward into the temporal side of the scar.

Almost three years have elapsed without recurrence of the growth and with great improvement of ocular functions. She still has occasional severe headache and recently (March, 1947) underwent pneumoencephalography, with negative results.

Comment. In retrospect it seems that failure to use surface coagulation in this case, at the time of the first operation, was a mistake. It might have prevented the necessity of the second operation. It is quite possible that 45 ma. of current is too much to use and that less scarring would result from a smaller amount. A smaller reaction without any hemorrhage would be ideal and may be possible with more experience.

Summary and Conclusions

Two patients with angiomatosis retinae were treated by diathermy coagulation and observed for 5½ years and 3 years respectively.

The first was an advanced case and while the angioma and large vessels were destroyed and the eyeball preserved, vision was not restored. The second case was early. The angioma was destroyed and normal vision was present after 34 months.

Due to the progressive nature of angiomatosis retinae it seems that all cases uncomplicated by intracranial or other serious involvement should be given the benefit of some type of treatment to destroy the tumors. Diathermy offers the best method for single angiomas, particularly when located far in the periphery. It is felt at present that the combination of surface diathermy along with multiple punctures into and around the angioma is, in the majority of cases, the procedure of choice.

GLAUCOMA ASSOCIATED WITH SUBLUXATION OF THE LENS IN SEVERAL MEMBERS OF A FAMILY*

J. PAGE HARSHMAN, M.D.
Toronto, Ontario

Ectopia lentis, or familial displacement of the lens, is most frequently manifested as a bilateral, symmetric displacement of the lens due to defects in the zonular fibers. Partial or complete luxation of the lens occurs and is frequently complicated by a secondary glaucoma. Falls and Cotterman,[1] in 1943, reviewed a family of 157 members, 24 of whom had ectopia lentis. Thirteen of these 24 members developed glaucoma; no case of glaucoma was found in the non-affected group.

It has long been recognized that glaucoma may be associated with changes of the lens. Following the classification of Parker Health,[2] glaucoma may arise either (1) when the lens is in position or (2) when it is displaced.

Under the first heading, we can include microphakia, glaucoma capsulare, and increase in the lens bulk. In microphakia, the associated glaucoma has its onset in youth and takes the form of acute attacks. Glaucoma capsulare, or desquamation of the lens capsule, may cause glaucoma by toxic, irritative, and mechanical methods. An increase in lens bulk may press on the ciliary body and cause an irritative process leading to blocking of the filtration angle.

In the second group are found both partial and complete luxation of the lens, whether due to congenital weakness of the zonule or to trauma. In ectopia lentis, or luxation of the congenital type, the lens sometimes comes in contact with the ciliary process and gives rise to an irritative vasomotor reaction. Local edema causes a forward displacement of the lens and blocking of the angle of the anterior chamber by the root of the iris. Complete dislocations of the lens, either into the anterior chamber or the vitreous body, are frequently followed by glaucoma.

This paper presents the case reports of two brothers and an analysis of the histories of the other members of their family.

CASE REPORTS

Case 1. L. O., a white man, aged 55 years, was seen in September, 1941, complaining of pain in the right eye of three days' duration. His left eye had been enucleated in 1938 for absolute glaucoma. The tension of the right eye was hard to fingers, the cornea was steamy, the pupil was fixed. Treatment with ¼-percent eserine drops produced only partial relief from the pain. Twelve hours

* From the Department of Ophthalmology, University of Toronto, and the Toronto Western Hospital.

later an iridectomy was performed. The iridectomy relieved the severe pain, but the tension remained above normal and treatment with pilocarpine solution was necessary from 1941 to 1944. Refraction of the right eye was: −1.75D. sph. ⌒ −1.0D. cyl. ax. 100° = 20/50−1.

On February 8, 1944, the patient bumped his head against another worker. This caused the rays to proceed "up" when reflected from objects, rather than "down as previously." Objects appeared upright and normal to him. There was no pain, and he could see to get around. He realized that he had dislocated the lens of his right eye. Examination four days later showed an oily translucent mass in the anterior chamber of the right eye. The eye was not tender and the tension was normal to palpation. The lens was removed on February 15th by loop extraction, little vitreous being lost. Recovery was satisfactory and on April 11th the right eye was white and quiet with normal tactile tension. Glasses were prescribed: O.D., +10.5 D. sph. ⌒ +3.5D. cyl. ax. 30° = 20/30.

This patient with glaucoma and dislocation of the lens responded satisfactorily to treatment when the lens was removed, and the good visual result has since been maintained.

Case 2. C. O., aged 54 years, the brother of L. O., was first seen on May 5, 1947. About six weeks previously the vision of the left eye had become blurred and his optometrist had found the eye had become more myopic. For three weeks his left eye had pained and he had noticed rings about the lights.

Vision was: O.D., 20/20; O.S., 20/200 correctible to 20/60 with a −3.75D. sph. ⌒ −1.25D. cyl. ax. 110°. Tension was O.D., 19 mm. Hg; O.S., 65 mm. Hg (Schiøtz). The right eye was normal. On the left side, the conjunctiva was injected, the cornea was steamy, the anterior chamber was almost completely filled with the lens which projected through the pupil. The right pupil was round, 2 mm., reacted to light and accommodation, consensually and directly. The left pupil was oval, 7 mm., and did not react. The fundus was hazy and no gross pathologic condition was seen.

He was treated with neosynephrine (10 percent) drops to the left eye. On May 6th, the tension was 30 mm. Hg, but the next day it was 70 mm. On May 9th, an intracapsular extraction of the left lens was done, with a peripheral iridectomy. The tension at the time of operation was 70 mm. Hg. At the first postoperative dressing there was a prolapse of iris at the 1-o'clock position. This was excised and the wound healed well. A month later refraction was O.S., +10.5D. sph. ⌒ +2.D cyl. ax. 30° = 20/30. The field was normal for 5/330 white test object. The tension has stayed normal since the operation.

Family history

Grandmother A. The first member of the family of which we have any record became blind at the age of 43 years from bilateral glaucoma. She had eight children, of whom five were affected, as follows:

M. O. This was the mother of L. O. At the age of 52 years she had an operation for glaucoma on her left eye, and four years later a cataract was removed from that eye. When 65 years old, her right eye was operated on in St. Michael's Hospital, Toronto, for glaucoma with secondary cataract. It is recorded that prior to operation, the lens was dislocated into the anterior chamber.

M. W. This was an aunt of L. O. She suffered, at the age of 46 years, an acute attack of glaucoma in the right eye, for which an iridectomy was performed. At 50 years of age, a right cataract was removed, and it was noted that an incipient cataract was present in the left eye.

T. A. This is an uncle of L. O. When 37 years of age, his right eye was operated on for glaucoma. There is no further report on this eye until at the age of 60 years, it was said to be blind. Five years later, Dr. A. B. Ritchie, of Guelph, Ontario, noted long-

standing glaucoma in the left eye with vision reduced to light perception only. An iridectomy was performed and some vitreous was lost at operation. The vision is now light perception only.

C. A. This was an uncle of L. O. He was known to have glaucoma, but no further information is available.

glaucoma in the right eye. The eye did not respond to miotics, but on instillation of a 1:100 solution of adrenalin, the tension dropped and the pupil dilated to reveal a dislocated lens. A basal iridectomy with extraction of the lens was done. Subsequent vision was 20/20.

One year later, acute glaucoma, which did

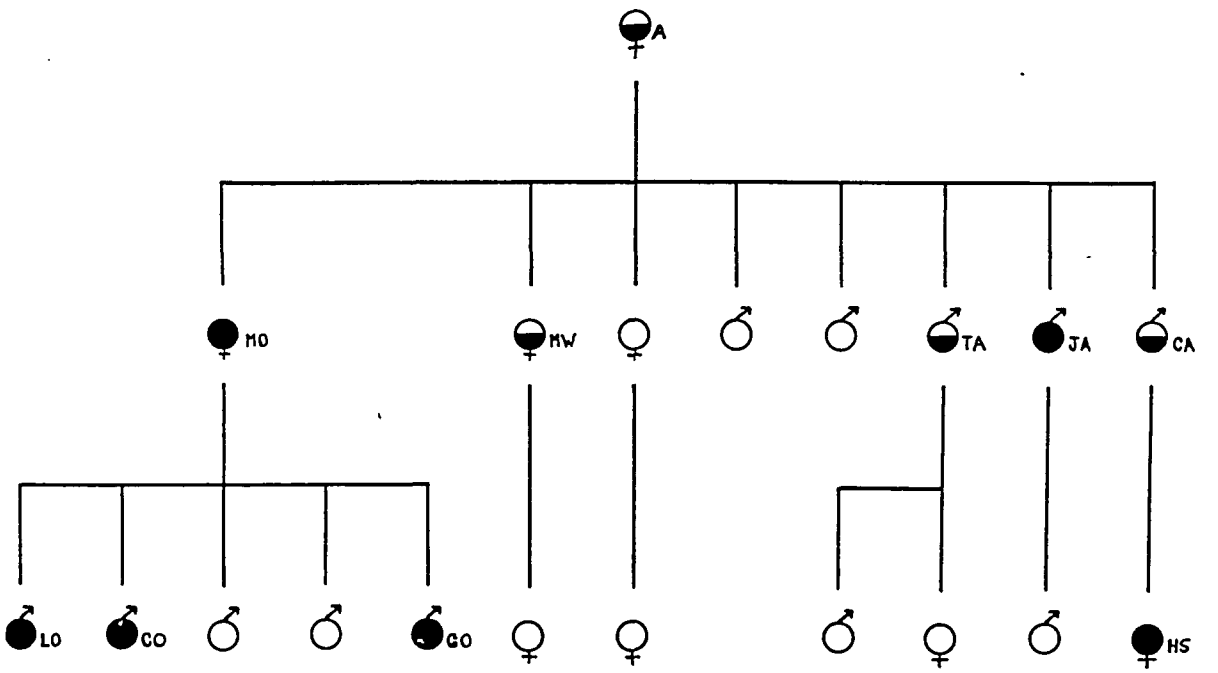

Fig. 1 (Harshman). Genealogic tree of a family in which several members suffered from glaucoma associated with subluxation of the lens. Half-blocked circles represent patients with glaucoma. Fully blocked circles represent patients with glaucoma and dislocated lenses.

J. A. This was an uncle of L. O. He has had eye trouble since the age of 40 years, and is known to have dislocated lenses. There is no medical report available.

Third generation

In the third generation, four members of the family are known to have dislocated lenses and glaucoma.

L. O. This case has been described above.

C. O. This case has been described above.

G. O. A brother of L. O. Dr. Gerald Spero, of Detroit, Michigan, states that the patient's first complaint was one of increasing myopia. At the age of 36 years, refraction was: −6.0D. sph. O.U. = 20/20; the tension and fields were normal. Six months later, the patient suffered an acute attack of

not respond to miotics or strong adrenalin, developed in the left eye. Dr. Kronfeld, of Chicago, did a basal iridectomy on the left eye. It was noted after operation that the left lens was dislocated. Nine months later, a loop extraction of the dislocated lens was done, and vision of 20/20, with correction, was obtained.

H. S. This is the daughter of C. A. and a cousin of L. O. When aged 42 years, she noticed a loss of vision for distant objects, and was told she was near-sighted. Glasses were prescribed. The glasses were changed a year later, and shortly after that Dr. Ruedemann, at the Cleveland Clinic, made a diagnosis of glaucoma. A few months later, the patient suffered an acute attack of glaucoma in the left eye, which was relieved by an

iridectomy and extraction of the dislocated lens. In the same year, she suffered an acute attack of glaucoma in the right eye. Iridectomy and extraction of the lens was again done. Dr. Ruedemann reports that the operation on the right eye was more successful than that on the left.

Comment

Stokes[3] has reported a family of five generations exhibiting glaucoma, and has reviewed the literature regarding hereditary glaucoma. He finds that the hereditary disease is usually chronic in form, and that permanently good results are obtained by a fistulizing operation, iris inclusion operation, or the Elliot trephining operation.

The family herein reported carries a hereditary tendency to glaucoma. Of the 10 members exhibiting the disease, 6 had dislocated lenses, and a 7th had an incipient cataract. Four patients showed a sudden increase in myopia prior to the appearance of the hypertension. Thus, the glaucoma is intimately associated with dislocation of the lens. The glaucoma exhibited its first clinical manifestations in the 4th to 6th decades, and its onset was acute in several of the cases.

Therefore, this series of cases does not belong in the usual group of hereditary glaucoma. They show a type of glaucoma secondary to a pathologic condition of the lens, whether it is faulty position causing a mechanical obstruction of the angle, or some irritative process of the ciliary body. For these reasons, the usual glaucoma operations fail to give complete relief.

Summary

A family, which contains many cases of glaucoma associated with subluxation of the lens, is presented and discussed. The disease, in this group, does not respond to the usual medical or surgical treatment for glaucoma, but is only permanently controlled by removal of the lens. Such cases should be remembered because they indicate that subluxation of the lens may be a factor in cases of glaucoma which do not respond to the ordinary operations.

I wish to thank Dr. R. J. P. McCulloch and Dr. Clement McCulloch for their kind permission to quote the case histories of patients L. O. and C. O.

THE OCULAR EFFECT OF SEVERAL IRRITANT DRUGS APPLIED DIRECTLY TO THE CONJUNCTIVA*

José J. Estable, M.D.†
Montevideo, Uruguay

The aim of this work is to compare the immediate and delayed effects of a variety of irritants on the cornea—a tissue normally devoid of blood vessels—with their effects on the vascular tissues of the sclera and eyelids.‡

Method

The observations were made on white rabbits, unless otherwise stated. The substance, as powder or dissolved in 0.7-percent solution of sodium chloride, was placed in the lower conjunctival sac of one eye and held there usually for one-half minute. This was repeated at intervals of one or several days, if necessary. The other eye was treated with 0.7-percent solution of sodium chloride and used as a control. The eyes were examined for evidence of inflammation, and changes in the corneal structures were observed with the biomicroscope.

Results

The reactions observed after the application of several substances are the following:

1. Anthraquinone

This drug, applied to the eyes as a dry powder, daily for several times, produces only immediate sensory and inflammatory reaction (discomfort, blepharospasm, and conjunctival congestion) that disappears very soon. The eyes appear normal in a few hours, and the conclusion is that the anthraquinone produces these reactions by the mechanical contact of the powder, which is almost insoluble in the eye secretion.

2. Arsenic trioxide

The arsenic was applied as dry powder or saturated solution. The saturated solution, prepared with cold saline solution, is too dilute to produce either immediate sensory or acute or delayed inflammatory reaction. The dry powder, when applied once in very small quantity, produces only discomfort, blepharospasm, and lacrimation. The increase of the ocular secretion washes the drug from the eyes, and does not produce inflammatory reaction. When it is applied for several days (once daily during three days) or in moderate quantity, it produces immediate discomfort, lid spasm, miosis, acute inflammatory conjunctival reaction (distended vessels, large hemorrhage, and thrombosis), and marked edema of the lids. These conditions increase in 24 hours. The cornea soon turns opaque, and a purulent secretion appears. If the epithelial corneal alteration is not severe and the conjunctival vessels around the limbus are not necrosed, a vascular invasion of the cornea from all parts of the limbus begins in a few days (fig. 1B).

If the corneal lesion is slight, it is very soon repaired; if it is severe, a perforation may be produced in a week followed by recovery, or by phthisis bulbi in 20 days if the dose of the drug was high. When the dose is very great (almost filling the lower conjunctival sac with the dry powder), the acute inflammatory reaction is more violent, the edema of the lids increases in a short time and encloses the drug, which is almost totally absorbed so that the animals die from the systemic arsenic effects before

* From the Department of Pharmacology, School of Medicine, Western Reserve University, Cleveland, Ohio.

‡ I am indebted to Dr. Torald Sollmann, professor emeritus of pharmacology, for the guidance and criticism, and to Dr. Lorand V. Johnson, assistant professor in ophthalmology, for checking the interpretation of the ocular lesions.

there is time to develop intense alterations in the ocular structures.

The events produced by moderate dose of arsenic trioxide appear similar to those described by Uhde[1] for B-chlorovinyl-dichlorarsine or Lewisite.

The damage to the nonvascular cornea as a dry powder and in saturated solution. With the dry powder, a single application is irritant and produces immediate sensory reaction, discomfort, blepharospasm, and conjunctival hyperemia. Edema appears with watery secretion on the day following the application, but the cornea is clear and in

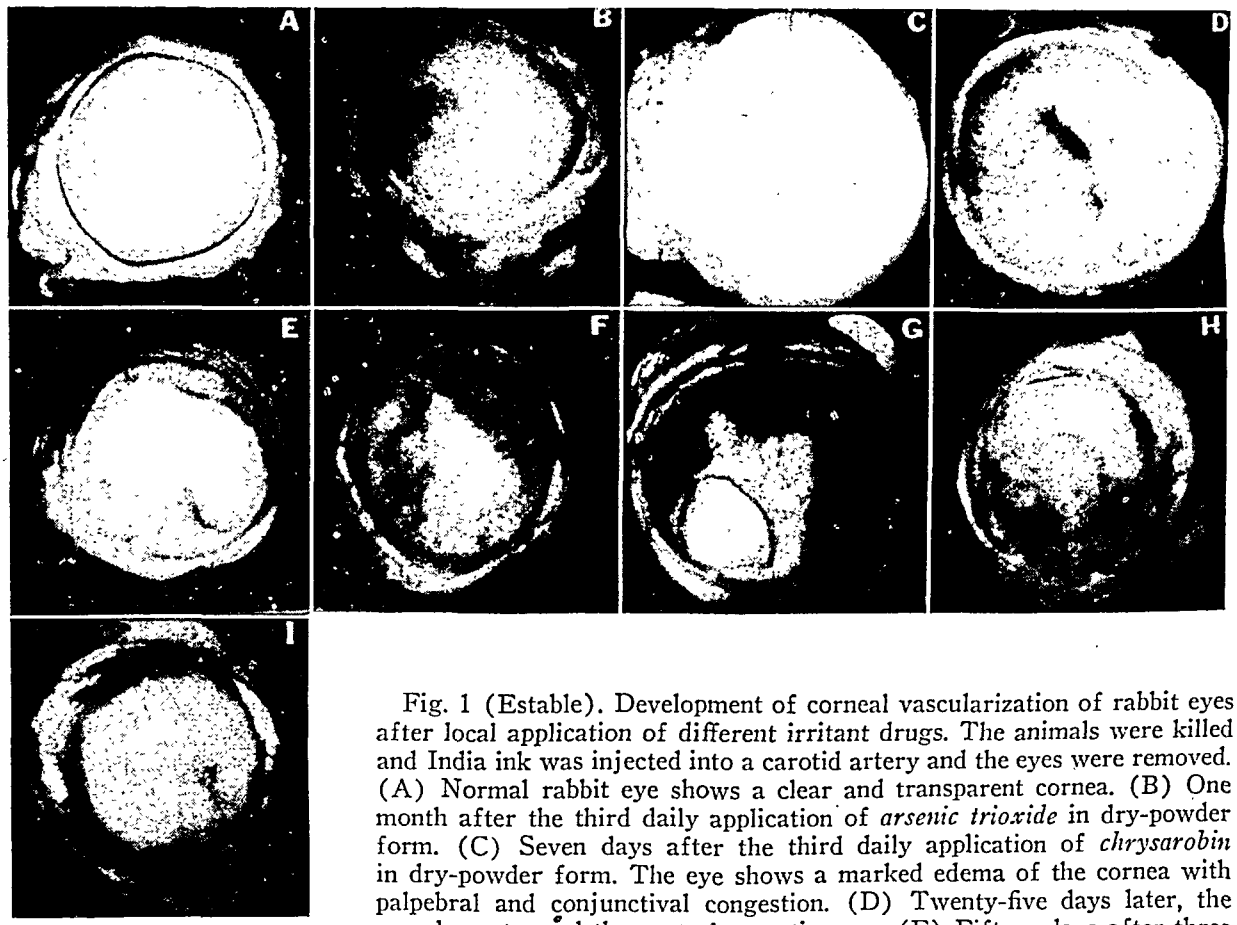

Fig. 1 (Estable). Development of corneal vascularization of rabbit eyes after local application of different irritant drugs. The animals were killed and India ink was injected into a carotid artery and the eyes were removed. (A) Normal rabbit eye shows a clear and transparent cornea. (B) One month after the third daily application of *arsenic trioxide* in dry-powder form. (C) Seven days after the third daily application of *chrysarobin* in dry-powder form. The eye shows a marked edema of the cornea with palpebral and conjunctival congestion. (D) Twenty-five days later, the vessels go toward the central necrotic zone. (E) Fifteen days after three applications of *emetine hydrochloride* (1:500). The cornea appears covered by superficial and deep blood vessels extending from sclerocorneal limbus to the central necrotic zone. (F) One month later, the blood vessels are well marked and the central zone of the cornea appears more clear. (G) Forty days after a single application of *quinone* in dry powder. The perforation was produced in 18 days. (H) Ten days after a single application of *quinone* in saturated solution. The eye shows a marked corneal necrosis with vascular proliferation on the conjunctiva as well as corneal invasion. (I) Forty days after a single application with *resorcinol* in dry-powder form.

shows that arsenic trioxide acts directly on the cells when it is applied topically in powdered form in moderate or great quantity, and not merely indirectly by the action of the drug on the capillaries.

3. Chrysarobin

This substance is very slightly soluble in water and in saline solution. It was applied four days the eyes appear to be normal.

A second application produces the same immediate and acute reaction, but the repetition of the applications, daily for several days, causes a severe inflammation. In the first few days, an ocular and palpebral conjunctival vascular reaction occurs, with increase of the ocular secretion. On the day after the third application, the cornea is

edematous and opaque, and the conjunctiva shows intense inflammation (conjunctivitis or keratitis), corresponding to the violent vascular conjunctival reaction described by Igersheimer.[2] Vascular invasion into the cornea begins in a few days, and depilation of the lids in a week. The saturated solution does not produce sensory, acute, or delayed reactions in the ocular structures, during or after several daily applications.

In conclusion, the chrysarobin in saturated solution does not produce any effect because of the slight solubility of the drug. A single application as dry powder causes immediate sensory and inflammatory reaction followed by acute conjunctivitis (hyperemia, edema, and watery secretion) that almost disappears in four days. Repeated daily applications result in marked irritant local reaction with intense edema of the cornea, conjunctiva, and lids, and vascular invasion of the avascular membrane (figs. 1C and 1D).

4. Colchicine

A dilute solution of colchicine (1:5,000) applied locally, daily for several days, does not produce immediate sensory or acute and delayed inflammatory reaction. Solution of 1:2,000 does not produce sensory reaction, but only a very slight hyperemia of the conjunctiva that disappears very soon. Daily applications produce the same effect. Solution of 1:1,000 produces only slight conjunctival congestion that disappears before 24 hours. Solution of 1:500 results in vascular conjunctival inflammation (hyperemia, vasodilatation) that is apparent 24 hours after the application and increases after the second and third application but without corneal modifications. The hyperemia has almost disappeared in 48 hours after the last application; and in four days the eyes are practically normal.

The same solution, applied every day for 10 days, also produces the same reaction, which does not progress and is very similar to the aspect of the first days. With strong solution (1:100), the vascular conjunctival reaction appears in a few hours and, after the third application, the cornea turns opaque and a vascular corneal invasion begins in a few days.

These alterations soon disappear and, in a few days only, the main vessels persist on a transparent cornea. For the increase and persistence of the corneal vascular reaction, more daily applications are necessary. When the dry powder is applied, immediate lacrimation, blepharospasm, and acute conjunctivitis appear; in 24 hours, the conjunctival congestion increases and extends to the iris, and slight edema of the palpebral conjunctiva develops. The eye is more closed than normally (photophobia?). The conjunctival congestion persists for 48 hours only, and in six days the eyes show corneal vascularization. The cornea remains almost clear throughout.

In conclusion, the eye symptoms shown by colchicine in dilute solution are slight and of short duration; a strong solution or dry powder produces an inflammatory reaction, with vascular invasion only if it is applied daily for several days.

5. Emetine hydrochloride

The irritant local action of the emetine on the conjunctiva was first pointed out by Lowin[3] and lately confirmed by Walters and others,[4] but their reports do not describe reactions in the nonvascular tissue (cornea). In two clinical cases, when a 4-percent emetine solution had accidentally splashed into the eyes, Blue[5] reports no immediate pain, but a few hours later "there is an uncomfortable scratchy feeling, intense photophobia, and lacrimation with conjunctival and circumcorneal injection."

The drug was placed into the conjunctival sac in various concentration, and one, two or more applications were made with intervals of one day. The immediate, acute, or delayed inflammatory reactions vary with the concentrations. Even a 1:50 solution does not produce an immediate sensory effect. The

application of a 1:10,000 solution, daily for several days, does not produce inflammatory effects. A 1:5,000 solution produces a slight conjunctivitis, 24 hours after the second application, that disappears very soon. With a more concentrated solution (1:2,000 and 1:1,000), the ocular and palpebral conjunctiva shows intense and prolonged congestion and a little edema but the cornea shows no changes, the local inflammatory reaction being confined to the vascular tissue.

The application of a 1:500 solution for three consecutive days is followed by intense conjunctivitis (hyperemia and vasodilatation), increase of the purulent ocular secretion, cloudiness of the cornea, and formation of new vessels in the conjunctiva, with coreal vascular invasion in a few days. With a 1:100 solution, conjunctivitis appears promptly and increases in 24 hours, with edema formation and purulent secretion. With a 1:50 solution, the immediate conjunctivitis increases rapidly, and edema and abundant purulent secretion are present in 24 hours. This picture remains unchanged for several days but, about the fifth day, cloudiness of the cornea appears and in seven days the cornea shows small vessels; in nine days, the skin of the lids is reddened and edematous and its depilation is evident.

The vascular invasion may become very great so that the vessels cover almost the entire surface of the cornea, leaving a small central necrotic zone free. The condition remains much the same for many days. Some 40 days after the last application, the corneal lesions begin to progress toward repair, and the vascular reaction disappears. In about two months the eyes usually recover without permanent damage and have normal aspect. A progressive development of corneal inflammatory reaction, after three applications of a solution 1:500, is shown in Figure 2.

The conclusion is that emetine hydrochloride produces a powerful and irritating local reaction on the eyes when relatively dilute solutions are applied for a few days. These begin in the vascular structures and progress to the nonvascular. The intensity and time of appearance of the irritating effect are related to the concentration of the solution and to the frequency of the application. These irritating actions are in contrast with the absence of immediate sensory effect.

6. Histamine biphosphate

A solution of histamine biphosphate (1:200) produces immediate sensory reaction, with slight acute conjunctival vasodilatation that disappears very soon. Dry powder produces discomfort, blepharospasm, lacrimation, and prompt vasodilatation, but these symptoms also disappear in a few minutes. Daily applications during several days produce the same effects. The slight conjunctival reaction with relatively concentrated solutions in rabbits is in contrast to the potent vasodilator effect produced in the human eye by 1:40,000 and 1:50,000 solutions as Gartner[6] shows in the photograph of blood vessels of the conjunctiva. Rabbits, therefore, appear relatively tolerant to action of histamine in this location.

7. Paraphenylenediamine (orsin)

The dry-powder form of this drug applied in the conjunctival sac produces immediate signs of discomfort or pain, lacrimation, blepharospasm, and a vascular conjunctival inflammatory reaction resembling allergic conjunctivitis, with promptly increasing palpebral edema. However, it does not produce any persistent alteration in the cornea and conjunctival membranes, even when the drug is applied several times. With a saturated solution, no immediate sensory reaction is observed, but the vascular conjunctival reaction appears immediately after the instillation of the drug, increases in a few minutes, and disappears very soon. This contrasts with the clinical reports of corneal ulceration, ophthalmia, and permanent blindness occurring in connection with its use as a brown dye for hair and fur.[7-12] However, these appear to involve individual allergic

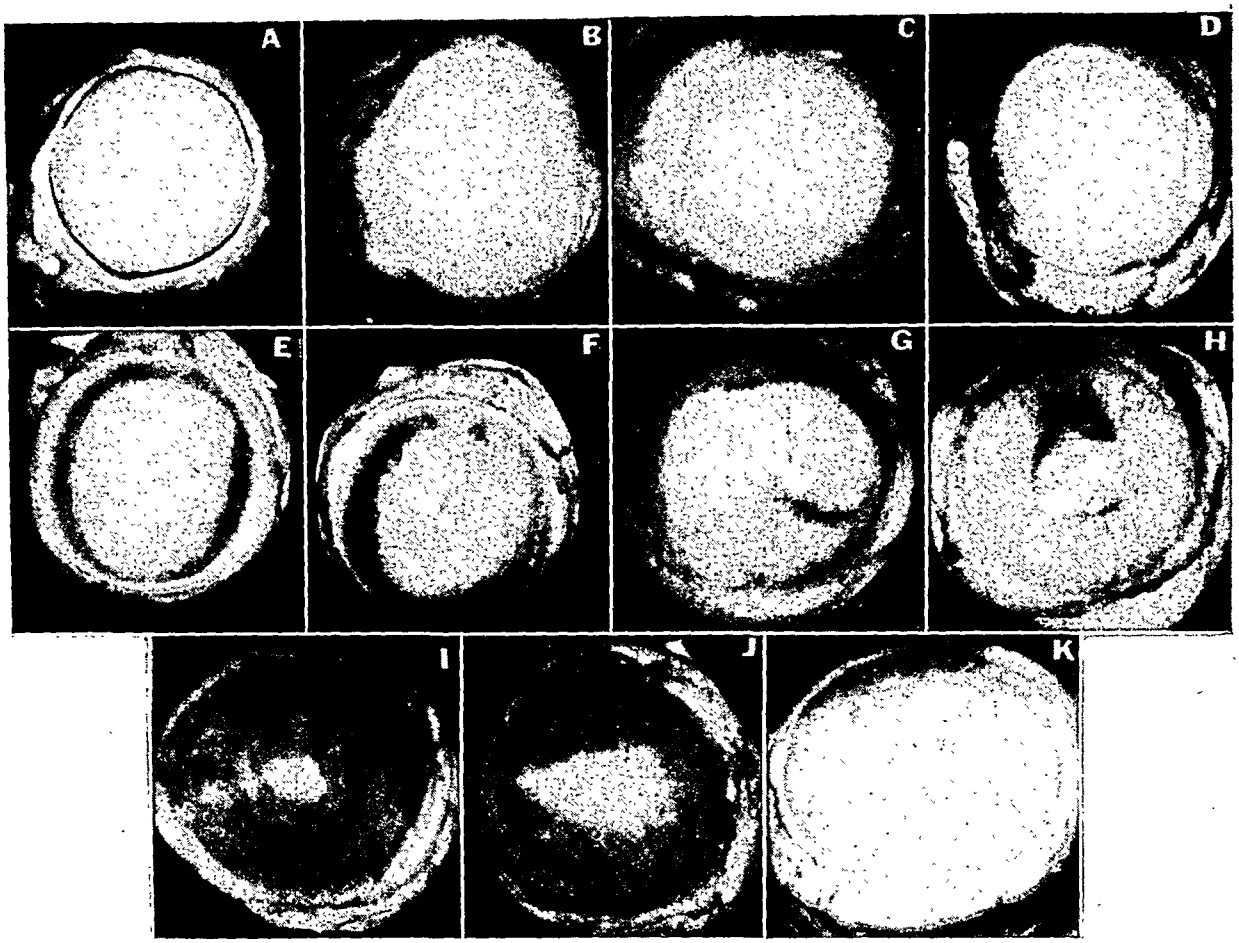

Fig. 2 (Estable). Progressive development of corneal inflammatory reaction of rabbit eyes after three applications of a solution (1:500) of *emetine hydrochloride*. The animals were killed and India ink was injected into a carotid artery and the eyes were removed. (A) Normal rabbit eye, the cornea is clear and transparent. (B) Twenty-four hours after the first local application. The sclera and palpebral conjunctiva are congested, but the cornea appears normal. (C) In 48 hours (24 after the second application) the conjunctivitis has increased. The cornea has lost its normal luster and appears slightly opaque. (D) In seven days, the superficial blood vessels around the limbus begin to extend into the edematous and rather opaque cornea. (E) In nine days, the aspect of the cornea is almost the same. (F) In 12 days, the corneal vascular invasion increases and a complete circular pannus appears. The corneal edema has spread, and superficial ulcerated zones are present. (G) In 15 days, the cornea shows the progressive advance of the vascular invasion. The superficial and deep blood vessels are extended on the opaque cornea toward the central necrotic zone. (H) In 20 days, the circular pannus is very regular. The large superficial vessels cover almost all the corneal membrane from the limbal plexus, leaving free only the central ulcerative zone. (I) In 25 days the cornea shows a similar aspect. (J) One month after the edema of the cornea has entirely disappeared, the opacity is relatively slight. (K) In 40 days, the cornea is much improved; the opacity has disappeared entirely, and the blood vessels are also rapidly disappearing.

susceptibility.

In conclusion, paraphenylenediamine, when applied to rabbit eyes, produces an inflammatory reaction resembling allergic conjunctivitis.

8. Podophyllin

This substance is very irritating to mucous membranes and eyes. Applied on the eyes as a dry powder, it produces immediate discomfort, blepharospasm, lacrimation, conjunctival vasodilatation, and edema that increase promptly. In 24 hours, the conjunctival congestion and the edema are very marked; in 48 hours, the cornea is slightly clouded and vascularization appears in five days. In 25 days, the cornea is normal. In conclusion, podophyllin in dry powder form

produces immediate sensory and inflammatory reactions that progress very rapidly.

9. Quinone

This has a very irritating action on the membrane of the eye when it is applied in powdered form and in solutions that are not too dilute. The 1:10,000 solution, applied daily for several days, only produces sensory reactions. These reactions are greater with 1:5,000, but without inflammatory effects. The 1:1,000 solution produces acute conjunctivitis (vasodilatation, edema, and purulent secretion) that disappears in some days. With daily applications it is more persistent, but always remains limited to the vascular membrane. With 1:500 solution, cloudiness of the cornea appears in 24 hours and its vascular invasion begins in four days. With a dry powder, the immediate sensory reactions are marked (discomfort, blepharospasm, lacrimation) and acute conjunctivitis appears in a few minutes. Marked edema and corneal opacity by necrosis is present before 24 hours, persists for a long time, and perforation of the cornea may result (figs. 1G and 1H).

In conclusion, quinone in different concentrations produces ocular reactions that grade from slight immediate sensory reaction with 1:10,000 solution, to violent conjunctivitis (vasodilatation, edema, purulent secretion), and marked necrosis of the cornea with the application of a dry powder.

The harmful ocular effects of quinone vapors were reported by Sterner, Oglesby, and Anderson.[13]

10. Menadione (2 methyl 1-4 naphtohoquinone)

Instillation of an aqueous solution of the bisulfite (1:1,000) produces immediate sensory reaction (discomfort and blepharospasm) with conjunctival congestion that disappears very soon without any evidence of injury. New applications produce the same effects.

11. Resorcinol

No immediate, acute, or delayed effects are produced by a 1:1,000 solution, even when applied daily during several days. With a solution of 1:100, slight blepharospasm and conjunctival congestion appear immediately but are of short duration and, in a few hours, the eyes present a normal appearance. Daily applications during several days produce the same effects. With a 1:10 solution, immediate sensory reaction is present, and clinical conjunctival inflammation with cloudiness of the cornea begins a few seconds after the instillation is started. A purulent secretion appears in 24 hours, and vascular invasion of the cornea begins in four days (fig. 1I). The application of the drug in dry powder form produces immediate discomfort and results in necrosis of the cornea, generally followed by perforation. If the necrosis is not very marked, a vascular invasion of the cornea develops.

General discussion

The irritant ocular reaction produced by the different substances herein reported may appear on the conjunctival structures alone, or on the conjunctival and ocular membranes, successively or simultaneously, but with different intensity and with a different type of reaction.

The clinical manifestations produced by the drugs studied are:

1. Immediate sensory irritant reactions—discomfort, blepharospasm, photophobia, and lacrimation.

2. Acute and subacute inflammatory reactions—hyperemia, vasodilatation, hemorrhage, edema, purulent secretion, and necrosis.

3. Delayed inflammatory reactions—corneal opacity, vascularization, necrosis, ulceration, and perforation of the cornea.

This clinical picture is not characteristic of any one drug. Several drugs may produce identical effects; and a given drug may produce them only in part, depending on (1) *Physical state* (all the drugs in powdered

form produce immediate sensory and acute reactions); (2) *Concentration* (very dilute solutions do not produce any apparent effect; for instance, arsenic trioxide and chrysarobin in saturated solutions; emetine (1:10,000); quinone (1:10,000); resorcinol (1:1,000); (3) *Time of contact* and *frequency of applications* (the clinical ocular picture with colchicine (1:100) is evident after the third application).

The actions of different drugs are influenced by their chemical affinity for the proteins of ocular membranes, by their physical adsorption,[14] and possibly by destruction or inhibition of enzyme systems in the cornea.

Some drugs produced delayed effect with sensory and inflammatory reactions, others acute inflammatory reactions without delayed effects; some produce only irritant sensory reactions but not lasting inflammatory changes and, finally, others show acute inflammation or acute followed by delayed effects without sensory reactions.

Some drugs produce only a vascular effect (anthraquinone, histamine, menadione, paraphenylenediamine); others cause both vascular and nonvascular changes, as illustrated by direct and indirect corneal alterations.

According to the intensity as well as qualitative effect produced by local application of different concentrations to the ocular structures, the different drugs that were studied may be classified in groups in order of potency:

1. Drugs without apparent effects in the following concentrations: arsenic and chrysarobin in saturated solution, colchicine (1:1,500), emetine (1:10,000), quinone (1:20,000), resorcinol (1:1,000).

2. Drugs that produce only immediate sensory reaction: anthraquinone and arsenic trioxide in powder and in small quantity; quinone solution (1:10,000 and 1:5,000).

3. Drugs that produce immediate sensory reactions followed by acute inflammatory effects: anthraquinone, chrysarobin, and paraphenylenediamine in dry powder, histamine (1:200), quinone (1:1,000), menadione (1:1,000), resorcinol (1:100).

4. Drugs that produce immediate sensory reactions followed by acute and delayed inflammatory effects: arsenic trioxide, chrysarobin (repeated daily applications), colchicine, and podophyllin in dry powder, quinone (1:500), resorcinol (1:10).

5. Drugs that produce only acute inflammatory reactions: colchicine (1:2,000, 1:1,000, and 1:500), emetine (1:5,000, 1:2,000, and 1:500), paraphenylenediamine in dilute solution.

6. Drugs that produce acute inflammatory reactions followed by delayed inflammatory effects: colchicine (1:100) (repeated daily applications), emetine (1:500, 1:100, 1:50).

Corneal turbidity as well as increase of the limbal capillaries appear to be necessary preliminaries to vascular invasion of the cornea. The destruction of the epithelium is followed by a secondary fibroblast formation, which facilitates the vascular progression. The turbidity of the cornea is related to the epithelium destruction or to the interstitial edema formation. Severe corneal necrosis does not produce vascular reaction, because the limbal blood vessels are necrosed. The opacity of the cornea and its vascularization are not specific of any drug. Every irritant substance that increases the capillary blood vessels of the ocular limbus and produces turbidity of the cornea may be followed by the vascular invasion.

The new formation of capillaries begins in the sclera and in the corneal limbus with the acute inflammatory conjunctival vascular reaction. When a slight corneal necrosis occurs, the vascular invasion progresses. The vessels appear on the cornea and invade almost all its surface from the limbus toward the center. The trunks pass from the limbus and there divide at right angles into numerous branches that form a loop plexus in the corneal margin, gradually extending toward the center.

The speed of return to the normal of the

ocular structures varies according to the intensity of the pathologic alterations. The corneal transparency is soon restored, but the blood vessels persist longer.

The eyes of several animals (rabbit, guinea pig, rat, mouse) show a similar picture, but pigeons show marked resistance to the ocular action of the several drugs. This apparent resistance may be related to the abundant watery conjunctival secretion which dilutes and washes out the drug.

It is not clear what relation the "exogenous" irritative vascularization of the cornea bears to the similar vascularization of the cornea which develops in animals with malnutrition from a diet deficient in vitamin A, riboflavin, or in aminoacids (histidine, phenylalanine, tryptophane, lysine, threonine, leucine, isoleucine methionine and so forth). The "endogenous" vascularization is an index of the nutritional conditions and regresses with return to normal diet and adequate respiratory enzymes.

Summary and Conclusions

The irritant local effects on the ocular membranes are studied by direct application of the drugs into the conjunctival sac of one eye of the rabbit; the other eye is treated with normal saline solution and used as a control.

The drugs tested, in several concentrations, were the following: Anthraquinone, arsenic trioxide, chrysarobin, colchicine, emetine, histamine, paraphenylenediamine, podophyllin, quinone, menadione, and resorcinol.

The clinical manifestations produced by different concentrations of these drugs are detailed and a classification in groups in order of potency and concentration is given.

The relation of solubility, physical state, concentration, time of contact, and frequency of application of the drugs and its irritant effect is discussed, as are the immediate, acute, and delayed inflammatory changes, and the opacity of the cornea and its vascularization.

SOME ASPECTS OF STUDYING BINOCULAR VISION*

KENNETH C. SWAN, M.D.
Portland, Oregon

It is the custom in modern medicine to classify disease processes on an etiologic basis and to direct treatment toward elimination of the causal condition. In disturbances of binocular vision a specific etiologic diagnosis is desirable, but it rarely suffices as a basis for therapy. History and physical examination must be directed toward determining the etiology, but in addition the status of the various complex components of binocular vision such as retinal correspondence and degree of simultaneous perception must be established before therapy can be outlined. These components may vary in diverse ways independently of the etiology.

The system of studying binocular vision in patients at The University of Oregon Medical School is based upon the concept that these anomalies are fundamentally deficiencies rather than positive phenomena. With few exceptions, patients with defective binocular coördination are lacking in one or more of the physiologic components of normal single binocular vision. Therefore, a systematic investigation of each of these physiologic components to determine if it is deficient or adequate provides a practical approach to the clinical study of binocular anomalies. A rigid routine of tests is not followed; rather, the physiologic components are investigated by the technique most applicable to the case.

The components of comfortable single binocular vision are interrelated, but, as a basis for examination, they may be divided into four sensory and four motor groups (fig. 1).

*From the Department of Ophthalmology, The University of Oregon Medical School. Aided by a grant given by Dr. and Mrs. John E. Weeks in memory of Dr. Frank R. Mount. Read before the sixth annual meeting of the American Association of Orthoptic Technicians, Chicago, Illinois, October 12, 1947.

SENSORY COMPONENTS

As a first step in examination of a given case, monocular tests are made to determine if vision in each eye is useful for binocular coördination. A full field of vision and normal visual acuity are not necessary, but, for orthoptic training, a patient must usually have at least 25 or 30 degrees of overlapping visual field in each eye and one eye must be capable of central fixation. Since the development in recent years of methods of peripheral fusion training,[1] acuity of 20/50 or better in each eye has not been essential for

PHYSIOLOGIC COMPONENTS OF BINOCULAR VISION

I - SENSORY

1. Useful vision and similar images in each eye.
2. Simultaneous binocular perception.
3. Normal retinal correspondence.
4. Cerebral integration of binocular perception (Fusion).

II - MOTOR

5. Full rotations and concomitant versions
6. Approximate parallelism of lines of distant fixation in fusion free position.
7. Ample fusional movements.
8. Accomodation - vergence balance.

Fig. 1 (Swan). Physiologic components of binocular vision.

binocular training. Every effort is made to restore vision in an amblyopic eye, but children with a persistent amblyopia of 20/100 or 20/200 in a squinting eye are no longer denied the benefits of orthoptics.

SIMILAR IMAGES IN EACH EYE

For maintenance of comfortable single binocular vision, the retinal images in the two eyes must be similar. It has not been possible to make routine studies for aniseikonia in patients with defective binocular vision, but otherwise every effort is made to detect inequality in vision of the two eyes. Accurate refraction is an essential part of every examination. Great care is taken to detect and correct oblique astigma-

tism and anisometropia, as well as hypermetropia and myopia. Textbooks emphasize the relationship of hypermetropia to esotropia and myopia to exotropia, because uncorrected, these refractive errors disturb the accommodation—vergence balance. This emphasis is justified but the high incidence of anisometropia, oblique astigmatism, and unilateral astigmatism in the common tropias of childhood is indicative that dissimi-

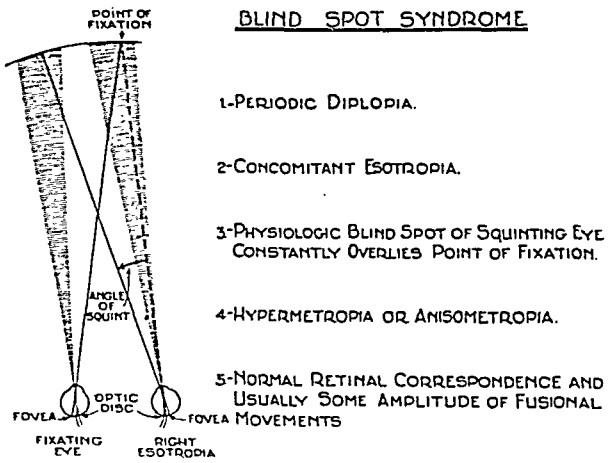

Fig. 2 (Swan). Blindspot syndrome.

lar retinal images are also of etiologic importance in binocular incoördination. A review of 1,000 cases of esotropia in children revealed this type of refractive error to be approximately four times as frequent as in children with normal binocular vision. The converse is also true. Disturbances of binocular vision seem almost invariable in the presence of uncorrected anisometropia of any appreciable degree. In addition to refraction, patients are carefully studied for any organic pathologic conditions which might produce an inequality in vision in the two eyes.

Simultaneous binocular perception

Simultaneous binocular perception is a second physiologic component of single binocular vision. Study of this faculty is of the greatest importance in all anomalies of binocular vision, but it seems commonly neglected or considered as a qualitative faculty. The degree of simultaneous perception varies greatly with the circumstances under which the eyes are used, that is with the type of the retinal stimulus and the particular retinal areas which are stimulated. For example, there are few patients with useful vision in each eye in whom some degree of binocular perception cannot be demonstrated under ideal circumstances, namely, by use of vertical prisms, a red glass, a totally dark room, and a bright point of light for fixation. Many patients may also demonstrate binocular perception on haploscopic devices, but otherwise may have some degree of suppression. It is essential, therefore, to study simultaneous perception as a quantitative phenomenon.

Establishment of good binocular coördination by training is futile if the patient has a useful degree of binocular perception only on haploscopic devices; therefore, it is particularly important to determine the degree of binocular perception which exists under ordinary visual conditions. A satisfactory method is to study the field of binocular vision on a large screen in a fully illuminated room with a filter-twin projection system. Either red and green color filters of the type described by Lancaster,[2] or of polaroid may be used with two projectors to separate the objects perceived by the two eyes. Normally it should be possible to demonstrate retinal rivalry and the absence of suppression scotomas in the central field of vision. If a suppression scotoma is found, it is important not only to plot its size, but also to determine its intensity by variations in the size and brilliance of the targets.

In esotropia, it is particularly important to determine the position of the physiologic blindspot because the normal blindspot is frequently a part of suppression scotomas. In some instances the blindspot may be utilized as a central scotoma by the squinting eye.[3] Recognition of this "blindspot syndrome" is important because it is common (fig. 2). If treatment is properly directed, the prognosis is favorable.

Bifoveal fixation under ordinary visual circumstances represents the highest degree of simultaneous binocular perception. It is not essential for comfortable single binocular vision, but its presence or absence is of clinical importance. For example, the demonstration of bifoveal fixation in a corrected case of unilateral esotropia has seemed the best indication that good visual acuity will persist in a formerly amblyopic eye. For studying bifoveal fixation, polaroid filters and twin projectors are used in a lighted room with the aluminized screen at least three meters from the patient. While the patient maintains perifoveal fusion, the central one degree of binocular field of vision is studied for scotomas with targets subtending small visual angles.

Normal retinal correspondence

Correspondence between the functions and the anatomy of the retinas and visual pathways of the two eyes is one of the essential components for normal single binocular vision, but is often lacking in the common tropias developing early in childhood. Study of retinal correspondence is, therefore, an essential part of the routine of examination in disturbances of binocular vision. Varied techniques must be used because the state of retinal correspondence may change with the circumstances of testing, particularly in cases receiving treatment. One test may indicate normal, while another test demonstrates anomalous correspondence, or the same test may yield inconsistencies. This is not an indication that one or the other test is erroneous; rather it provides the examiner with an indication of the stability of the correspondence and the circumstances under which it varies.

It is our custom to study the state of retinal correspondence at the same time that the field of binocular vision is plotted with a filter-twin projection system because anomalous retinal correspondence invariably is associated with some degree of suppression.[4] Haploscopic tests of retinal correspondence are made with a major amblyoscope. The after-image test is also used in most cases. Demonstration that the two foveal regions have the same visual direction is considered evidence of normal correspondence.

Cerebral integration

The term fusion is often used synonymously with single binocular vision. In a strict sense, fusion is the subconscious

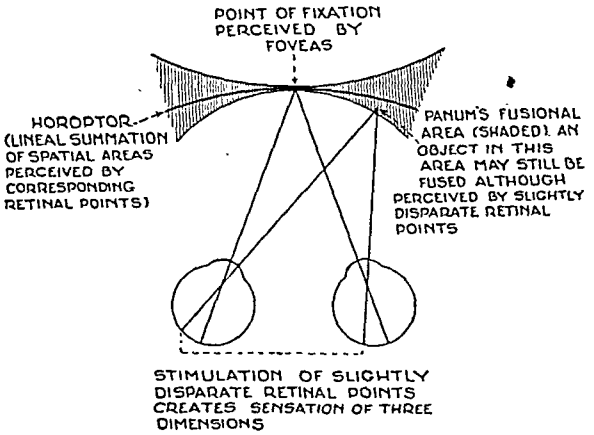

Fig. 3 (Swan). Horopter.

cerebral integration of simultaneous perceptions of the two eyes into a single conscious impression. It is commonly assumed that patients either have or do not have this faculty, but our experience indicates that it is quantitative. Normally it is possible mentally to integrate into a single impression retinal images of three dimensional objects, despite the fact that some parts of these objects must necessarily be visualized by slightly disparate retinal areas. Normal stereoscopic vision is dependent upon this ability to fuse images slightly dissimilar in the horizontal meridians, as is the normal ability to overcome the aniseikonia induced by asymmetric convergence.

Some of our patients have demonstrated a lower grade of fusional ability. Tested on haploscopic devices the only targets that these patients seem able to fuse are those identical in size and shape, such as two simple discs; that is, corresponding parts of

the two targets have to be visualized by exactly corresponding retinal points. It seems evident that in these patients the horopter lacks the depth which is called Panum's fusional area (fig. 3). Depth of this fusional area may be determined by studying the patient's ability to fuse objects of different dimensions in the various meridians.

Patients who lack the normal ability to overcome an artificially induced aniseikonia may be divided into two clinical groups. These cases will be described and discussed in detail in a subsequent report,[5] but may be summarized here. In the first group the disparate parts of the target seem selectively suppressed when aniseikonia is induced, but fusion of nondisparate areas is maintained. These patients are able to fuse stereoscopic targets but the sensation of depth is lacking. Three patients with this apparent selective suppression of disparate images have been observed over a period of five years. These individuals had comfortable single binocular vision, but failed tests for stereopsis. These patients must not be confused with the many corrected cases of esotropia who lack stereopsis because only peripheral fusion exists. In the latter the defect is associated with a nonselective suppression of the central field of vision of the nondominant eye.

In the second group of four cases, suppression of slightly disparate retinal images did not occur and annoying diplopia resulted. Initially these patients had had an alternating type of esotropia with anomalous retinal correspondence. In each case the deviation was corrected surgically. Also, intensive and prolonged orthoptic training was required before normal correspondence was established and an appreciable amplitude of fusional movements obtained. Then true fusion could be demonstrated only with simple two dimensional targets. These patients were unable to fuse targets with any degree of disparity, such as the standard targets for testing stereopsis. They could superimpose the images, but would describe either retinal rivalry or a constant sliding of the targets over each other. In an ordinary room they would describe three dimensional objects as not completely separating into two images but shimmering constantly.

When they were placed in a dark room and allowed to perceive a single, simple, two dimensional object, such as a flat illuminated picture on the wall, the shimmering would disappear and the picture would appear single and sharply defined. In 2 of the 4 patients suppression developed within six months after termination of orthoptic training. It was not possible to follow one case for more than three months, but in the fourth case the patient was still diplopic after two years. Experiences with the above cases have led us to study the fusional faculty as a quantitative phenomena. An ability to overcome induced aniseikonia is investigated in every case of long-standing alternating esotropia. Lack of this ability and the absence of suppression seem a possible explanation for one type of so called "horrors fusionis."

Motor components

Full rotations

The motor phase of the investigation is usually initiated with studies of the ocular rotations. Good rotations are essential components of comfortable, single binocular vision. In our examination, duction (monocular rotation) tests are not neglected, but in detection of spastic and paralytic phenomena greater emphasis is placed on the concomitance of binocular rotations in the cardinal fields of gaze. These tests are conducted in the usual manner, but in the search for those slight degrees of nonconcomitance which may occur with a muscle paresis, the Lancaster red-green test used at a distance of 5 or 6 meters seems more accurate, as well as simpler, than the commonly used diplopia fields plotted with red glass and point light. Ophthalmographic studies provide a highly objective and sensitive means of studying concomitance for near fixation. Twin tele-

scopes are used to pick up and focus the corneal reflexes on a calibrated ground-glass plate for direct study or on moving film for permanent recording.

Parallelism of lines

For comfortable, single binocular vision, deviation of the eyes in the fusion-free position must not be greater than that which can be readily overcome by a reasonable amplitude of fusional movements; that is, approximate parallelism of the line of distant fixation of the two eyes is another component of normal binocular vision. To study this component the deviations are measured in the cardinal fields and in the primary position by the usual techniques, but under varying circumstances. Where possible, objective tests such as the cover and corneal reflex are supplemented by the usually more precise subjective procedures such as measuring the separation of the images by a filter-projection system or devices such as the Maddox rod.

Amplitude of fusional movements

Another component of comfortable binocular vision is amplitude of fusional movements adequate to overcome easily any deviation of the eyes in the fusion-free position and to permit the maintenance of binocular vision when fixation is shifted from a near to a distant object and vice versa. Both associating and dissociating types of fusional movements are studied under varying circumstances and by diverse techniques. The amplitude of fusional movements is affected by fatigue and other circumstances; therefore, conclusions as to the amplitude of fusional movements are never made from a single examination. Normally, complex and detailed stereoscopic targets may stimulate fusional movements, but in a patient with defective binocular vision they are apt to be confusing and lead to suppression or retinal rivalry. In our experience simple two dimensional targets are most suitable for indicating a patient's potentialities in regard to fusional movements. In all cases it is important to measure the range of convergence and divergence from the fusion-free position of the eyes as well as in relation to orthophoria; that is, to measure the absolute convergence and divergence.

Vergences are coördinated fusional movements which must not be confused with the uncontrolled ductions of the nonfixating eye that may occur when fusion is disrupted. Comparison of fusion-free deviations for near and distant fixation is of value but does not indicate the state of the accommodation vergence relationship. To diagnose an insufficiency or excess of divergence or convergence on this basis alone is not physiologically sound. For example, uncontrolled adduction of the nonfixating eye occurs with accommodation in the so-called accommodative types of squint. Before hypermetropia is corrected and binocular vision is established, such patients are often mistakenly diagnosed as having a convergence excess because the inward deviation of the eyes is much greater for near than for distant fixation. A true convergence excess does not exist, as is demonstrated when the refractive error is corrected and single binocular vision is reëstablished. Then a marked deficiency of convergence almost invariably exists.

Accommodation-vergence balance

A final physiologic component of single binocular vision is a good balance between accommodation and the horizontal vergences. Accurate study of balance between accommodation and vergences is not possible until after the patient is able to maintain fusion and has acquired some amplitude of fusional movements. Then the amplitudes of divergence and convergence are determined in relation to a fixed amount of accommodation and the amplitude of accommodation is measured in relation to a fixed degree of convergence. Fine fixation targets are used over measured periods to detect accommodative spasm or fatigue.

Management of individual cases

Knowledge of phenomena other than those described above is vital to the management of individual cases. For this reason the ophthalmologist must not restrict himself by adhering to a fixed routine of tests or techniques. The system of studying binocular vision described above is a comparison of the individual patient's binocular status with the normal by the technique most applicable to his case. The system of investigation frequently elicits phenomena which necessitate special study. For example, if paresis or paralysis of an extraocular muscle is demonstrated, an examination must be made for secondary phenomena such as contracture of the direct antagonist or overaction of the yoke muscle in certain fields of gaze. Also in such cases determination of the usually fixating eye has great importance. Finally, it should be stressed that the study of binocular vision is only one part of a complete ophthalmic history and examination. Disturbances of binocular vision frequently result from organic disease of the eyes. This is particularly true in young children because any disturbance of vision is almost certain to alter binocular development.

Interpretation of data

In interpretation of data obtained from any type of examination, it must be kept in mind that the status of the various components of binocular vision varies with the circumstances under which the eyes are tested. This is particularly true if binocular vision is defective; therefore, the study of the same binocular phenomena should be made by the ophthalmologist and the orthoptic technician using different techniques and working under varying circumstances. In this respect we commonly observe two extremes. At one extreme is the ophthalmologist who thinks of orthoptics only in terms of therapy and therefore neglects to use orthoptic facilities in his diagnoses. He is prone to send patients to the orthoptic technician without a specific diagnosis or purpose. The results are certain to be poor. At the other extreme is the busy ophthalmologist who, when orthoptic facilities and a skilled technician are available, neglects his own simple tests such as are made with prisms. He may feel that the phenomena of binocular vision can be more accurately and extensively investigated by the technician utilizing equipment such as the major amblyoscope.

Determine usual status of functions

The major amblyoscope is excellent for determination of the patient's binocular potentialities because circumstances can be created which are nearly ideal for single binocular vision. Considerable deviation can be overcome without distortion of the targets, the patient's field of vision can be limited to a few degrees, and the technician may stimulate retinal areas of her choice. The intensity and the character of the stimulus can be altered by changing the color, illumination, size, shape, and background of the target. Even the duration of the stimulus can be accurately controlled. Nevertheless, the conditions of this type of examination are artificial and strikingly different from those in which we ordinarily use our eyes. Therefore, it seems best to rely more upon other types of tests to determine the usual status of the patient's binocular functions.

Study of binocular function in an illuminated room containing three dimensional objects and maintaining the patient's full field of vision is essential if normal conditions are to be simulated. In this respect filter-twin projection devices fill an important place, as a supplement to prisms, the screen test and similar office procedures. With two projectors which can be directed in accordance with the deviation of the patient's eyes, and with the use of polaroid or color filters to separate the objects perceived by the two eyes, it is possible to duplicate many of the binocular visual tests which

must otherwise be performed on haploscopic devices. It is possible to stimulate retinal areas of the operator's choice and at the same time to maintain a full peripheral field of vision. In determining the status of binocular vision for near fixation, emphasis is placed upon bar-reading tests and ophthalmographic studies made while the patient is actually reading or writing.

After data obtained by examination is interpreted, the deficiencies of the case are summarized and binocular potentialities are discussed by the ophthalmologist and orthoptic technician before treatment is planned. It seems essential that responsibilities for treatment be delegated specifically. Orthoptic training is not given unless its purpose is agreed upon by the ophthalmologist and orthoptic technician. It is important that, during the course of treatment, the patient's condition be reviewed by both at frequent intervals.

Criteria for functional cure

No system of studying anomalies of binocular vision is complete unless the criteria for a functional cure are established. Dependence must not be solely upon tests made under the artificial circumstances which haploscopic devices provide. Most disappointing are those patients, who, after intensive treatment, demonstrate parallelism and a high degree of binocular vision upon the stereoscope, but who, under the ordinary circumstances of using their eyes, lack even simultaneous binocular perception. We designate these patients as "stereoscopic cures" because they have good single binocular vision only under ideal circumstances which such haploscopic devices provide. Anomalies of binocular vision cannot be considered fully corrected until the presence of comfortable single binocular vision is demonstrated under circumstances in which the patient normally uses his eyes.

Summary

In cases with defective binocular vision, it is desirable to make an etiologic diagnosis; but to plan treatment and evaluate therapy the status of the various components of binocular vision must be determined. Anomalies of binocular vision seem fundamentally deficiencies in which the patient is lacking in one or more of the physiologic components of single binocular vision. These are interrelated, but for purposes of examination they can be divided into four motor and four sensory groups. Systematic investigation of these physiologic components provides a convenient and flexible routine for clinical study of patients with anomalies of binocular vision. Components such as simultaneous binocular perception and the faculty of fusion are quantitative phenomena, and must be studied accordingly.

It is important to study the field of binocular vision, and to determine the size and intensity of suppression scotomas. In esotropia, the normal blindspot is frequently utilized as a central scotoma. Localization of the normal blindspot of the squinting eye is, therefore, essential to recognize the "blindspot" syndrome. Absence of Panum's fusional area is discussed as a possible explanation of one type of horrors fusionis.

When binocular vision is defective, the status of such phenomena as simultaneous binocular perception and retinal correspondence varies with the circumstances under which the tests are conducted; consequently, it is important for the ophthalmologist and the orthoptic technician working coöperatively to study the various binocular phenomena separately and by varied techniques. In general, haploscopic devices on which it is possible to create nearly ideal circumstances for binocular vision are most suitable to determine the potentialities of a given case, but study under ordinary visual conditions is essential to determine the usual status of binocular function. In this respect filter-twin projection systems seem of particular value.

In diagnosis and treatment of binocular anomalies there is no need for complex

classifications. A summary of a patient's deficiencies and analysis of his binocular potentialities serve as a basis for therapy. In evaluation of treatment, it is stressed that a patient may have parallelism of his eyes and demonstrate a high degree of single binocular vision under the ideal circumstances which haploscopic devices provide, but cannot be considered normal until the presence of comfortable single binocular vision is demonstrated under the conditions in which the patient customarily uses his eyes.

Discussion of Dr. Swan's paper

Elizabeth K. Stark, A.M.
New York

I think that everyone who has just heard Dr. Swan's paper must now be looking forward to its publication and the opportunity of reading and studying it. It covers so much that is vital to orthoptics that once over is not enough.

In analyzing the sensory and motor components necessary to maintain single binocular vision, Dr. Swan has worked out a logical and concise classification. Nevertheless, it forms the basis for a more thorough examination of squinters than is customarily made, with emphasis on quantitative determinations whenever specific data can be obtained. This is, perhaps, best exemplified in his studies of simultaneous binocular perception in which he makes accurate plottings of the fields of binocular vision and of suppression scotomas.

In this connection, I would like to ask Dr. Swan on how young a patient he can obtain these data. I have felt quite triumphant when, once or twice, I have been able to map the blindspots of a five-year-old child. On the other hand, it is possible to determine the status of retinal correspondence and to start fusion training with most four-year-old children and some who are three years of age. If Dr. Swan can plot the binocular fields and suppression scotomas of these little patients, then I think that he must be "Superman!"

Although techniques have not been worked out, as Dr. Swan indicates, for making quantitative routine studies of aniseikonia in patients with defective binocular vision, one occasionally gets an indication of its presence in squinters during the course of carrying on orthoptic treatments with a major amblyoscope. In such cases, the spontaneous report is given that the target before one eye is larger than that before the other; specifically, "the lion is too big for the cage," or with the second-grade targets "the bunny with the flower is bigger than the bunny with the tail."

There are no more important tests for binocular function than those for retinal correspondence, as evidenced by the fact that at least 50 percent of all squinters develop an abnormal retinal correspondence, and that any unsupervised orthoptic training in its presence will serve to confirm rather than correct the squint. It is sometimes dif-

ncult for those who have not made the various tests to appreciate how variable retinal correspondence can be. However, the orthoptic technician is inclined to rely primarily on the results obtained with a major amblyoscope, since the training directed toward correcting an abnormal correspondence is carried on under the same conditions as those under which the test is made.

The two grades of fusion observed by Dr. Swan are comparable, it seems to me, to the second and third grades of binocular vision described by Worth, namely simple fusion and stereopsis.

In my experience, some simple fusion can be elicited in most squinters under ideal instrument conditions during the course of orthoptic treatments, but a fairly large percentage of these patients never learn to interpret the disparity of stereopsis targets in terms of depth, even though they may have attained binocular vision for casual seeing. I do not know whether, in daily life, these patients have better binocular than monocular perception of depth. Is this not another example where the instrument situation should be compared with that of ordinary function?

During tests made this past year, I found only one individual who was acutely aware of a diplopia of the disparate elements of stereopsis targets. She was a young adult, having had surgery some years ago, and was complaining of a diplopia of recent development. At the time, I considered the orthoptic prognosis good, but Dr. Swan's results with similar cases seem to indicate otherwise.

In the manuscript which Dr. Swan sent me, he called attention only to the fact that many cases of so-called convergence excess reveal a marked deficiency of convergence "when their hyperopia is corrected and single binocular vision is established." I am pleased to learn from his remarks tonight that he has noted, as I have, that this deficiency of convergence is demonstrable even earlier, during the course of routine examinations with a major amblyoscope.

It is not necessary to discuss in detail the battery of tests for ocular motility, muscle balance, and fusion amplitudes which complete Dr. Swan's exhaustive study of binocular functions. The advantages of a variety of tests and of repeated tests need no further elucidation. His warning against relying wholly on results of preliminary tests and final evaluations obtained with instruments cannot be too strongly underscored. A divergence excess may simulate an esophoria on the major amblyoscope and an apparent cure simulate a functional one.

The transfer of training from the instrument situation to that of daily life presents one of the major problems of orthoptics. Many patients develop a pattern or set for the particular exercise situation and any binocular ability which they attain is active only during training periods. How to effect the conversion of these specialized visual skills to the routine binocular habits of daily seeing presents a constant challenge to the orthoptic technician. Those patients, designated by Dr. Swan as "stereoscopic cures," who do not achieve this final step are in reality orthoptic failures.

Dr. Swan emphasizes that the final goal of orthoptics is "comfortable binocular vision under circumstances of normal seeing." In spite of the admitted orthoptic failures, he implies throughout his paper that this final goal can be achieved by a sufficient number of patients with binocular disturbances to make orthoptic training worthwhile. Were this not so, then such comprehensive studies of binocular functions as he carries on would have little practical value and they would belong in the field of academic research.

30 East 40th Street (16).

FURTHER EXPERIENCES WITH INTEGRATED EYES AND VITALLIUM IMPLANTS*

WENDELL L. HUGHES, M.D.
Hempstead, New York

Since Ruedemann's[1] epoch-making report on his work on artificial-eye implants for use in enucleation, much has been done by him and others to improve on technical details. Most of the work has been done with the idea of developing a permanent implant with which can be integrated a removable eye.

The idea behind the development of Vitallium implants was to provide: (1) An implant to which the muscles and fascia of the eye may be permanently attached at the time of enucleation. (2) A similar implant that may be used in evisceration. (3) A similar implant which may be used for the late replacement of buried implants.

A series of implants were made of Vitallium in which cracks and crevices could not develop, and each was provided with an exposed, standard, flat anterior face in which there was a uniform oval depression for the reception of an integrating peg on the posterior surface of the artificial eye.

Vitallium was selected because of its extensive use in surgery and dentistry for many years and its ability to be cast in permanent form in the shape of a hollow sphere. Each implant is made in permanent form so there can be no shrinking of plastic parts away from metal parts or cracks developing due to the aging process, as in the case of plastic. There can be no question of allergy or other reaction to a plastic, and the removable eye is later fitted to the implant.

The advantage of replaceability is obvious when one considers that scratches may develop and changes in color (no permanent dyes have yet been found) may take place over a period of years. The position of the eye can be changed at will by simply relocating the peg on the back of the eye without any surgical procedure. Also, any enophthalmos or exophthalmos can easily be corrected by altering the thickness of the artificial eye.

Vitallium is a metal of low electropotential in the body and has, therefore, very little tissue reaction, as shown by the studies of Venable and Stock.[2, 3]

A preliminary report on the use of these implants in enucleation and evisceration has already been given.[4] This paper will primarily be concerned with changes in technique and shape that have been made from the original form.

A. CHANGES IN FORM OF IMPLANTS

1. ENUCLEATION

The entire implant is now polished and the depression on the anterior surface is made with steeper sides so that the integrating peg can be more accurately fitted and the eye and the implant more completely integrated (fig. 1B).

Changes in technique. It is found that when silk sutures are used, much less discharge is present than when cotton or linen is used.† The discharge lessens gradually over a period of 1 to 4 months and is reduced to a minimum by the occasional use (once or twice weekly) of sulfacetimide (15-percent drops) and sulfathiazole ointment placed in the depression on the face of the implant.

2. EVISCERATION IMPLANT

This implant is inserted through the usual corneal opening enlarged by two radial incisions. Two additional incisions are made posteriorly in the sclera from within, one above and one below to receive the anchor bars.

* Presented at the 83rd annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June, 1947.

† Absorbable plain gut sutures (3-0) are now used.

The bars are then easily pulled through the openings by four double-armed 3-0 plain gut sutures. They are first threaded around the bars and then passed through each end of the scleral openings and brought out through the conjunctiva in each fornix, and tied in the conjunctival fornices. When these sutures are tied, the bars are forcibly held through the sclera. A small transparent plastic cup 12 mm. in diameter, with two slits corresponding to the position of the bars, aids in locating these scleral openings properly.

The sclera is then wrapped around the peg can be used on the back of the eye as on the other implants.

The ring for the muscle and fascial attachments is necessarily smaller than the ring on the standard enucleation implant and only four supports are used to provide more space for the tissues to pass around the bar.

Change in surgical technique

Operative procedure

The conjunctiva of the back of the socket is separated from the underlying tissues by

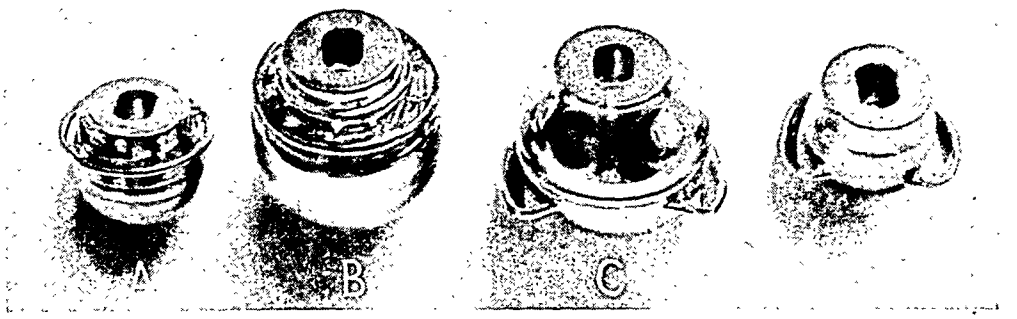

Fig. 1 (Hughes). New design of metal implants all with the same depression on the anterior face for the reception of the integrating peg on the artificial eye. (A) Smaller sized implant for use in replacing buried implants. (B) The depression on the anterior surface of this enucleation implant is made with steeper sides so that the integrating peg can be more accurately fitted. (C) Regular 18-mm. evisceration implant. (D) Smaller sized evisceration implant with a 12-mm. body.

neck of the implant and covered over with conjunctiva. The sclera contracts around the body of the implant and the anchor bars remain outside of the sclera. This gives a firmly anchored implant of perfect motility. It is made in two sizes, regular 18-mm. (fig. 1C) and a smaller size with a 12-mm. body to be used in case of a shrunken eye (fig. 1D).

3. Replacement implant

This is a smaller sized implant for use in replacing buried implants, somewhat similar in design to the enucleation implant and has been used since the preliminary report was given (fig. 1A).

This implant is made 12 mm. in diameter at its equator but the anterior face and depression are kept standard so that the same

ballooning it up with a very superficial injection of procaine hydrochloride or saline (fig. 2A). A strip of tissue about 4-mm. wide is dissected up anterior to and in line with each of the recti tendons to increase the effective length of the tendon (fig. 2B) so there will be enough tissue to pass around the attachment bar without tension.

A suture is placed in one side of the end of each tendon and tied in place. The tendons are individually passed forward between the bar and the body of the implant, and then folded over the bar and attached back to themselves (fig. 2C). Another suture is placed in the other side of each of the tendon strips to spread them out. Tenon's capsule is brought up on each side of each muscle tendon and folded back over the bar in a manner similar to the muscle tendon

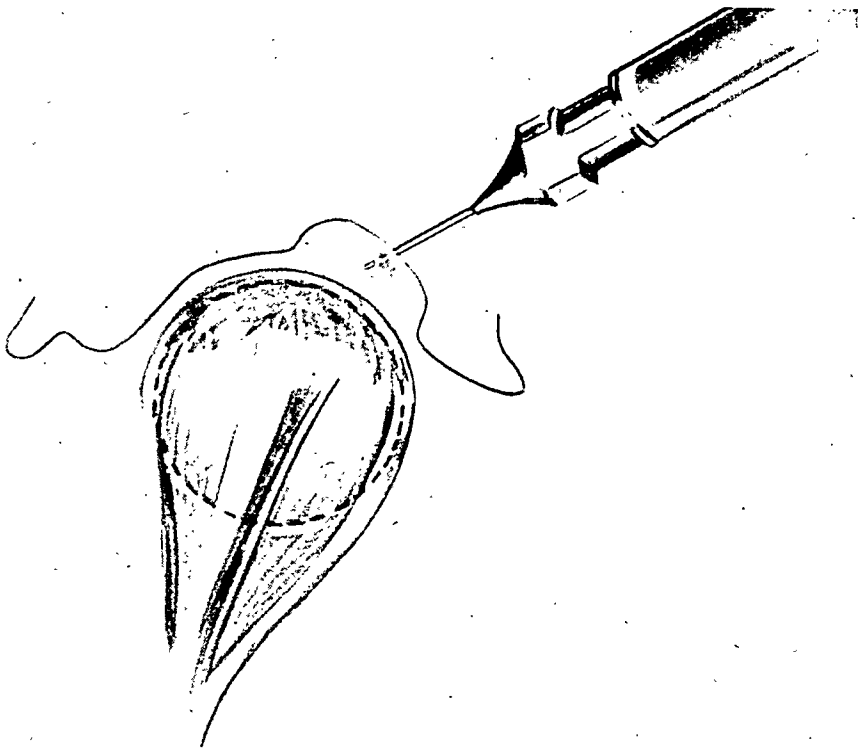

Fig. 2A (Hughes). Ballooning up conjunctiva overlying muscles and sclera.

strips (fig. 2D). Each portion is then sewed back to itself.

The conjunctiva is then anchored around the face of the implant (fig. 2E), and the surgical form is fitted to retain the fornices and to steady the implant in proper position during the early healing process (fig. 2F).

This surgical form is made of clear plastic in order to be able to see that the peg on its posterior surface is actually fitted into the depression on the anterior surface of the implant. It also has two holes drilled obliquely in the anterior convex face for the reception of a Lester forceps to aid in its manipulation or removal and replacement. It is oval and can be obtained in various sizes. The standard one is 22 mm. by 29 mm.

A moderate pressure dressing is applied,

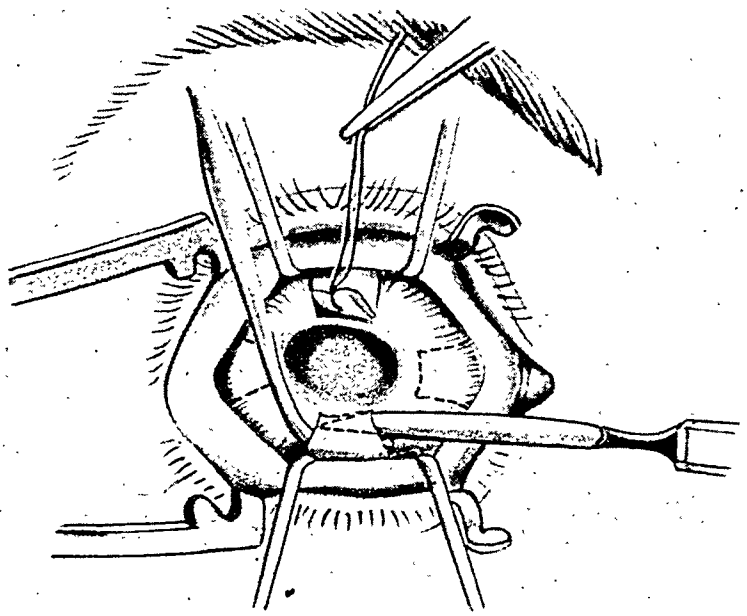

Fig. 2B (Hughes). Dissection of muscles, each with a scleral tip (same as for enucleation).

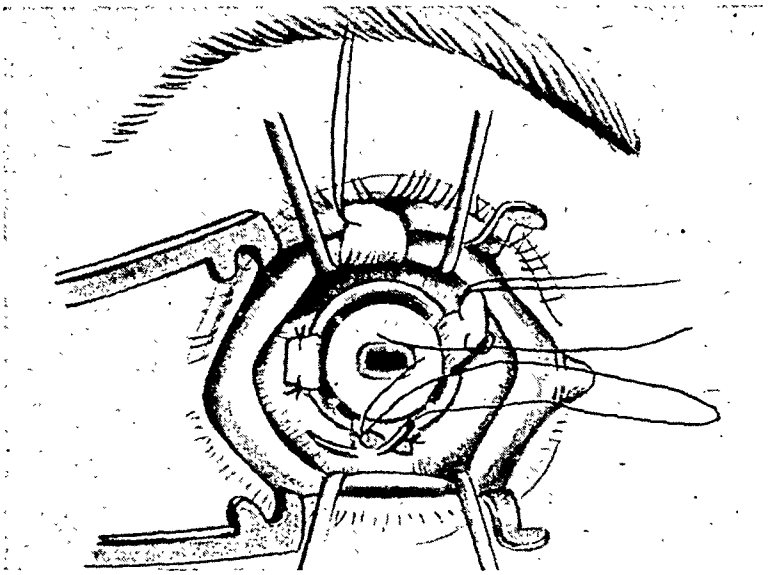

Fig. 2C (Hughes). Each muscle strip is passed forward around bar and attached back onto itself passing around the bar.

and a mask with a hole, 2-cm. across, in front of the good eye is used to limit its rotation for the first two weeks. In this way there is less strain put on the muscles during the early healing process.

The tissues may be inspected through this form at the dressings and, if the condition appears satisfactory, it may not need to be removed for 2 or 3 weeks. At the end of three weeks, an artificial eye may be fitted.

Integrating of the Eye with the Implant

An ordinary stock plastic eye is selected first for color, size, and general fit. Then the position of the peg in relation to the corneal position is determined. A trial eye with a peg located centrally can be placed in position to see if the eye is properly located in relation to the other one. If it is divergent, the peg must be placed more temporally than on the final eye. If it is slightly

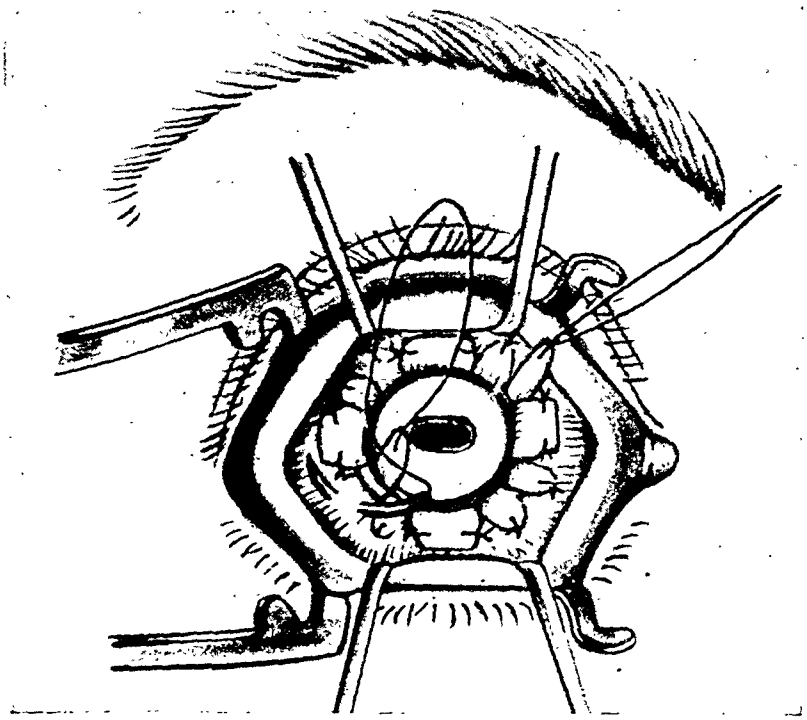

Fig. 2D (Hughes). A scleral strip on each side of each muscle is likewise passed around the bar and attached back to itself.

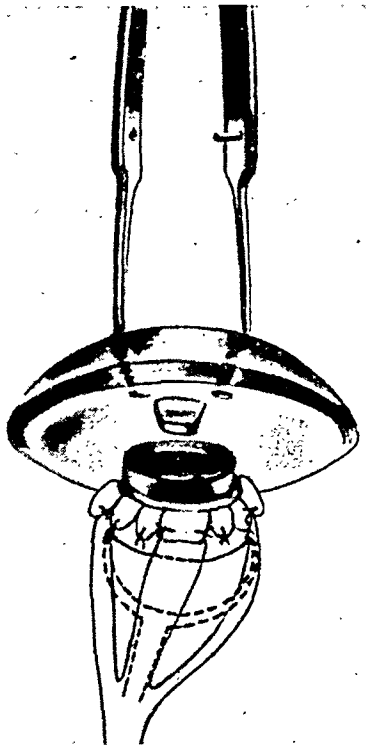

Fig. 2E (Hughes). Body of implant fits into scleral cup formed by posterior half of sclera.

convergent, the peg must be moved nasally to bring the cornea into line with that of the other eye. If it is too high or too low, a similar adjustment can be made to give the eye the correct position.

Another method would be to use the Hirschberg reflex from the normal cornea and compare its position with the similar reflex from the front of the transparent surgical form to locate the position of the reflex in relation to the peg on the posterior surface.

Case Reports

Case 1

History. Mr. A. W., aged 67 years, presented a case of evisceration in which a Vitallium implant had been inserted four months previously. He was operated on the day following its extrusion for the insertion of a Vitallium replacement implant (12-mm. body).

Technique. The conjunctiva was ballooned up and dissected free from the underlying muscles and fascial tissues. The muscle tendons were isolated and a strip of tissue, 3-mm. wide, anterior to the tendon, was dissected up with each tendon. A suture was put in one side of the end of this strip and the first part of a surgeon's knot was tied. Each of the muscle tendons was isolated from the globe and the anterior portion of the sclera removed. The posterior one half

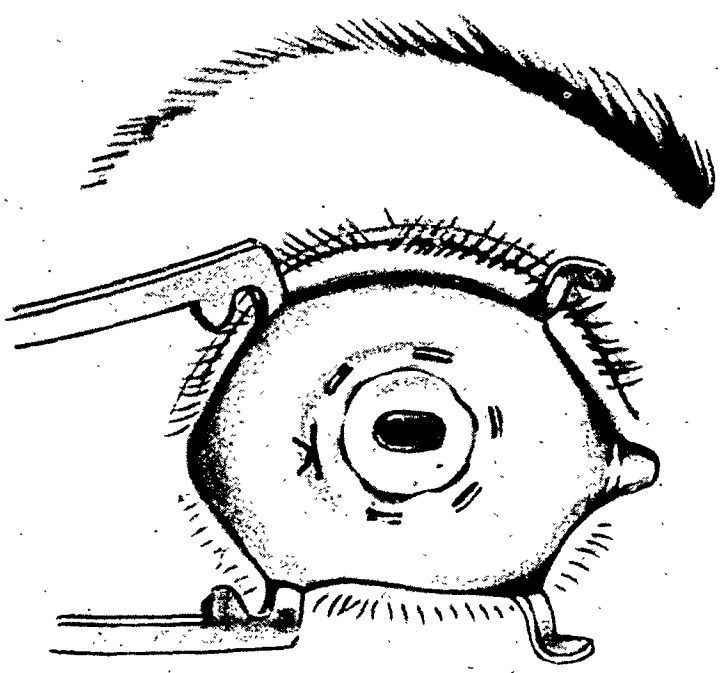

Fig. 2F (Hughes). Conjunctiva is anchored around the open face of the implant.

of the sclera was not disturbed and was retained and served as a cup for the reception of the body of the implant. The muscle tendons were attached to the ring as illustrated and the fascial strips brought forward on each side of the muscle strips and sewed back on themselves as has been described.

The regular sized enucleation implant (17 mm.) was tried first to see if it would fit. It was found that there was not sufficient room to admit the body of the implant.

The integrated eye has now been fitted, with excellent movement and a normal upper lid.

CASE 2

Evisceration with insertion of a new model Vitallium implant with anchor bars. Mr. W. B. complained of pain in an eye that had been blind for several years. A band keratitis was present with calcareous degeneration and breaks in the epithelial covering. There was considerable staining of the cornea with fluorescein. A corneal curettage was done and, due to chronic irritation, it was decided to do an evisceration two months after the patient was originally seen. The eye was widely divergent (about a 30-degree arc).

Technique. The procedure already described under evisceration was used except that the incisions were made under the lateral and medial recti for the purpose of doing the evisceration and placing the implant. Also a resection of about 6 mm. was done on the medial rectus to help straighten the eye.

Healing was uneventful but there was still a divergence of about 20 degrees. The surgical form was exchanged for an artificial integrated eye at the end of three weeks, with excellent motility except for slight limitation in the nasal field. The condition of the upper lid was normal.

In this case the implant was made with the anchor bars opposite the long axis of the oval depression on the anterior surface of the implant for comparison with the result when the bars were placed in the vertical meridian. No conclusion on this problem can be reached until a larger series of cases has been done.

CASE 3

History. A boy, aged 16 years, had his left eye injured by an explosion of a .22 bullet. Enucleation with insertion of 18-mm. implant was done. This boy insisted on playing baseball one week after his operation and would not coöperate. Two weeks after his operation, he tripped and fell and suddenly felt something "give way." The attachment bar was found to be exposed temporally and he was returned to the operating room where the lateral rectus and adjoining fascia were dissected up and reattached to the bar, and the conjunctiva was closed again.

He has now been fitted with an artificial eye but there must still be some question about the final outcome even though the present condition is satisfactory.

CASE 4

History. Miss V. Y. has worn an artificial eye for many years following an enucleation for a severe injury to the eye. There was very limited motility in all directions and some sinking in of the upper lid.

The muscle cone was dissected down its center by sharp, followed by blunt, dissection, with surprising ease. The tissue strips in the region of the recti muscles were dissected and looped around the attachment ring and sewed in position. The conjunctiva was anchored around the open face of the implant and the surgical form inserted (fig. 3).

The integrated eye was fitted in three weeks with excellent cosmetic results both static and dynamic.

CASE 5

History. Mr. D. F. aged 40 years, had an enucleation without implant 28 years ago. The patient had been kicked by a horse and

the left eye was removed one year later. No ball was put in at the time. There was poor motility of the artificial eye. A procedure similar to that in Case 4 was done. Three weeks later the integrated artificial eye was fitted with excellent appearance and motility.

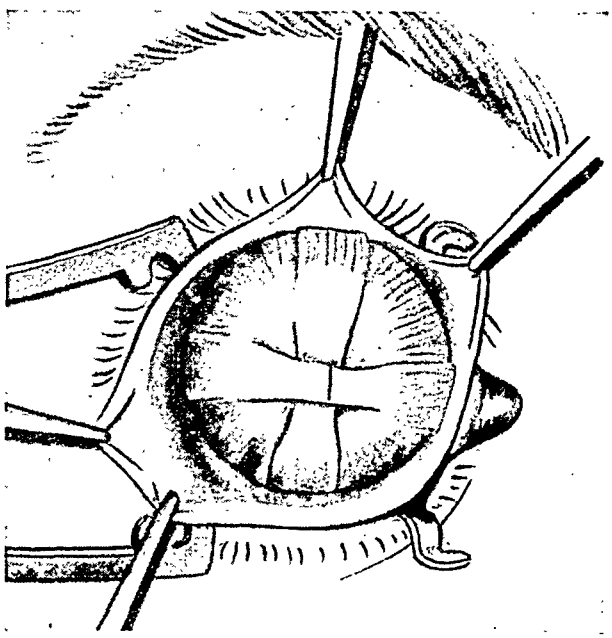

Fig. 3 (Hughes). Plan of operation in cases where enucleation was done previously with or without a buried implant.

Conclusion

It is too early to draw definite conclusions, and it will be 10 years or more before final results can be truly evaluated, but from preliminary results, it is evident that a definite improvement in the appearance, especially of the upper lid, and of the motility of an artificial eye is possible.

These implants, made in a hollow-sphere construction of Vitallium, noncorrosive, nonelectrolytic metal in which cracks and crevices cannot develop, are thought to be superior to implants made solely of plastic or a combination of plastic and metal.

No amalgam reaction is present with mercury compounds given internally or applied externally as may occur with gold or other compounds. This is important when one considers the fact that, if mercurials are given internally, sufficient mercury is secreted through the skin to cause amalgam formation in gold spectacle frames worn over long periods. This consideration would also be of importance to persons who work with mercury, such as reported by Dr. W. S. Atkinson.[5]

The integration of the eye with the implant by means of an oval peg is designed to prevent rotation of the prosthesis. The shape of the depression is standard for all sizes and shapes of implant.

These implants provide a series of shapes and sizes for various types of procedure; namely, enucleation, evisceration (2 sizes) or replacement.

A replaceable eye is obviously an advantage over a permanently placed eye, since it can be changed if the color is not correct or if color or position change in the course of years. Its position, horizontal, vertical, and anteroposteriorly, for the correction of an enophthalmos or exophthalmos, can be easily altered without any further surgical procedure.

A NOTE ON PLASTIC TEST OBJECTS FOR PERIMETRY*

LOUISE L. SLOAN, PH.D.
Baltimore, Maryland

It is generally recognized that the early detection of scotomas and other localized defects in the visual field may require the use of test objects of very low visibility. Low visibility may be obtained either by means of white test objects subtending very small visual angles, or by the substitution of colored for white test objects.

Several arguments in favor of the second of these procedures may be advanced. (1) Examination of the visual field with both red and blue test objects frequently provides information of diagnostic importance that is not given by the use of white test objects. (2) In order to obtain low visibility it may be necessary to employ 1/1000 or 1/2000 white targets; whereas, approximately the same level of visibility is provided by 1/330 or 3/1000 red and blue test objects.† Because of their greater visual angle the colored test objects of equivalent visibility are less influenced by an uncorrected error of refraction.

White test objects, on the other hand, possess many practical advantages in comparison with the colored paper discs commonly employed. Any ordinary white paper or paint may be used; whereas, in the case of the colors, standardization, not only of the reflectance, but also of the hue and the saturation of the color is necessary if tests made at different times and by different examiners are to be comparable. Frequent replacement of the colored paper discs when they become soiled or faded is essential. It is difficult to obtain a satisfactory adhesive for mounting the discs that will not change their color.

White, red, and blue test objects cut from plastic material in sheet form have been used for the past nine years at the Wilmer Institute and have proven far more satisfactory than paper test objects. The flat discs are secured to the wands by means of a special plastic cement. If the test target becomes soiled it is easily and quickly restored to its original color by wiping its surface with a damp cloth. Samples of the plastic materials, after exposure to direct sunlight for a period of several weeks, showed no perceptible change when compared with unexposed samples.

Colorimetric specifications of the white, red, and blue plastics in artificial daylight illumination (Illuminant C) are given in Table 1. The reflectances of the red and blue samples, 0.1026 and 0.1053 respectively, are practically identical and are a close match to the reflectance of the gray arc of the Ferree-Rand perimeter. It has been

TABLE 1

	Hue	Value	Chroma		x	y
White	4.7 PB	8.78	2.1	0.7400	0.298	0.305
Red	5.1 R	3.72	11.0	0.1026	0.534	0.312
Blue	6.2 PB	3.77	9.8	0.1053	0.202	0.179

* From the Wilmer Ophthalmological Institute of The Johns Hopkins University and Hospital.

† A 1/1000 test object subtends a visual angle of 3.4 minutes; 1/2000, 1.7 minutes; 1/330, 10.4 minutes; 3/1000, 10.3 minutes.

shown that best results are obtained in color perimetry when the color is viewed against a background of approximately the same brightness.* The colors are more nearly equal in chroma than are the Heidelberg red and blue papers. Normal subjects, therefore, have fields of about the same extent for red and blue test objects of the same size. With Heidelberg colors, on the other hand, the normal field for blue is significantly wider than the field for red. Approximately equal visibility of red and blue test objects in the case of the normal eye is desirable, in order to detect a differential impairment of sensitivity to the two colors.

In summary, it is believed that the special features of these plastic test objects eliminate the major difficulties which have led to the virtual abandonment of colored test objects by many perimetrists.

Johns Hopkins Hospital (5).

B. PYOCYANEUS CORNEAL ULCER TREATED WITH PENICILLIN†

S. E. Pendexter, Jr., M.D.
New York

Corneal ulcer caused by B. pyocyaneus is a rather uncommon condition, somewhat less than a hundred cases having been described in the literature. It is also one of the most destructive corneal lesions. Before the advent of the sulfonamides, the usual end result was a total loss of vision. In 1942 and 1943, however, successful treatment of this type of ulcer with sulfapyridine and sulfadiazine was reported by several authors.[1]

Penicillin treatment of pyocyaneus ulcer has apparently been reported only once. In 1945, Juler and Young[2] had such a case in a series of ulcers treated with penicillin locally. This case, described as severe but without hypopyon, spread rapidly and showed no response to penicillin; further details of the outcome were not given.

Case report

D. C., a 9-year-old white girl, was admitted to the Manhattan Eye, Ear, and Throat Hospital on June 17, 1947. Four days prior to admission she had had a foreign body and rust ring of the left cornea removed at another hospital. During these four days, the left eye became increasingly red and painful.

Examination. When the patient was first seen at this Hospital, there was marked blepharospasm and tearing of the left eye. Conjunctival injection was severe, and in the central cornea there was a horseshoe-shaped ulcer involving perhaps a third of the cornea; the edges of the ulcer were elevated but not undermined. A small hypopyon (3 to 4-mm. wide) was present, and the iris was moderately dilated (previous mydriatic). Examination of the deeper structures was impossible; vision was light perception.

The right eye was normal. Vision was: O.D., 20/20. There was no history of previous eye disease or injury.

Treatment. On admission, a culture of the ulcer was taken. Treatment consisted of local instillations of 1-percent atropine three times daily; penicillin drops (5,000 units per cc.) every four hours, and later every two hours during the daytime; intramuscular penicillin G, 50,000 units every four hours day and night.

Culture. The admission culture, as well as a second one taken four days later, grew a gram-negative, green pigment-producing rod considered to be B. pyocyaneus.

Course. Within 48 hours after admission, considerable improvement was apparent, the hypopyon having disappeared. Because of this it was felt that continued treatment with penicillin alone was justified. By the 10th

† From the Manhattan Eye, Ear, and Throat Hospital.

day, there was no staining of the cornea, and on the 14th day the patient was discharged from the Hospital. At this time, there was only slight injection; a central macula was present, involving the anterior layers of the cornea and preventing a clear view of the fundus; and vision was limited to counting fingers at one foot.

After discharge, local treatment with penicillin and atropine was continued for 10 days. Three months after the onset of the present illness, the corneal macula is still present, but has shown some clearing. Vision is now 20/200, O.S.

Conclusion

A case of B. pyocyaneus corneal ulcer is presented which apparently responded to local and parenteral penicillin therapy.

MALIGNANT MELANOMA OF THE IRIS

Jesse M. Levitt, M.D.
Brooklyn, New York

Case report

T/4 R. E. H., a white man, aged 30 years, was admitted to Fletcher General Hospital, Cambridge, Ohio, on September 4, 1944. He had been evacuated from the E.T.O. where he had been examined by several ophthalmologists, including the Consultant in the E.T.O., all of whom had diagnosed malignant melanoma of the iris of the right eye.

History. The patient related that, while stationed in Iceland, his right eye became red and painful and a tiny black pinpoint spot was noticed on the globe. He had had about six attacks of pain in the right eye, each lasting 7 to 10 days. The black spot on the globe had increased gradually to its then present size over the course of 13 months. The vision of the right eye had become slightly blurred during the same period of time. He also complained of headaches behind the right eyeball at night. There was no history of any trauma to the eye.

Examination disclosed vision to be: O.D., 20/40, J1 corrected with a −0.75D. cyl. ax. 90° to 20/20; O.S., 20/20−3, J1, corrected with a −0.25D. cyl. ax. 180° to 20/20. There was no muscle imbalance.

The right globe was white; there was a fleshy pterygium nasally encroaching 2 mm. on the cornea; a pear-shaped pupil pointing up at the 1-o'clock position and reacting actively to light except above; a blue-black crescent-shaped lesion, measuring 4 by 2 mm. and elevated about 1 mm. above the surface of the cornea, situated at the periphery of the cornea and overriding the limbus corneae extending from the 12- to the 1-o'clock positions and occupying the anterior-chamber angle.

Slitlamp examination showed numerous blood vessels coursing over the surface of the lesion. The temporal part of the lesion was translucent; the nasal periphery was faintly translucent. The iris presented numerous "freckles," rust-colored conglomerations of pigment. The media were entirely clear. The optic disc color was good. There was a small central cupping of the disc. There was an irregular whitish area with fine pigmentary changes located at

the first bifurcation of the superior temporal vein about one disc diameter from the nasal border of the disc. Tension was 18 mm. Hg (Schiøtz).

The left eye, externally, was negative in

Fig. 1 (Levitt). Lesion simulating malignant melanoma of the iris.

every respect. The iris presented numerous nevi of a character similar to that noted in the right eye. The media were clear. The optic disc and fundus generally were normal. The disc was not cupped. Tension was 18 mm. Hg (Schiøtz).

X-ray films of the right globe were negative.

General physical examination yielded negative results. Blood Wassermann was negative.

Diagnosis. My diagnoses were (1) malignant melanoma of the iris of the right eye; (2) benign melanoma of iris, multiple, bilateral; (3) pterygium, right eye.

The right eye was enucleated under intravenous pentothal anesthesia on September 15, 1944. Healing was uneventful.

Microscopic report

The following is the microscopic report of Col. J. E. Ash:

Gross. The specimen consists of a firm eye measuring 24 by 24 by 23 mm. A small elevated pigmented lesion (3.5 by 2 mm.) is situated at the limbus between the 12- and 2-o'clock positions. There is hemorrhagic thickening of the limbus at the 4-o'clock position (in paraffin). The pupil is eccentric. The eye is opened between the vertical and horizontal planes. There are multiple retinal folds posteriorly. The iris adheres to the posterior surface of the cornea on one side. The optic nerve is too short for cross section.

Microscopic. Descemet's membrane is interrupted at the site of a bulging keratoiritic scar which is covered by conjunctiva and surface epithelium and is lined by atrophic iris and its pigment epithelium. On this side the filtration angle is occluded by anterior synechia. Redistributed pigment is present in the atrophic iris and the spaces of Fontana and around the canal of Schlemm. Chronic inflammatory cells are very sparsely scattered throughout the iris and there is ectropion uveae. The choroid is thin. There is cystic degeneration of the retina at the ora serrata. The lamina cribrosa appears somewhat depressed but this may be due to operative trauma. One separate paraffin section shows hemorrhagic detachment of the ciliary epithelium and another elastosis and hyalinization of the stroma of the limbal conjunctiva.

Diagnosis. Pterygium; perforation of cornea near limbus; prolapse of iris; cystoid cicatrix; low-grade iritis, with atrophy and redistribution of pigment.

991 Ocean Avenue (26).

CORNEAL SCISSORS

Walter Moehle, M.D.
Brooklyn, New York

The present trend in cataract surgery indicates the employment of a small corneal section made with a keratome or Graefe knife. This incision is enlarged for free passage of the lens, a procedure easily ac-

complished by using scissors especially designed* for the purpose.

When these scissors are visualized as lying on a flat surface, the blades are seen to curve in two planes: (1) upward from the plane of the shanks, and (2) laterally away from the line of the shanks. Both pairs are identical except that the lateral curve is to the right or to the left for use on corresponding sides of the corneal incision.

The lateral curve naturally follows the corneal rim as the tip of the lower blade, which is blunt to avoid engaging the iris stroma, enters the chamber along the plane of the iris. The curve away from the horizontal plane facilitates the handling of the scissors, especially in deep-set eyes.

The blades are the same length, being 14- to 15-mm. long. On either side of the pivot hinge, the scissors are 4- to 5-mm. wide. It is believed that this width, together with the double curve, permits strength and firmness in the blade which eliminates slippage or springing apart of the blades sometime encountered in scissors of a lighter construction. I have used these scissors for more than six years and have found them to be most satisfactory.

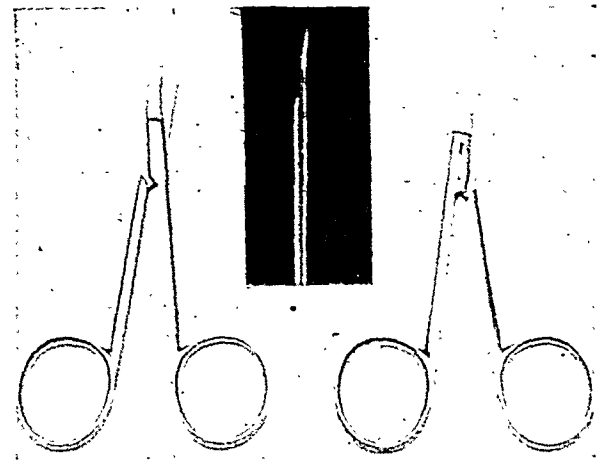

Fig. 1 (Moehle). Specially designed corneal scissors for cataract surgery.

Historical Miniature

The history of the ophthalmoscope illustrates how the solution of a problem must await the mind of genius and how easy it is to make a modification, once the master has showed the way. Kussmaul clearly understood all details of the problem, but succeeded only in building an ophthalmoscope that had a serious defect: it did not reveal the fundus. On the other hand Donders easily substituted a perforated silvered mirror for the multiple cover glasses that Helmholz had described, because he could not curb his impatience while waiting for an instrument of Helmholz's design to be delivered to him.

September 9, 1947

ATOPIC CATARACTS

DR. J. WESLEY MCKINNEY reported the case of W. M. S., aged 31 years, who was seen in February, 1947. His history was that the vision had become progressively worse for the past three months. He had had chronic eczema over the face and body for many years and also was asthmatic. He had received a number of small doses of X ray. Vision was corrected to 20/40 mostly, right eye; 20/50 mostly, left eye. The eyes were entirely normal except for central anterior and posterior subcapsular lens opacities in each lens. The skin of the face, parts of the body, and extremities was leathery, scaly, and slightly reddened. This is the stage of lichenification of chronic eczema. The association of cataract with chronic eczema in a young person is rare, only 40 cases having been reported in the literature up until 1940. It is supposed that the lens, being an ectodermal structure, may take part in this allergic disease of the skin with the formation of cataract. Linear cataract extraction was performed on the left eye in April, 1947. The resulting vision was 20/20, J1.

PAPILLEDEMA OF UNKNOWN ETIOLOGY

DR. J. WESLEY MCKINNEY reported the case of Miss A. McC., aged 17 years, who was first seen December 31, 1940. For most of her life she had been subject to attacks of semicoma which was considered to be petit-mal epilepsy. The attacks lasted for only a few moments as a rule and she was otherwise a normal healthy girl. Because of the finding of choked discs she had been subjected to a complete neurologic study including the spinal fluid and air injection. All examinations were negative. The ocular examination revealed vision to be 6/6, J1 in each eye. There was a quarter diopter of hyperopic astigmatism in each eye. The pupils were equal and active. The ocular movements were normal. The ophthalmoscopic examination revealed two diopters of papilledema of both discs. The vessels on the discs showed sheathing. The retinal veins were slightly dilated. Fields showed general contraction and enlargement of the blind-spots. The patient, now 23 years of age, was last seen in March, 1946. She had been checked at intervals for six years without change in the fundus picture. The fields have varied from full to marked general contraction. No other symptoms have developed.

LOCALIZED EDEMA OF THE RETINA

DR. J. WESLEY MCKINNEY reported the case of Mrs. R. G., aged 43 years, who was first seen for this affection on September 7, 1945. She complained of a central area of dim vision which had been present for seven days. Vision was: O.D. 6/6; O.S., 6/24, improved to 6/9 partly with +1.5D. sph. There was edema of the retina of about 1½ disc diameters in the area immediately below and involving the macula. There were no hemorrhages or exudates, and the blood vessels of the region of the lesion seemed normal. There was a paracentral scotoma, the lower margin of which just missed the macula. The peripheral field was normal. Physical examination was completely negative. It was thought that this might be a case of Gifford's central angiospastic retinopathy. However, no evidence of vasospastic disease could be made out. The edema and paracentral scotoma persisted for a month and gradually subsided. Five months later the retinal edema was entirely gone leaving behind a few fine yellow spots. A small rela-

tive paracentral scotoma persisted. The refraction which had been +1.5D. sph. was now +0.25D. sph.

Recurrent retrobulbar neuritis, chiasmal arachnoiditis

Dr. R. O. Rychener reported a case of recurrent retrobulbar neuritis apparently due to multiple sclerosis. E. C., aged 18 years, was admitted to the Memphis Eye, Ear, Nose, and Throat Hospital on February 26, 1942, because of acute failure of vision of the right eye during the previous week. There was no light perception in his right eye, the pupil measured 4 mm. and reacted to light, consensual reflex being present. The visual acuity of the left eye was normal. No intraocular pathologic condition was apparent, and the diagnosis of retrobulbar neuritis was made. Treatment with foreign protein and vasodilators over a period of two weeks caused improvement of vision to counting fingers at two feet and, in the course of the next three months, the visual acuity of 6/7.5, J4 was obtained. The right nerve was definitely pale.

On June 11, 1943, the patient awoke with blurring vision in the left eye and reported after three days with vision diminished to moving objects. Hospitalization and the same treatment were given with visual improvement of the left eye to 6/18 after six months. At this time there was definite pallor of both optic discs.

On November 3, 1944, visual acuity was 6/7.5, J1 and 6/9, J1, as recorded. Ten days later visual diminution in the right eye was again noticed, vision being recorded at 6/24, foreign-protien therapy was again instituted with visual recovery in two weeks to 6/10, J3.

On October 30, 1946, acute visual failure was again evidenced in the left eye, visual acuity being 1/40 which, under treatment, improved only to 2/60, J12.

During these episodes complete general and neurologic examinations were made with entirely negative results.

In April, 1947, he was seen in consultation by Dr. W. L. Benedict at the Mayo Clinic where the findings above were confirmed but all examinations proved to be negative with regard to etiology. At this time the visual fields were concentrically reduced two thirds in the right eye and one half in the left eye.

On August 12, 1947, he submitted to chiasmal exploration by Dr. J. C. Love at the Mayo Clinic who reported the visual apparatus at the chiasm completely surrounded by dense proliferative arachnoiditis with a collection of fluid causing distinct pressure on the nerves and chiasm. The fluid was evacuated, the proliferating arachnoid was resected, thus thoroughly decompressing the nerves, chiasm, and tracts. On August 28, Dr. Henry Wagener thought there was some slight improvement in visual acuity and visual fields.

The patient apparently made a satisfactory convalescence from this intracranial surgery but on October 26, 1947, suddenly developed paraplegia and retention of urine and was brought to the Baptist Hospital for care by Dr. Semmes and Dr. Murphey. The patient suddenly died on the 10th day following the development of these symptoms, and the diagnosis was not established since no postmortem examination was allowed. In the light of the previous history of recurrent attacks of retrobulbar neuritis and the concluding syndrome it was thought that this patient had multiple sclerosis.

Pseudotumor of orbit

Dr. Charles M. King reported a case of inflammatory pseudotumor of the orbit in a white man, aged 27 years.

Mr. K. R. was first seen on July 31, 1947, with history that for the past six weeks the right eye had been uncomfortable, red at times, and the vision was blurred. Discomfort was not severe enough to prevent his teaching school. No history of recent injury could be obtained. There was a history of sinusitis several years ago while

he was in the armed forces in Europe, but only supportive treatment was necessary.

Examination showed the right eye to be slightly red, but no secretion was present. The palpebral conjunctiva was normal. There was a manifest hypertropia of 10$^{\Delta}$ to 15$^{\Delta}$ but the patient was not aware of diplopia until tests elicited it. The pupil was round and reacted well to light. Movement of the eye was limited down and out and diplopia was greatest in this field, although it was present on looking directly out, and up and out. There was slight exophthalmos, measuring O.D., 18 mm., O.S., 16 mm. (Hertel).

Fundus examination revealed the media to be clear. Above the macula, and also below, and including the temporal aspect of the disc margin, the retina appeared wrinkled and somewhat elevated. Marked tortuosity of the vessels was present. The A-V ratio was about normal. There was a small indistinct grayish area temporal to and below the macula. The left fundus was normal.

Vision was: O.D., 20/40, corrected to 20/20; O.S., 20/20.

The patient was not seen again until August 30, 1947. There had been less pain in the eye although there was constant diplopia. Medial rotation of the eye was possible but movements in all other directions were markedly reduced or absent. The fundus picture was about the same. Corrected vision was still 20/20. Visual fields showed approximately normal perimetric form for a one-degree white target. X-ray examination on this date failed to reveal any definite mass or change in the orbit.

On September 15, 1947, the patient was next seen. Meanwhile he had been seen by a local ophthalmologist as well as by an ophthalmologist and an otolarygologist in another city. A diagnostic irrigation of the right antrum was done elsewhere and no evidence of infection in the antrum was found. At this time the patient was not able to move the eye out or downward. Hypertropia 15$^{\Delta}$ to 20$^{\Delta}$ was still present. A firm mass could be palpated over the outer half of the lower orbital rim extending from the region of the external canthus to the midline and backward along the floor of the orbit. The lower lid was firmly bound to this mass; the lower fornix being almost obliterated. Only slight tenderness was elicited on forceful palpation of the mass.

On September 25, 1947, an orbitotomy was done by transconjunctival approach over the tumor itself. Densely matted fibrous and vascular tissue filled the lower half of the orbit binding the external rectus and the inferior rectus within its substance. These muscles were dissected with much difficulty and isolated. The inferior oblique was exposed from its origin to its insertion and resembled a piece of firm, resistant spaghetti. On severing this from its attachment to the globe a clear fluid was seen to flow out spontaneously. The entire muscle was excised. Biopsy of other regions in the mass was done, it being impossible to remove the whole thing from the orbital floor.

The pathologic report was chronic inflammatory tissue, fibrosis, focal necrosis, and degeneration of striated muscle. No evidence of malignancy was found. Blood Kahn was negative on two separate tests. A mild leukocytosis was the only other positive laboratory finding.

Convalescence was uneventful and the patient left the hospital on the third day. On October 21, 1947, the right eye was almost straight, there being about 5$^{\Delta}$ hypertropia. Good levator action was present and there was no exophthalmos. There was no diplopia, because visual acuity had decreased to 10/200, correctible to 20/70. Tortuosity of the retinal vessels was still marked, but the posterior pole area had no apparent edematous areas. The patient was comfortable and has continued his work.

Orbital tumor

Dr. Charles M. King reported a case of orbital tumor in a white girl, aged three years, which proved to be a lymphocytic

nodule in an acute state of lymphatic leukemia.

C. A. W., an apparently healthy child, was first seen on September 4, 1947. The mother stated there had been a puffiness of the lower lid for two months and recently she had felt a hard lump in the lid. No history of serious illness of any nature could be obtained.

Examination revealed a definite, hard, smooth mass, palpable through the left lower eyelid along the lower orbital rim and extending from the midline to the outer canthus. No displacement of the globe was present. No limitation of motion of the globe was found. There was no evidence of external inflammatory changes. The mass was movable from below upward and slightly movable from side to side. Transillumination of the mass was clear. Over the left mastoid region were three distinct nodular masses about the size of a pea, none of which was tender to palpation. There was one similar nodule over the right mastoid region, and palpable nodes along the posterior cervical chain on either side were present.

On September 8, 1947, a skin incision was made along the temporal two thirds of the lower orbital rim and a well-encapsulated smooth, fibrous tumor, measuring approximately 3½ by 2½ by 1 cm. was removed from within the lower aspect of the orbit. None of the extraocular muscles was involved. There was little difficulty in removing the entire mass intact by blunt dissection. The fascia was closed with interrupted catgut sutures and the skin closed with a subcuticular suture of black silk.

Laboratory findings:

Date	RBC	WBC	Hb
9-5-47	4,130,000	5,580	12.4 mg.%
9-13-47	3,550,000	4,300	10.5 mg.%

Concentrated smear showed 100% lymphocytes.

Preoperative X-ray examination showed a destructive process involving the floor of the orbit and roof of the left antrum. However, at operation these bony changes were not evident by palpation of the lower orbital rim or floor of the orbit.

Pathologic diagnosis was lymphatic leukemia and the lesion in the orbit was interpreted as a leukemic infiltration of the subcutaneous tissue.

The immediate postoperative course, in so far as the orbit was concerned, was uneventful. However, the typical symptoms of acute leukemia became more marked clinically. The daily temperature showed spiking and fluctuated from 100°F. to 104°F. (rectal reading). On the 12th hospital day the parents wished to take the child home. At last reports the patient was still alive but was incoherent part of the time and unable to be out of bed.

This case of acute lymphatic leukemia is of interest to us in that the first clinical evidence of the disease was manifest in the orbit and serves to impress upon us the many possibilities in diagnosing tumors of the orbit.

Optic neuritis treated with histamine

Dr. Philip Meriwether Lewis reported a severe bilateral optic neuritis, which responded rapidly to treatment with histamine.

C. M., a white man, aged 27 years, was first seen on February 2, 1947, because of marked visual failure. Two weeks previously he began to have severe headaches and lost the vision of his right eye. Ten days later the vision began to fail in the left eye. He was told that his trouble was due to sinus disease and, without benefit of X-ray studies or consultation with a rhinologist, was treated daily for the supposed infection of his sinuses. When first seen, vision was reduced to light perception in the right eye and 20/50 in the left. This had fallen by the next morning to counting fingers at four feet. The pupil of the right eye did not react to light and that of the left eye only sluggishly. The discs were both moderately swollen and red to almost the same degree. The retinal vessels were engorged but there

were no hemorrhages. The visual field of the left eye was mostly lost below and temporally. General physical examination and blood studies were negative. Dr. Sam Sanders found the sinuses normal and suggested using histamine intravenously after the method of Horton. This was done—2.75 mg. in 300 cc. of normal saline, intravenously, daily for a total of six times. In addition typhoid-H antigen was administered. Improvement was rapid and he was dismissed from the hospital on the 12th day with vision of O.D., 20/50; O.S., 20/40. The edema had subsided.

Two weeks later vision had improved to O.D., 20/40; O.S., 20/30. Both nerves appeared normal, but the right blindspot was still twice the normal size. He had resumed work and noticed only a very slight headache occasionally. Observation every 6 or 8 weeks was advised.

Comment. It was felt that this was a case of early multiple sclerosis and that while the neuritis would probably have subsided eventually without treatment, the use of histamine intravenously was beneficial in hastening recovery.

Monocular hysterical blindness

Dr. Philip Meriwether Lewis reported two cases of hysterical blindness of one eye.

Case 1. A white man, aged 38 years, who was in charge of the public schools of a nearby community, was first seen in March, 1944, because of nervousness which he attributed to his eyes. Examination showed his eyes to be normal except for a slight hyperopic astigmatism (+0.50D. cyl. ax. 90°, O.U.). His vision was 20/20, J1 in each eye. His accommodation was rather low, being only four diopters. Glasses were prescribed for reading.

The patient was next seen in August, 1946. He stated that his right eye had become sore and red the previous day and that it had lost its vision. He had been having some recent headaches and said he was quite nervous. Examination showed some congestion of the conjunctiva with slight chemosis. The pupil was normal in size and reaction. The fundus was normal. Vision was no light perception. In the left eye, it was 20/20. The right eye was tender to pressure and painful on motion. The visual field and blindspot of the left eye were normal. A diagnosis of an acute retrobulbar neuritis was made and he was hospitalized for study and treatment.

Complete physical, neurologic, laboratory, and X-ray examinations were made and found negative. Treatment consisted of dionine and hot compresses, locally; nitroscleran, intravenously; foreign-protein injections, and even penicillin. After two weeks, the patient was sent home. The only improvement was that the eye had lost its redness, edema, and soreness. He still could not perceive even a bright light.

His vision was unimproved when seen a week later. When seen again about three weeks after leaving the hospital, he still claimed inability to see light with his right eye. More than five weeks had elapsed since the blindness began, but the fundus was still normal. For the first time hysteria or malingering was suspected. With a strong fogging lens over his left eye, he read 20/50 with his right eye; and with a stereoscope, he could see the right image as well as the left. He was then told that he would positively recover his vision and probably normal vision. From that time on improvement was steady and by late October (10 weeks after onset) his vision was 20/20, J1 in both eyes with correcting glasses.

Case 2. A healthy white girl, aged 18 years, was seen in November, 1946. She claimed that four days previously she had lost the sight of her right eye. Since then she had been totally blind in that eye and had had a severe headache constantly.

Examination was completely negative. The central vision, visual field, and blindspot of the left eye were normal. By retinoscopy both eyes were found to have

practically no refractive error (+0.50D. sph.). She professed inability to see any light with her right eye. With a strong plus lens over her left eye she read 20/40 with her alleged blind eye. Careful questioning failed to elicit the cause of this hysteria or malingering, whichever it really was. Her family was told that her trouble was of nervous origin and she was referred to her family physician. After several weeks of pseudoblindness, which eventually proved to be due to dislike for her work, she recovered completely.

Comment. The first patient was a well educated and intelligent man. He had been studying very hard for an M.A. degree in addition to being overworked with his occupation. He was not satisfied unless he made the highest marks in his studies. It was felt that the probable cause of his hysterical amaurosis was that he was afraid that he would be unable to maintain the high standard which was expected of him. He therefore subconsciously used the blindness of one eye as an escape mechanism. His recovery was more rapid than usual. Most hysterical blindness is bilateral and may last for years. The second case may have been more malingering than hysteria. It is often difficult to differentiate hysterical from simulated blindness.

Daniel F. Fisher,
Recorder for Eye Section.

CHICAGO OPHTHALMOLOGICAL SOCIETY

DR. BEULAH CUSHMAN, *president*
October 6, 1947

The clinical meeting was conducted by the Department of Ophthalmology, Northwestern University Medical School.

Scientific Program

SURGERY FOR CORRECTION OF MUSCLE ANOMALY

DR. WATSON GAILEY (Bloomington, Illinois), presented this subject. An abstract of his paper follows.

Great advances have been made in recent years in muscle surgery, a branch of surgery not too difficult for the average ophthalmic surgeon. However, it is not corrective surgery we should worry about. Rather it is the proper evaluation of a given case and the thorough study of the under- or overaction of the various muscles involved which should be carefully considered before any definite surgical campaign is adopted.

These preoperative studies should engage our full attention. Following this the surgical treatment should be comparatively simple. Every case is a case in itself and some require repeated examinations. Particular study should be given to fixation and the findings in screen cover tests in all fields.

I am sure that we all know that the correction or near correction of squints of all types would be simple if we could determine *accurately* in millimeters the amount of resection or recession necessary to effect the cure of a given amount of deviation measured in diopters.

For some years in our clinic we have attempted to establish a standard of surgical procedure on which we can rely—based on our cover-test findings and translated into millimeters of recession and resection—with only a reasonable degree of success. By the cover test we painstakingly work out the lateral and vertical deviations in diopters. We estimate the degree of paresis as best we can in certain muscles, the degree of secondary contraction in the paretic muscle's antagonist, and how much the vertical component might increase the lateral deviation and record these findings on our chart. After this, we decide which muscles are to be exposed and how much recession and how much shortening these muscles must undergo. But we reserve the right to change our minds and either decrease or increase the amount of shortening or recession.

To put it simply, outline a definite procedure but do not hew to the line. Reserve

for yourself the right to change your mind and your method of attack and become more conservative or more radical as your good judgment directs.

There are certain rules which we have found to be useful in our clinic:

1. In monocular squints with amblyopia of the squinting eye we confine our surgery to the amblyopic eye if possible.

2. If the power of convergence is unlimited, there should be no fear in doing a reasonable amount of recession. If the P.C.B. is 100 or more, for instance, it is much safer to strengthen the laterals only.

3. Vertical deviations should always be searched for diligently.

4. We have concluded that: it is smart to expose the opposing muscles involved in convergent or divergent squint of any type before deciding definitely how much strengthening or weakening to do on either.

5. It is a great problem to decide how much to correct in convergent squints—partially or wholly accommodative—for great danger lies in obtaining orthophoria for distance and near without correction of the refractive error only to find that this beautiful result is converted into a very unwelcome divergence when the correcting lenses are worn.

6. A slight overcorrection is worse than 10 to 15 degrees of undercorrection and these cases must be approached with great caution. We always attempt to under correct partially accommodative squints.

7. When the P.C.B. is 90 mm. or over in convergent squints, external rectus resection is indicated. Operate verticals first if the hyper defect is greater than the laterals.

8. Visual acuity should be made equal if possible before surgery, not necessarily normal.

9. With equal paresis of superior recti of moderate degree and equal upshoot of contralateral inferior obliques, recede both obliques. But, watch your step if both superior recti are markedly paretic for you may, by recession of both inferior obliques, destroy elevation and find your patient tilting his head backward.

10. If there is a moderate paresis of both superior recti and there is 10 or 15 degrees' difference in the hypertropia, recess the oblique showing the greater secondary deviation and later you may resect or shorten the superior rectus of the same eye.

11. If there is an under correction of hypertropia after recession of an overshooting inferior oblique after three months and some increase in the hypertropia in the field of the contralateral inferior rectus muscle, this muscle must be receded.

12. When we find marked bilateral superior rectus paresis unequal, strengthen one or both superior recti, proportionately. In marked bilateral superior rectus paresis associated with esotropia or exotropia, we find these cases are liable to over correction if laterals are operated first.

13. In moderate bilateral superior rectus paresis: if fixing left in eyes right and fixing right in eyes left, correction of convergent or divergent may be all that is necessary, but, look out for P.C.B.

14. If we have an amblyopic eye with either a convergent or divergent squint accompanied by a big upshoot of the squinting eye we do a complete tenotomy or myomectomy on inferior oblique of the upshooting eye while operating the lateral.

15. In marked superior oblique paresis, a liberal recession of the secondarily contracted inferior oblique is sometimes gratifying.

16. When one superior rectus is almost completely paralyzed, resect this paretic muscle. When both superior recti are very paretic, with marked overshooting of inferior obliques, leave inferior obliques alone and resect both superior recti.

17. Inferior rectus recession. In recession of a secondarily deviated inferior oblique, as evidenced in a contralateral paretic superior rectus and a secondarily contracted inferior rectus, it is well to be cautious. We are quite satisfied to wait several months

before recessing this inferior rectus muscle as one finds frequently that the recession of the overshooting inferior oblique will tend to ease this secondary contraction in whole or part. Tensity in this muscle is greatly reduced in amount after recession of the contralateral inferior oblique and strengthening of the ipsilateral superior rectus.

18. First, strengthen the too weak muscles and weaken the too strong muscles by any effective method with which you are familiar. Although one goal of these measures is cosmetic parallelism, the most important aim for which one strives is a parallelism that permits of single binocular vision and stereopsis; in other words—a satisfactory functional result.

19. A complete chart of our findings in an individual case is on the wall of the surgery showing the full information we have gleaned concerning each case. This chart is as important as X-ray films in reduction of fractures. This bit of prophylaxis was made a must in our clinic some years ago after a muscle was recessed instead of resected. It might have been disastrous had we resected instead of recessed.

Never promise that a single operation will cure any squint. We feel safer in promising them three, when we feel that we could accomplish a cosmetic result in one. If you feel sure of your findings and confident of your conclusions and there are no contraindications to any procedure you propose to employ, there seems to be no limit to the number of muscles you may operate at one sitting providing of course you are a respector of tissue.

Discussion. Dr. Walter Stevenson approved of Dr. Gailey's treatment preliminary to operation. While muscle surgery is certainly not exact and many times does not give the desired result, any time spent in careful effort to make a proper diagnosis is well spent. It is just as important to have in the operating room a chart showing the essential findings as determined in the office, as it is to have X-ray films in certain types of surgery. One should have an open mind, as Dr. Gailey said, and at times should change the preconceived idea of what is to be done in muscle surgery.

There should be a definite understanding with the parents, before surgery is undertaken, that it may be necessary to do two, three, or even four operations. While as physicians we should be interested in the functional rather than the cosmetic result, it must be remembered that parents bring children for correction of a squint and adults come for correction of a squint because of the cosmetic defect in almost all cases. Dr. Gailey is correct in saying that if the vertical defect is greater than the lateral, the vertical should be operated on first, although he himself does not always do so. If the vertical deviation is greater than the lateral, the decision as to procedure should depend upon the amount of deviation in various fields. For example, if there were 14 degrees of right hypertropia in the primary position, which increases to the left and up, this would indicate a left superior rectus paresis and surgery should be directed to the right inferior oblique, provided there was no false ptosis of the left upper lid. In such a case, with only a small esotropia one would expect an increase after surgery, because the abducting power of the right inferior oblique would be decreased. On the other hand, an exotropia, if present, would be decreased if the right inferior oblique were weakened. Likewise, if the left superior rectus were resected, the esotropia would increase; the reverse would be true in exotropia.

As stated in the paper, everything possible should be done before surgery to correct the imbalance; a patch on the good eye is helpful. Many cases can undoubtedly be helped by orthoptic training. It should also be stated that with the use of a rotoscope, in certain instances, a vertical deviation can be markedly increased.

Dr. Stevenson was in agreement with practically all the points brought out, al-

though he felt that through a tenotomy of the inferior oblique at its insertion, one obtained more correction there than elsewhere, in addition to its being more easy to do. One should be extremely careful in operating on internal squints that are partly corrected by plus lenses, particularly if the lenses improve vision. It is very easy to convert such a squint into an external squint.

He agreed definitely with Dr. Gailey's methods of anesthesia, but did not consider shaving the eyebrow unnecessary; he also agreed that age should not be considered in correction of squint if one is sure that surgery is necessary. Plain catgut, he felt, was quite satisfactory for buried sutures.

Dr. Stevenson does not incise Tenon's capsule widely above and below the muscles, feeling too wide an incision might cause release of tension, although there must be sufficient exposure for complete observation. He emphasized the importance of dissecting the conjunctiva over the caruncle, following recession operations; if this is not done the caruncle is apt to disappear, leaving a starey eye. To remove every part of the muscle stump from the sclera may leave a depression, with sometimes discoloration.

With reference to the O'Connor cinch operation, he felt it was a clumsy looking operation and had not performed it, although all surgeons who use it are pleased with it. There has been opposition to the transplantation of a part of the superior and inferior rectus to the external rectus in abducens paralysis, but it has been satisfactory in his hands. One should be extremely careful with a hook in strabismus fixus. It is understandable that one could pull out a piece of the sclera in an effort to pull forward a muscle that under no circumstances will so pull. His results with the retraction syndrome were just as disappointing as those of Dr. Gailey.

From what has been said, one inexperienced in squint surgery might feel that convalescence in these cases is uncomplicated but a frightening experience may occur as the slides shown illustrate.

Dr. Paul V. Carelli agreed that definite diagnosis must be made before surgery is attempted. This can be done only after repeated examinations and with the screen cover test in all the cardinal fields. The amount of resection or recession to be done is learned only through experience. The late Dr. White would not commit himself by saying that so many millimeters of recession or resection would correct a certain number of diopters, merely replying to the question by saying "Do enough." Results vary with the individual surgeon; one may get a certain correction by a 3-mm. recession of the medials, while another may obtain a different correction by the same means.

In the squinting amblyopic eye, the good eye is totally occluded for about three weeks prior to surgery, and macular stimulation of the amblyopic eye is instituted. Thus it is possible to improve fixation, vision, and bring out the total deviation so that an accurate diagnosis may be made prior to surgery.

Dr. Gailey's statement that he attempts to undercorrect partly accommodative squints is probably in reference to those cases in which glasses are to be worn. In cases in which an attempt is made to remove the glasses, is an overcorrection sought?

In recession operations, he agreed that the overshooting inferior oblique must be recessed if the patient prefers the paretic eye or alternates freely. In the past six years, in a series of 250 squints, Dr. Carelli had found overacting inferior obliques in 112 patients; in 29 operated cases, recessions have been done ranging from 5 to 10 or 12 mm. with satisfactory results. He was glad to hear that Dr. Gailey has abandoned the tucking and advancement. He felt that in lateral rectus surgery more can be obtained with a bold resection than with a small resection and advancement. In recession of the medial rectus, Dr. Gailey's method of

placing sutures at upper and lower borders, 1.5 mm. from the tendon attachment to the globe instead of using the Prince forceps, is excellent. More accurate results are obtained.

In the technique of inferior oblique recession surgery, Dr. Carelli was in accord with Dr. Gailey except in one step. Recently, for fear that the scleral bite might not be placed in the proper line for proper action of the inferior oblique, he had switched to the following: After proper isolation of the muscle, a small hemostat or Kelly forceps is placed on the tendon at its insertion; sutures are then inserted at the desired point. Thus, while the muscle is still attached to the globe, it is possible to place the scleral sutures properly. The tendon is then severed from the globe and the sutures placed through the muscle. Also, Dr. Carelli agreed as to tenotomy of the inferior oblique at its insertion, because when this muscle retracts one cannot tell where it will reattach and how it will function thereafter.

Surgery in the retraction syndrome must be carefully guarded, because resection of the fibrotic exterior rectus may cause exophthalmus. Surgery in such cases should be directed toward increasing the binocular field.

Very little improvement has been reported in the procedure of joining the outer third of the superior and inferior rectus to the external rectus in paretic cases. It should be considered poor surgery if it limits depression and elevation, especially when the abduction resulting is questionable in most cases.

Dr. Gailey (closing) said that he was pleased to hear that Dr. Stevenson and Dr. Carelli agreed with him on so many points in surgical management of squints. Dr. Stevenson's report of the unfortunate complication which he so beautifuly illustrated should make us realize that postoperative complications arise even in the most skilled surgical hands. The O'Connor cinch operation might be stressed particularly in the phorias and mild tropias uncomplicated by vertical anomalies; it is not difficult, but does require practice.

What Dr. Carelli said regarding learning by experience in the amount of resection or recession in a given case is certainly true. One is bound to under- or overcorrect early in one's practice, but it is through these errors that proper judgment is acquired. Careful records of the types of muscles encountered, together with postoperative studies of the amount of correction accomplished, will be valuable.

Dr. Carelli apparently misunderstood the remarks concerning surgery employed for lateral rectus paralysis. The inner halves of the superior and inferior recti rather than the lateral halves have been used, and the results have been good.

Partially accommodative squints are always undercorrected if the hypertropia is greater than two diopters, because of the possibility that when this correction must be worn by the patient, the orthoptic state is convered into a divergence.

Dacryocystitis of Infancy

Dr. J. V. Cassady (South Bend, Indiana) presented a paper on this subject which is published in full on page 773 of this Journal.

Discussion. Dr. Roy O. Riser felt that Dr. Cassady had done the society a favor tonight in provoking the question of earlier probings in congenital dacryostenosis. His results are perfect, and the lack of complications in so large a series is evidence of his skill. In performing the procedure without general anesthesia he has avoided the pulmonary complications that cause many to hesitate to do probing. Since other branches of medicine and surgery have accelerated many procedures, we also should have an open mind. The main reasons for delay have been that the patient is inarticulate; symptoms are not too alarming; and most parents

shrink from subjecting an infant to the surgical procedure.

He wished to correct the statistics quoted from his paper. Seventy-seven percent of the eyes in his own series that were treated conservatively cleared without probing. If Dr. Cassady's series of babies had been watched until six months of age, using Dr. Riser's percentages, more than 60 of the 100 cases should have cleared without probing at all. However, Dr. Cassady's procedure had prevented 3 or 4 months of blockage and stagnation of tears. One must judge for himself as to the more desirable situation, early and safe cure by probing, or a two thirds possibility of no probing by waiting. The statistical results from probing at the age of six months are equal to those done at an earlier age. His preference was for the term "dacryostenosis" for, as brought out in his thesis, a true dacryocystitis in a child is another and far more stubborn problem.

Dr. R. C. Gamble also felt indebted to Dr. Cassady for this report, to no part of which one could take exception. He has explained clearly the embryology and pathology, his series is large, his technique is very clever, and is his own. The results are perfect.

In choosing between immediate probing and massage, antiseptics and later probing if necessary, one is right either way. The situation should be explained to the parents for their decision; usually the conservative procedure is chosen. This is not meant to imply that immediate probing is radical; it is safe, simple, and effective.

A few facts should be considered in deciding the situation. The most important is that congenital obstruction of the lower end of the nasolacrimal duct very rarely, if ever, causes an acute phlegmon of the sac or the intractable infection seen in later life. These are different conditions and have a different origin. A second, less important point, is that while spontaneous recovery takes place in the majority of cases of congenital dacryostenosis, there is often moderate tearing for a few years after the pus discharge has disappeared, and there is less tearing after probing than after spontaneous recovery. A third point is that probably no ophthalmologist really knows the true percentage of spontaneous recovery; it is probably much higher than we think. Most pediatricians understand this condition quite well, and refer only the most stubborn cases to the ophthalmologist and in this they are right.

He asked Dr. Cassady whether this series of 100 cases was consecutive, or if all cases which had bony obstruction of the duct, phlegmon of the sac, fistulas, or other evidence of acquired obstruction, were eliminated. These, in his experience do not respond well to probing.

Dr. Elias Selinger agreed that early probing is indicated in most cases seen by the oculist, since these patients have already been under so-called conservative treatment by the pediatrician or general practitioner.

It is advisable to stress a few points of the technique of conservative treatment and of probing of the tear sac. The term "massage" of the tear sac is a misnomer. What one actually attempts is to employ hydrostatic pressure, that is, use the accumulated fluid in the sac and exert pressure through it in such a way that it will be forced toward the lower orifice of the tear sac and cause a rupture of the occluding membrane. For that reason, pressure should not be exerted in the upward and nasalward direction. Instead, the mother or nurse should be instructed to exert pressure nasalward and downward, beginning just below the medial canthus, as if she were trying to force the contents of the tear sac into the nose.

The need for repeated probing indicates faulty technique in most instances. Once is usually all that is necessary to establish patency. In small infants it is preferable to probe through the upper canaliculus, as in that way strictures of the more important lower canaliculus are avoided. Also, the tear sac is more easily entered if the probe has been passed through the upper canaliculus.

Introduction of the probe is greatly simplified if the upper lid is held in an inverted position. The probe must be carried along the canaliculus nasalward and slightly posteriorward, to pass behind the caruncle. When the nasal wall of the sac has been reached, the tip of the probe must maintain contact with it while the probe is being rotated into a vertical position. Withdrawal of the probe predisposes to faulty direction. Dr. Selinger has employed a No. 0 (No. ½) Bowman probe in seven premature infants with purulent tear-sac infection; the smallest of these weighed only 2 pounds 10 ounces. In this case there was a phlegmonous inflammation around the sac that failed to respond to systemic penicillin and sulfonamide therapy. Purulent secretion broke through the skin on three different occasions under this form of therapy. One probing resulted in permanent cure. In one infant the probe was passed through a fistulous tract into the tear sac and down through the nasolacrimal duct.

Dr. J. V. Cassady (closing) said, in reply to Dr. Gamble's question, that these were consecutive cases. Some of them had acute dacryocystitis with external drainage of the phlegmon and more than 50 percent had had mucopurulent secretion. No complications occurred from probing the ducts through these infected sacs.

He apologized if he had misquoted Dr. Riser. It was the total number of patients, in some of whom both sacs were infected, which gave the apparent discrepancy.

Sac massage such as described by Dr. Selinger would be of advantage were sac distension and infection to persist after the duct has been probed open and is patent, and he thanked him for his description of the procedure.

Richard C. Gamble,
Secretary.

Historical Miniature

Neither Hippocrates nor Galen used "nystagmus" to designate rapid oscillation of the eyeball. Indeed the word did not suggest rapid motion to a Greek, but on the contrary the dropping off to sleep. They called the phenomenon "hippus," little horse. The introuction of the error in the modern use of the word nystagmus to designate restless pupils may be ascribed to Mauchart who used it in a dissertation in 1742.

Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 664 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE AMERICAN OPHTHALMOLOGICAL SOCIETY MEETING

The 84th annual meeting of the American Ophthalmological Society, presided over by Dr. Henry C. Haden, was held at Hot Springs, Virginia, May 17 to 19, 1948. In attendance were 121 members and 21 guests. Twenty-three papers on various ophthalmic subjects were presented and the program was well balanced in content.

Because of the usual high quality of its program, it is always difficult to single out, at any meeting of this society, papers that are particularly outstanding.

Lyle discussed "Cataract and Tetany Produced by Parathyroid Deficiency during Pregnancy, Lactation, and Menstruation," a combination of the work reported before the last meeting.

Reese described "Herniation of the Anterior Hyaloid Membrane Following Uncomplicated Intracapsular Cataract Extraction," and pointed out that the treatment of this condition consists in the use of strong miotics (D.F.P.) alternating, if indicated, with dilatation of the pupil with neosyn-

ephrin and recumbent position of the patient.

W. P. McGuire's paper on "The Effect of Dicumarol on the Visual Fields in Glaucoma" provoked much thought and discussion. The extraordinary improvement in the fields of vision of controlled glaucomatous subjects under dicumarol treatment reported by McGuire was most startling. If supported by experience, this is indeed a noteworthy contribution to ophthalmology.

Castroviejo summarized his vast experience in transplantation of the cornea in keratoconus, and showed many beautiful colored slides of his cases. He indicated the necessity of including the entire conical area of the cornea in excision. Thus, a large graft is frequently necessary and in his capable hands the results were excellent.

Haessler and Heise's subject "Therapy for Some Ocular Inflammations Based on Immunologic Principles," was illustrated by a clever, instructive, and amusing animated motion picture. It will be useful in teaching.

Cordes presented a case of primary malignant melanoma of the optic disc and emphasized the great rarity of this finding. It occurred in a 52-year-old Negress. Calhoun in discussing Cordes's paper brought out the fact that ocular melanoma in the pure Negro has not been observed, and ventured the guess that Cordes's patient may have been of mixed blood. This was verified by Cordes.

Harrington described his studies on "The Mechanics of Intracapsular Cataract Extraction" and demonstrated the role of the vitreous as an important factor in the dislocation of the lens. Col. Henry Smith's pioneer work in this field was thus reemphasized.

Rychener reported a case of retinoblastoma occurring in a woman, aged 33 years, the fifth such case on record. Thygeson reported his recent studies on the epidemiology of epidemic keratoconjunctivitis. He and the discussors of his paper disclosed that a large number of ophthalmologists had suffered this infection during the recent widespread epidemic.

Heath's paper on "Ocular Lymphomas" summarized and classified in a lucid manner, our knowledge of this condition.

H. Gifford pointed out that retrobulbar injection of novocaine alone is efficient in reducing temporarily the intraocular pressure, and suggested among other things that this procedure would be useful in determining the base pressure in glaucomatous individuals. Scheie's studies showed that the mydriasis produced by retrobulbar injection of novocaine could only be overcome by pilocarpine until the effect of the injection had worn off.

Since many of these papers, as well as others not mentioned, will appear in forthcoming issues of the JOURNAL, it is unnecessary to go into further details. They are mentioned here only as samples of the ophthalmologic feast spread out before the members and guests of the society. As usual the discussions of the papers were often the most valuable part of the program itself.

The reception given to the new members was made particularly gracious by honoring Dr. Walter B. Lancaster who had just celebrated his 85th birthday. He was, therefore, one year old when the society was organized. This vigorous leader of American ophthalmology enchanted his audience during the scientific meeting with a discussion of some secondary subjective effects produced by prisms, delivered in his customary logical and meticulous style.

The Howe Medal was awarded to Dr. William Zentmayer of Philadelphia for his many years of faithful and distinguished service to ophthalmology. The choice of the recipient was a happy and popular one. The influence of Dr. Zentmayer as teacher, friend, counsellor, and physician has been and is of great strength.

Although the weather was unkind, it did not prevent to any appreciable extent popular indulgence in the outdoor diversions of

tennis, riding, and golf. To those less venturesome, the verandas and lobbies invited groups to sit and enjoy shop talk, a favorite and important sport of the occasion.

Bernard Samuels of New York was elected president; Parker Heath of Boston, vice-president, and Maynard C. Wheeler of New York succeeded Walter Atkinson as secretary. The latter was appointed member of the council in recognition of his many years of efficient service as secretary to the society. It was voted to hold the next annual meeting in Hot Springs, Virginia, June 2 to 4, 1949. Derrick Vail.

CORRESPONDENCE

New drainage operation for glaucoma

Editor,
American Journal of Ophthalmology:

The operation of iridencleisis is discussed in a paper by Dr. Oscar Lavine and Dr. Karl Langenstrass, "A New Drainage Operation for the Relief of Glaucoma" (American Journal of Ophthalmology, 31: 78-80 [Jan.] 1948), in a way which is much at variance with the experiences of many other ophthalmologists.

The authors write:

"The scleral incision tends to close immediately and tightly due to the inherent elasticity of the scleral tissue. The incision heals quickly and firmly because large areas of mesodermal surfaces are in intimate contact. The included iris tends to undergo pressure atrophy as the result of sharp compression by the scleral lips. This event renders the operation practically valueless."

With reference to this quotation, I would like to point out that the object of Holth's iridencleisis subconjunctivalis is to create an epithelium-clad drainage canal from the anterior chamber to the subconjunctival space. Holth succeeded in proving that this objective had been attained; witness his microscopic examinations of eyes which had been enucleated directly after the death of patients who had successfully undergone iridencleisis up to six years earlier. His observations were presented as early as 1913 at the Ophthalmological Congress in Heidelberg XXXIX. His later investigations were published in December, 1930, in the *Archives of Ophthalmology* and elsewhere. Here Holth showed that pigmented epithelium lined the walls of a fistula through the sclera to the subconjunctival space. He emphasized, as an important factor in the operation, that as little subconjunctival scar tissue as possible is provoked so that drainage of the aqueous humor is facilitated. For the same reason no conjunctival flap is made, but only a subconjunctival "tunnel" at the same time that the scleral incision is made. Further, as much as possible of the fistula-forming iris tissue should be retained. On this account iri*dec*tomy is not undertaken, only a meridional irido*to*my with both iris flaps lying in the scleral wound.

Very many ophthalmologists must surely disagree with the authors' comments on the value of iridencleisis and the other fistula-forming glaucoma operations. With reference to iridencleisis, I would like to refer to my own work: "The Results of Iridencleisis," published in Acta ophthalmologica, 25:3, 1947. Permit me to quote the summary of this article:

"The results of iridencleisis subconjunctivalis cum iridotomia meridionali for glaucoma simplex in 455 eyes at least one year after this operation are presented. Vision was the same or better in 83.4 percent, the field of vision in 96.8 percent. Tension was normal without myotics in 79.8 percent, and in a further 12.5 percent it was normal under pilocarpine with which normal tension could not be maintained before the operation. Thus, as far as tension was concerned, good results were achieved altogether in 92.3 percent.

"A classification of the material in various stages according to the degree of development of the disease shows that the chances of maintaining the functions of the eye un-

changed are best when the operation is carried out in an early stage of the disease.

"An observation period of one year after iridencleisis is presumed to be long enough to give a correct picture of the state of tension."

(Signed) J. C. Holst,
Oslo, Norway.

RELIEF OF EPISCLERITIS

Editor,
American Journal of Ophthalmology:

I am able to confirm the statement of Dr. Edwin M. Shepherd who obtained immediate relief of symptoms in episcleritis with instillation of histamine diphosphate (1:1,000) described in the American Journal of Ophthalmology, 30:907-909 (July) 1947.

Personally, I advise the use of ionization, which prevents side reactions. The principal indication is represented by rheumatic, focal episcleritis. My technique is: A histamine solution (1:10,000) is applied using 1 ma. for 1 minute, anode, positive pole. The advantage of this procedure consists in applying the drug on the focus of infection alone; it may also be repeated. Chemosis is eliminated by preliminary anesthesia.

This was studied by P. Payot (Ophthalmologica, 112:1 (July) 1946). My method was described in 1935 (Szemészet) and in my monograph on physical therapy published in 1941. (Both of these papers are published in Hungarian.)

(Signed) Stephen de Grósz,
Budapest, Hungary.

BOOK REVIEWS

LA CONCEPTION DES COUCHES-LENTILLES CORNÉENNES, ALTERNANTES MÉCANIQUEMENT ET OPTIQUEMENT. By M. Carapancea. Standard Graphica-Marvan, Bucarest.

The corneal stroma, which occupies nine-tenths of the cornea, is of even thickness as is also the endothelium, but the other corneal components are lentiform structures. The concave meniscus of the epithelium is balanced by the convex meniscus of Bowman's membrane, while Descemet's membrane is again a concave meniscus. This architecture has the physiologic function of providing resistance both to the atmospheric pressure from without and to the intraocular pressure from within. Optically however the cornea acts as a unit, the refractive surfaces being simply its anterior and posterior surfaces.

James E. Lebensohn.

THE PHYSIOPATHOLOGY OF THE EYE IN THE AVIATOR. By A. Mercier and J. Duguet. A report presented before the meeting of the Société d'Ophthalmologie de Paris, November, 1947, pp. 1-230.

This monograph on the ocular physiopathology of the aviator is a report of the authors' thorough investigation and a review of the present status of knowledge on this subject. It is not a discussion of the physical requirements of pilots nor of the ophthalmic tests routinely used by flight surgeons but is limited to a description of the effect of flying on the organs of vision and visual functions.

The first chapter is devoted to the influence of altitude on the visual organs and describes the effect of anoxemia and atmospheric depression on the retina, choroid, pupils, visual acuity, fields, stereoscopic vision, and adaptation. It also includes a discussion on the application of oxygen and on airtight cabins in airplanes.

The second chapter deals with the influence of increasing speed on the visual organs, the brutal effect of centrifugal and rectilinear forces on the human body, and the dangers of sudden changes in the direction of flight. All these facts should limit the acceleration of the airplanes below a certain standard, at least for the time being.

The actions of physical factors are the

topics of the third chapter. The intensity of the sunlight in high altitudes, the relation of the direction of the light waves to the direction of the flight, the effect of the reflected lights and their phototraumatic and photochemical action on the retina are discussed in detail. The dangers of extreme cold are described with special emphasis on corneal changes. The deformations of the soft part of the face and of the lids through the action of the wind are demonstrated in a series of pictures. The effect of vibration on the sympathetic nervous system and visual efficiency are discussed and the hazards, which originate when all those unfavorable factors act in summation, are outlined.

The fourth chapter covers the problem of vision and orientation in the air, visual illusions in flying and flight without visibility. It explains the meaning of aerial orientation and aerial equilibration and discusses the possible impairment in the function of the labyrinth and the resulting abnormal reactions and impressions. It refers to and explains the artificial horizon as a help which provides the pilot with the knowledge of the horizontal plane and the changes in direction.

The origin, clinical appearance, and treatment of injuries and burns are the subjects of chapter 5. In the next two chapters are discussed the psychoneuroses in pilots and the intoxications which might be caused in the air by such toxic agents as gas, carbon oxide, and nitrogen tetraethyl.

The protective measures are described in the eighth chapter. The effect of ultraviolet rays on the eye, the mechanical value of protective glasses, and the importance of Noviol glasses are discussed at length.

Visual problems in connection with the construction of airplanes are reported in the ninth chapter. Among many details the placement of the cockpit to allow the largest possible field, transparent surfaces and good illumination are especially important. There are 45 illustrations and a valuable bibliography of 357 references.

Alice R. Deutsch.

CAUSES OF BLINDNESS AMONG RECIPIENTS OF AID TO THE BLIND. By Ralph G. Hurlin, Sadie Saffian, and Carl E. Rice, M.D. Washington, D.C., Federal Security Agency, Social Security Administration, Bureau of Public Assistance, 1947.

The Federal Security Agency, Washington, D.C., has issued a report which presents information on more than 20,000 recipients reported on a voluntary basis by 20 state agencies. This is the first information that has been collected on the eye conditions of recipients of aid to the blind and the underlying causes of their blindness.

The volume of information included in the report is larger than that of any previous study of causes of blindness in this country in which the cause data have been taken from medical records.

The publication will have considerable interest for those concerned with the statistics of causes of blindness.

F. H. Haessler.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea; sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

7

CONJUNCTIVA, CORNEA, SCLERA

Palm, Erik. **A case of crystal deposits in the cornea.** Acta ophth. 25:165-174, 1947.

A woman 46 years of age had chronic arthritis followed by ocular discomfort, lacrimation and photophobia, which increased in intensity with the joint involvement. The objective examination revealed small, irregularly shaped, opaque, uniformly scattered spots over the corneal surface, with a clear area 1 mm. in width adjacent to the limbus. On retro-illumination each spot was found to consist of a small cubic crystalline structure, situated immediately beneath the corneal epithelium, and raising it slightly. The crystals are probably identical with the globulin crystallizing from the blood plasma. The crystallization from the blood appeared to be initiated by a change in pH following the loss of carbon dioxide from the blood. The author suggests that the loss of carbon dioxide from the superficial corneal layers may have caused a shifting of the pH toward the alkaline side, which resulted in the precipitation of these crystals. Brief reference is made to the literature on corneal opacities caused by various precipitates. The author found two cases similar to his. Meesman's patient had small amorphous desposits formed by Bence-Jones protein scattered through the entire depth of the cornea and Blobner's patient had lustrous crystals in the cornea and conjunctiva, the exact nature of which was not identified. (2 illustrations.)

Ray K. Daily.

Panzardi, D., and Pasca, G. **Bacteriologic and clinical investigations concerning the action of streptomycin on conjunctivitis due to gonococci, Koch-Weeks bacilli, diplobacilli, and on epidemic keratoconjunctivitis.** Boll. d'ocul. 26:581-589, Sept. 1947.

Four patients with gonorrheal conjunctivitis, 15 with Koch-Weeks conjunctivitis, 29 with Morax-Axenfeld conjunctivitis, and three with epidemic keratoconjunctivitis were given four to six instillations of a streptomycin solution containing 10,000 US units per cc. for one to five days. In all cases of conjunctivitis, a complete cure was achieved within one to three days; no effect was seen in the cases of epidemic keratoconjunctivitis. In the conjunctival diseases, however, the

drug proved definitely superior to all the known ocular antiseptic solutions.

K. W. Ascher.

Ry Andersen, S. **Malignant melanoma of the conjunctiva with metastasis to the choroid.** Acta ophth. 25:311-319, 1947.

The left eye of a woman, 35 years of age, was enucleated with the diagnosis of limbal naevus in a state of malignant proliferation. Histologic examination showed a small flat tumor in the choroid, extending backward from the equator. The limbus growth had existed for five years and the choroidal nodule was considered metastatic. The author suggests that the nomenclature of melanocarcinoma or melanosarcoma be abandoned in favor of the term malignant melanoma, which is used in the Anglo-American literature.

Louis Daily, Jr.

Verrey F. **Acute keratoglobus.** Ophthalmologica 114:284-288, Oct.-Nov., 1947.

"If the term keratoglobus did not exist, it would have to be invented to describe the corneal malformation" which existed in both eyes of a girl, 21 years of age. Her corneas measured from 13 to 13.5 mm. at their base, were perfectly clear, about one-third as thick as normal, of conical shape in the periphery and strongly and astigmatically curved in the center. With spherocylindrical lenses the vision of the right eye was improved to 20/200, that of the left eye to 20/40. The condition was probably related to keratoconus, since in the left eye several acute phases of inbibition of aqueous (the equivalent of acute keratoconus) could be observed.

P. C. Kronfeld.

8

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Bardram, M. T. **A case of iridocyclitis leprosa.** Acta ophth. 25:265-269, 1947.

A man, 41 years of age, had lived for 15 years in the East. Eight years after the initial skin lesion on the left upper arm he developed a bilateral iridocyclitis with increased tension and lepromata on the left iris. After eight months of unsuccessful therapy his visual acuity was 3/26 in the right eye, and 2/60 in the left.

Louis Daily, Jr.

Björk, Ake. **Antistreptolysintitration in acute iritides.** Acta ophth. 25:127-138, 1947.

Björk applied the method of titer determination to study the relation between acute iritis and rheumatic disease. The material of his study consisted of 52 cases of acute iritis of undetermined etiology, in adults, of which 22 had had previous attacks. The tabulated data of their antistreptolysin titer show an increased titer in 10 percent, which corresponds to the findings reported in a normal population. He concludes that hemolytic streptococci do not have a significant part in the etiology of acute iritis, and doubts that there is a close relation between iritis and rheumatic disease. (1 table, references.)

Ray K. Daily.

Dubois-Poulsen, and Dubois-Verlière. **Cutaneous tuberculous allergy in iridocyclitis.** Ann. d'ocul. 181:65-81, Feb., 1948.

Following the technique of Canetti, the authors employ four intracutaneous injections in the arm at one sitting. These contain 1/10 cc. of tuberculin (obtained from the Pasteur Institute) which is diluted to 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}. The allergic reaction is considered strong, medium, weak, or absent depending on the minimal reaction beginning with the highest number. Thirty-five women and 20 men with iridocyclitis of different etiology were thus examined. Of the entire group, 71 percent showed a strongly positive reaction. In 15 patients with definitely non-tuberculous lesions the reaction was strongly positive in 45 percent and in

13 cases presumably tuberculous, the percentage was 85. In 10 cases of unknown origin, the reaction was strongly positive in 60 percent. In patients with uveal, dermal, ganglionic and osseous tuberculosis the reaction is usually strongly positive. Patients with pulmonary tuberculosis react less strongly, and the intensity of the reaction decreases with age. A strongly positive reaction alone is not sufficient to establish the tuberculous origin of a uveitis. Chas. A. Bahn.

Loewenstein, A., Foster, J., and Sledge, S. K. **A further case of iridoschisis.** Brit. J. Ophth. 32:129-134, March, 1948.

The ninth case of iridoschisis to be reported occurred in a 46-year-old man, who had received a severe blow which broke his nose. Aside from a "black eye" on the right side, there was no apparent eye injury. Ten weeks later he noted that the color of the right iris was changing from its normal hazel to a dark blue. The vision in each eye was correctible to 6/6. The affected iris presented large brown patches of atrophy. Many of the fibers of the anterior layer had separated at the pupillary end and were hanging suspended in the aqueous or were attached to the posterior corneal surface near the limbus. The lens, vitreous, and fundus were normal but the tension was 35 mm. Schiøtz. The diagnosis was iridoschisis with secondary glaucoma. A broad basal iridectomy led to uneventful recovery. The authors explained the phenomenon as a result of the blow whereby the aqueous was forced into the spongy iris tissue where proteolytic enzymes destroyed the stroma. The pigment thus liberated blocked the drainage channels and caused the secondary glaucoma. (4 figures.)

Morris Kaplan.

Sichel, A. W., and Louw, J. G. **A case of sympathetic ophthalmitis of unusual onset responding satisfactorily to treatment.** Brit. J. Ophth. 32:180-184, March, 1948.

A 54-year-old farmer with a severe laceration of the right eye refused to have the eye enucleated. It remained moderately painful and three months later was removed when the patient was annoyed by epiphora of the good eye. This irritability and tearing continued for almost a month. Then a mild papillitis and cloudiness of vitreous were noted and one week later typical signs of sympathetic ophthalmia appeared in the anterior segment. The patient was given large doses of penicillin and salicylates and two injections of neoarsphenamine. Large doses of sulphadiazine and sodium iodide and dionin were added. After two months improvement was satisfactory and the corrected vision was normal. The patient has remained well for several months.

GLAUCOMA AND OCULAR TENSION

Allen, T. D. **To prevent cycloplegic glaucoma.** Ophth. Ibero am. 9:217-220, 1948.

Precautions listed by the author include (1) awareness of the fact that cycloplegic glaucoma may follow the use of cycloplegia; (2) a careful precycloplegic examination; (3) careful records of corneal size and transparency, pericorneal vascular condition, depth of anterior chamber, and other details; (4) tonometry before and after the use of mydriatic or cycloplegic drugs; (5) postcycloplegic test as to possible need for miotics.

W. H. Crisp.

Diaz Domínguez, Diego. **A new technique for cyclodiathermy.** Arch. Soc. oftal. hispano-am. 8:117-129, Feb. 1948.

The literature on the techniques of cyclodiathermy is reviewed. The corneal complications following the Vogt tech-

nique led many investigators to modify the procedure. The author prefers Thiel's technique of subscleral diathermy-coagulation of the ciliary body, which diminishes the function of the ciliary processes, and provides for aqueous drainage through the suprachoroidal space. The technique is that of cyclodialysis, with the spatula as a diathermy electrode; the spatula is introduced between the sclera and ciliary body until its end appears in the anterior chamber, the current is then turned on, and the spatula moved up and down, coagulating one-third or one-fourth of the ciliary body. The current is disconnected, and the spatula removed. The limited number of cases in which this technique was used does not permit of definite conclusions. The results, however, are not inferior to those of the Vogt cyclodiathermy, at least in simple glaucoma in adults. The addition of diathermy-coagulation to cyclodialysis does not increase the risk of the operation, and the author believes that is it indicated wherever fistulating operations are not suitable.

Ray K. Daily.

Holst, J. C. **The results of subconjunctival iridencleisis with meridional iridotomy in the period 1928-1939.** Acta ophth. 25:271-278, 1947.

The author discusses 1019 patients with simple glaucoma, on whom 1318 operations had been performed. A period of one year of observation was possible in 455 eyes. Vision was the same or better in 83.4 percent of eyes, and the field of vision was improved in 96.8 percent. Tension was normal without miotics in 79.8 percent, and in a further 12.5 percent it was normal under pilocarpine, which had been ineffective before operation. The chances of maintaining the functions of the eye unchanged are best if the operation is performed early. (3 tables.)

Louis Daily, Jr.

Márquez, M. **Old and new ideas about ocular hypertension and glaucoma.** Ophth. Ibero am. 9:123-147 (in Spanish), 148-169 (in English), 1948.

The author speaks of these two conditions as more or less distinct entities although they frequently coincide: which one develops sometimes depends chiefly upon susceptibility of the optic nerve to what is ordinarily thought of as normal or relatively normal tension. (Bibliography.)

W. H. Crisp.

Moreu, Angel. **Gonioscopy in glaucoma.** Arch. Soc. oftal. hispano-am. 8:80-89, Jan., 1948.

Moreu enthusiastically advocate gonioscopy, which he has been doing since 1933. He began with the Troncoso gonioscope and the Koeppe contact lens, and now uses the Goldman contact lens with the slit lamp. For experimental purposes he uses dogs, which are easy to gonioscope. He points out that most of the investigations on gonioscopy were done in the Americas, the Europeans having manifested but little interest in the subject. Supporting his opinions by extensive gonioscopic investigations, he argues against the acceptance of the anatomic structure of the anterior chamber angle as a factor in the pathogenesis of glaucoma. The size of the angle varies, and is subject to changes in the same eye. He has seen acute glaucoma in eyes with wide open angles free of synechia, and chronic glaucoma with a narrow angle and peripheral synechia. Moreau regards the changes in the angle of the anterior chamber as a consequence of glaucoma and not its cause. The early glaucomatous change is an edematous ciliary band, with foci of fine exudate. Gonioscopy makes possible the study of the ocular physiology, and combined with intravenous or intramuscular fluorescin injections it reveals much of the physiology of the aqueous veins and Schlemm's canal. Gonios-

copy is valuable in the study of postoperative results, and the anatomic effects of surgical procedures. The site for cyclodialysis should be selected by gonioscopy. If the cyclodialysis spatula hits where there is a synechia no dialysis results; there is merely a perforation which closes on the following day. Ordinarily after a cyclodialysis a small hematoma fills the dialyzed area, and as the hematoma absorbs, a synechia, which was not there before the operation, is left in its place; the surgical result may nevertheless be good. Following fistulating operations gonioscopy sometimes reveals that there is no fistulization; but the ciliary edema in the ciliary body and processes is gone, and the intraocular tension is reduced. The favorable results are due to the effect of the operation on the uveal circulation. Moreu is a firm believer in the vascular basis of glaucoma. Ray K. Daily.

Moreu, Angel. **Reflections on some points relative to the pathogenesis of true glaucoma.** Arch. Soc. oftal. hispano-am. 8:64-79, Jan., 1948.

Moreu stresses the importance of differentiating between secondary hypertension, caused by obstruction in the angle of the anterior chamber, and true glaucoma caused by a disturbance in the ocular circulation on the basis of a neurovegetative dystonia. Reference is made to the recent investigations of Duke-Elder, Kinsey and Grant, and Barany on the production of aqueous humor, and the investigations on the function of Schlemm's canal are critically analyzed. The author's own experiments with the reaction of Schlemm's canal to puncture of the anterior chamber and the analysis of the aqueous humor withdrawn in the various types of glaucoma are described in detail. As a result of these investigations he sounds a warning on the use of vasodilators, recently advocated in glaucoma; they augment the volume of blood which enters the eye, and in case of inability of this blood to leave the eye through obstructed drainage pathways may precipitate an acute attack. In an eye with good drainage passages vasodilators may be used even in an acute stage. Vitamin P, which diminishes vascular permeability affects favorably the ocular tension and the composition of the aqueous. Ray K. Daily.

Owens, W. C. **Glaucoma following cataract extraction.** South. M. J. 41:357, April, 1948.

A series of 2,086 cases seen at the Wilmer Ophthalmological Institute from 1925 to 1943 was studied. The percentage of all glaucoma cases was 4.2. In the group with intracapsular extraction with round pupil it was 1.6. Most of the prevention of glaucoma is technical, at the time of operation, such as removing all or as much as possible of the lens to minimize postoperative iridocyclitis, the most common cause. Loss of vitreous is reduced by adequate anesthesia, a speculum which does not press on the eye, and detention when possible of a round pupil. Corneoscleral sutures were used to close the wound well and to prevent delayed reformation of the anterior chamber. If it had not reformed at the end of six days, air was injected. To prevent mechanical block by vitreous an adequate peripheral iridotomy or iridectomy should be done at the time of operation.

In treatment of glaucoma that was associated with an acute iridocyclitis, foreign protein and mydriatics were used. When lens material is retained, desensitization with lens protein may help. A trephine operation is advised if these measures fail. In cases without iridocyclitis, miotics were used, and the tension carefully recorded. If operation was necessary, the choice was cyclodialysis, in the upper quadrant if possible, with miotics for at least several weeks afterwards. This operation may be repeated.

If it failed, trephining was recommended.

In only 39.5 percent of cases of glaucoma following cataract extraction was the final vision 20/70 or better. (1 table, references.) Bennett W. Muir.

Posner, A., and Schlossman, A. **The role of inheritance in glaucoma.** Tr. Am. Acad. Ophth. pp. 145-158, Jan.-Feb., 1948. (See Section 19, Congenital deformities, heredity.)

Simonelli, Mario. **The use of prostigmine in the treatment of glaucoma.** Riv. di oftal. 2:119-124, March-April, 1947.

The author concludes that prostigmine used as a collyrium in three-percent solution induces a miosis and a drop in ocular tension sufficiently marked to make it especially indicated in the therapy of glaucoma. Prostigmine has an action which is more effective than that of pilocarpine and can be compared with eserine. However, it is of prompter action, longer duration, and, above all, does not show the usual secondary reactions characteristic of eserine even though it is used over a long period of time. Finally, prostigmine is completely stable.

The author used prostigmine in 18 cases of glaucoma (6 acute, 4 chronic inflammatory and 8 chronic simple), and in all cases the results were superior to those obtained with pilocarpine. In the patients with chronic inflammatory glaucoma, pilocarpine and prostigmine were used alternately and there was always a rise in tension after pilocarpine and a lowering after prostigmine.

Francis P. Guida.

Thomassen, Thore Lie. **The cause of the increase of tension in iridocyclitis glaucomatosa.** Acta ophth. 25:243-252, 1947.

Two series of experiments were performed in this investigation. Five eyes with iritis glaucomatosa were subjected to a weight compression of 25 gm. during two minutes and the ocular tension measured before the compression, and 5, 15, and 35 minutes after the removal of compression. The data show that the response of eyes with iridocyclitis with hypertension to compression is the same as it is in simple glaucoma. In the increasing phase of ocular tension there is a distinct relative hypertension and no fall in pressure; in the decreasing phase there is a marked fall in pressure, with no relative hypertension. The fall in pressure in response to compression is believed to be due to the pressing out of the aqueous through Schlemm's canal, which is hampered in the rising phase.

The material for the second series consisted of nine eyes with iridocyclitis glaucomatosa. Curves of the ocular pressure and of the pressure in the episcleral veins were made daily for 12 days. The technic used was identical with that applied to the study of simple glaucoma, except that the tension was taken every hour, instead of every half hour because of the increased sensitiveness of these eyes. The curves of the data thus obtained show that the relations between the ocular and venous tensions are the same in iridocyclitis with high tension and in simple glaucoma. The venous tension is high in proportion to the intraocular pressure in its rising phase, in the decreasing phase the venous tension is low. The changes in the venous tension precede those of the intraocular pressure. The conclusion of the studies is that the rise in intraocular pressure in iridocyclitis glaucomatosa as well as in simple glaucoma is due to functional changes in the vascular system of the eyes. (2 curves.)

Louis Daily, Jr.

Thomassen, Thore Lie. **The arterial tension in glaumatous eyes.** Acta ophth. 25:253-264, 1947.

A review of former investigations on the arterial ocular tension and its relation to the general blood pressure and the

ocular tension brings out the scarcity of established data. The author's experimental work consisted of measuring with a water manometer the diastolic and systolic arterial tensions in an anterior ciliary artery at the point where it enters the sclera. The pressure was taken at the first discernible pulsation, and at the moment when the artery became empty. The material consisted of 16 glaucomatous eyes, and the ocular tension and the tension in the episcleral vein were taken as well. Because of the great pressure to which the globe must be subjected in these measurements, the arterial tension was taken only a few times daily; it was, however, taken at hours of greatest variation in the ocular tension. The curves of the data show that the arterial tension remains constant despite marked oscillations in the ocular and venous tensions. The instillation of pylocarpine into one eye also failed to affect the arterial tension, while producing a distinct fall in the ocular and venous tensions. Applying these data to the explanation of the pathogenesis of glaucoma the author concludes that the primary change in disturbances of ocular tension takes place in the minute vessels of the eyes, in which resistance to the blood flow becomes reduced; this leads to a rapid rise in the pressure of the capillaries and veins. The increased capillary tension promotes an augmentation in the quantity of aqueous humor with the consequent rise in ocular tension. The rise in the venous tension takes place rapidly, while the increase of aqueous humor takes place more slowly; this conception is supported by the experimental data, which show that the rise in venous tension precedes the rise in ocular tension. CRYSTALLINE LENS

Arruga, H. **Comments on cataract extraction.** Arch. soc. oftal. hispano-am. 8: 5-22, Jan., 1948.

Because a small pupil facilitates the making of a peripheral iridectomy or iridotomy and holds back the vitreous after rupture of the hyaloid membrane, Arruga operates by preference with a pupil of 6 mm. He uses larocain which does not dilate the pupil, or adds 1 percent pylocarpine to instillations of cocain and adrenalin. In restless patients he uses 30 percent alcohol with the akinesis, which prolongs the relaxation of the lids, at the price of a somewhat painful injection, and lid edema. He makes a corneal section, and closes the wound with corneal sutures, using as many as five in restless patients. The corneal section prevents hemorrhage during and after the operation; healing however, is slower, and corneal suturing requires very fine and sharp needles. For this purpose he found the American atraumatic needles inadequate. He makes two peripheral iridotomies. The importance of a good capsule forceps for intracapsular extraction is emphasized and the Arruga forceps is described and illustrated in detail. The anterior chamber is filled with sterile water after loss of vitreous. (11 illustrations.)

Buffington, W. R., **Congenital ocular anomalies resulting from (a) premature birth (b) rubella infection of mother during pregnancy.** New Orleans M. and S. J. 100:466-474, April, 1948.

Three cases of bilateral retrolental fibroplasia in premature infants are reported and two cases of congenital cataract in infants whose mothers had German measles in the first two months of pregnancy. Irwin E. Gaynon.

Doherty, W. B. **A discussion of deformities of the shape of the lens. With a report of a case of posterior lenticonus.** Am. J. Ophth. 31:455-460, April, 1948. (2 figures, 35 references.)

Gill, E. G. **Cataract surgery: recent advances.** South. M. J. 41:191-197, March, 1948.

The author uses local anesthesia, van Lint akinesia, a keratome incision widened to 180 degrees with scissors, a combination of two corneoscleral sutures, and a 180-degree conjunctival flap closed by additional sutures. The lids are held open, and the eye down with silk sutures, and the lens is delivered by the Verhoeff method. The patient is generally allowed to get out of bed 24 hours after operation. With this technic the author has achieved a visual acuity of 20/25 or better in 90 percent of patients; he has reduced hemorrhage to 3 percent and vitreous loss to 2 percent. He emphasizes that this operation is not designed for speed but for safety and accuracy.

The author discusses one case of bilateral cataracta nigra in which he carried out a histochemical investigation. This revealed the presence of fatty substances which he considers a localized metamorphosis of lenticular protein, especially the amino acids.

Francis P. Guida.

Schulte, D. **Abscess-like collection of pus between the lamina of the posterior lens capsule.** Klin. Monatsbl. f. Augenh. 112:193-203, 1947.

An eye which had been enucleated because of an acute metastatic panophthalmitis had a collection of more or less encapsulated pus between the lamina of the posterior lens capsule. Such a finding is extremely rare. The author assumes that the leucocytes entered the lens capsule along the zonula and the limiting membrane of the vitreous through the Wieger ligament and the lamina of the zonula. The histologic findings confirm the anatomic concepts concerning the Wieger ligament, the anterior limiting membrane of the vitreous and the connection between vitreous, lamina of the zonula and lens. They also illustrate the lamellar structure of the lens capsule. (8 figures, references.)

Max Hirschfelder.

Velhagen, K., Jr. **Cataract operation in myopia.** Klin. Monatsbl. f. Augenh. 112: 225-232, 1947.

The author discusses the advantages and disadvantages of intracapsular and

extracapsular cataract extraction in patients with high myopia. The various complications such as loss of vitreous, retinal detachment, iris prolapse and late hemorrhage are statistically compared for the two methods of operation. The author's figures and extensive statistics from the literature are cited. The author prefers intracapsular extraction in high myopia, in spite of a slightly higher percentage of complications. He points out that these complications can be dealt with more easily than in the extracapsular extraction but the latter is often disappointing because of the particularly bad secondary cataract in myopic patients. The average end result with intracapsular extraction was 0.4 vision, whereas in extracapsular extraction it was only 0.28. The author's own figures for vitreous loss in high myopia were 6 percent for the intracapsular and 3 percent for the extracapsular method. (Bibliography.)

Max Hirschfelder.

Williamson-Noble, F. A. **A complication of intracapsular cataract extraction.** Brit. J. Ophth., 32:161-162, March, 1948.

This very brief article explains the author's technique for extracting a lens after the capsule has ruptured unexpectedly. Rather than use a loop, he inserts two cystitomes into the lens and pulls it out with some pressure assistance of a squint hook. He has used this procedure in three cases. Morris Kaplan.

11
RETINA AND VITREOUS

Arruga, H. **Some observations on the treatment of retinal detachment.** Arch. Soc. oftal. hispano-am. 7:1001-1008, Oct., 1947.

Advancement in the treatment of retinal detachment has raised the percentage of cures to 70 to 80 percent of the eyes that are operated upon. Eyes with retinal holes, which are operated on before detachment takes place always heal perfectly. In patients who had a retinal detachment in one eye the recognition of early visual disturbances in the other eye may lead to the diagnosis of the retinal hole before the retina becomes detached. In 23 such cases Arruga achieved perfect results, without a diminution in visual acuity, by coagulation with a weak current. Coagulation with a weak current of vacuolar degenerated retinal areas in the remaining eye of a patient who lost the other from retinal detachment is also productive of good results. Poor surgical results, in cases in which one expected success because the retina returned to its normal position after rest in bed, are attributed by Arruga to an increased sensitivity of the choroid, or to the presence of a chronic inflammatory process which is activated by the surgical procedure. There is no way of predicting this unfavorable reaction. Macular holes have a poor prognosis, and their surgery is technically difficult. They are produced not by a pull of the vitreous as is the case with retinal holes in other areas, but by the push of the choroidal exudate on the retina towards the interior of the eyeball. They are round holes, without flaps, and the retina does not flatten after rest in bed. Disinsertions at the ora serrata are never reattached; the surgical goal is here to reattach the retina to the underlying choroid, but not to its original insertion. The lateral portion of the retina must be sacrificed to save central vision. To achieve this it is useless to coagulate at the periphery; the retina should be coagulated so that the disinserted area is thoroughly isolated. Detachments with holes in the lower portion of the retina also have a poor prognosis, chiefly because they interfere but little with vision at first, and patients come to the ophthalmologist after the underlying choroid has degenerated and become incapable of pro-

ducing an exudate. In such cases also coagulation is effective only in isolating the detached retina, but not in reattaching it. Ray K. Daily.

Arruga, H. **Considerations on the treatment of detachment of the retina.** Proc. Roy. Soc. Med. 65:68-72, Jan., 1948.

The author presents substantially the same material as in the preceding abstract.
F. H. Haessler.

Belmonte González, José. **Experimental vitreous transplantation.** Arch. Soc. oftal. hispano-am. 7:1091-1096, Nov., 1947.

The technical methods of vitreous transplantation are the same as described by Cutler. Rabbit's vitreous was used in this work. Some was transplanted immediately and others 6 hours, 24 hours, 3 days, or 6 days after the enucleation of the eye. A biomicroscopic study was made in every case. It was found that better results were obtained when fresh vitreous or vitreous obtained only a few hours after the enucleation was used. The donor's eyes were preserved in isotonic saline solution. (Several colored pictures.)

Bockhoven, S., and Levatin, P. **Treatment of Lindau's disease.** Arch. Ophth. 38:461-467, Oct., 1947.

Lindau's disease is an angiomatosis of the central nervous system characterized by the occurrence of single or multiple hemiangioblastomas in the cerebellum, brain stem or spinal cord, associated with angiomatosis of the retina (von Hippel's disease). The authors report a case of Lindau's disease in a 27-year-old negro. Signs of spinal cord involvement developed. At operation an extensive sclerosing hemiangioma of the cord was found. An asymptomatic angioma was found in the upper temporal portion of the fundus, with marked dilatation of the vein and artery. This was treated by diathermy puncture which largely destroyed the growth but did not completely occlude the feeding blood vessels. The electrocoagulation was carried out without any loss of vision and is regarded as the method of choice in treating retinal angiomatosis. The tumor of the cord was treated by roentgen radiation but further cord involvement occurred.
John C. Long.

Calhoun, F. P. **Observations on the treatment of detachment of the retina.** South. M. J. 41:311-316, April, 1948.

A normal retina does not become detached. Careful examination with maximum dilatation, repeated especially after bed rest, is of utmost importance. Transillumination should always be done. The author prefers local anesthesia, with O'Brien or Van Lint akinesia, without subconjunctival injection. Muscles are retracted by a suture passed beneath them rather than with a muscle hook. He prefers to localize a hole ophthalmoscopically after a test application of nonperforating diathermy. Then the initial localization is surrounded by a double ring of partially penetrating applications with a 0.5-mm. electrode at intervals of three millimeters. Frequent ophthalmoscopic examination during operation is stressed. Holes for drainage should be a short distance from the retinal hole rather than right over it, and cutting current, if available, is used, with a 1.5-mm. Kronfeld or Pischel electrode. If air is injected it should be through the flat portion of the ciliary body away from the area of diathermy, for which a large pointed electrode 2 to 3 mm. long is used first, then a needle and syringe. The amount of air usually is 2 to 3 cc. More often air is put into the anterior chamber through a paracentesis wound, at the end of operation. One half to one cc. usually is enough. The causes of failure are sometimes quite obvious, such as large or multiple rents, or trac-

tion bands, but often there is no obvious reason. (2 figures, discussion, references.)

Bennett W. Muir.

Doggart, J. H. **The prognosis in macular lesions.** Tr. Ophth. Soc. U. Kingdom 65:347-353, 1945.

The ophthalmologic picture of primary degeneration may closely simulate that of changes due to previous inflammation or trauma. The progress of a lesion is difficult to determine without repeated examinations as deterioration may be arrested at any stage.

The first step towards prognosis is the attempted recognition of the similarity of the lesion to one in one of the groups identified by authoritative observers. Systematic exploration of the whole fundus and the comparison of the two eyes are helpful in diagnosis as well as prognosis.

The prognostic value of case records is enhanced by a series of drawings indicating the size and position of macular changes at successive examinations.

Beulah Cushman.

Friede, R. **The nature of inherited retinitis pigmentosa.** Klin. Monatsbl. f. Augenh. 112:214-221, 1947.

The factors which conceivably can play a part in the pathogenesis of retinitis pigmentosa are discussed. Such inherited factors may act locally or generally. The anatomic or pathologic structure of the choriocapillaris may be involved, as it influences the flow of blood and, therefore, the nutrition of the underlying retina. There is often only little choroidal sclerosis in retinitis pigmentosa. In the author's opinion, the lamina vitrea plays the primary and most important part in the development of retinitis pigmentosa. It is the vitrea which regulates the nutrition of the neuroepithelium by osmosis. Hyalinization of this structure leads to serious disturbance of the metabolism of the retina. It also prevents the passage of vitamin A and produces the accompanying hemeralopia. The possibility that retinitis pigmentosa is only a part of a generalized disturbance is discussed. Patients in whom the disease is associated with inherited deafness or with the Laurence-Moon-Biedl syndrome are cited. Leber's theory of an overstimulation of the retina by light and the theories of a primary liver disturbance are mentioned, but their correctness is held to be questionable.

Max Hirschfelder.

Gartner, S., and Priestley, B. S. **Transplantation of the vitreous.** Arch. Ophth. 38:487-493, Oct., 1947.

Transplantation of vitreous has been successfully performed in rabbit eyes. Vitreous from the other eye of the same rabbit or from the eyes of other rabbits was used, as well as vitreous from the human eye and from the kitten eye. A method of simultaneous injection and withdrawal of vitreous with a specially devised double syringe and needle arrangement was the only method found to give regularly successful results. It was found that unless the injection of new vitreous was carried out simultaneously with the withdrawal of vitreous extensive hemorrhages and deteriorative changes followed.

Further studies are needed before the method is applicable to the human eye.

John C. Long.

Gordon, D. M. **The experimental treatment of retinitis pigmentosa.** Tr. Am. Acad. Ophth. pp. 191-195, Jan.-Feb., 1948.

The records of 128 patients who received a reasonable amount of treatment by Filatov's tissue therapy are critically reviewed. This therapy consists of injections of cod liver oil and the implantation subconjunctivally or subcutaneously of placenta and other substances ranging from aloes to ovaries. These patients, 16 to 73 years of age, had visions that ranged from the ability to barely count fingers

to 20/20. In 26 percent there was slight improvement in vision in at least one eye; of these 11 showed slight improvement in visual fields, 4 in light adaptation and 2 were doubtful. The visual improvement was so slight, however, that one wonders whether or not the greater urge to see was not the most important factor. No change in the fundus was observed. Temporary improvement is also obtained by large doses of nicotinic acid and vasodilators and there the duration of such improvement as well as the secondary reaction is questionable. This treatment is not advised until its advantages and disadvantages have been much more thoroughly investigated. Chas. A. Bahn.

Hayden, R. **Retinitis pigmentosa with unilateral involvement of fundus.** Proc. Ophth. Soc. Vienna p. 16, May 18, 1942.

A woman, 39 years of age, noted progressive deterioration of vision and increasing night blindness for the last five years. The corrected vision in the right eye was normal, but dark adaptation curves showed diminishing of threshold values. The left eye showed typical advanced pigment degeneration of the retina, minimal visual acuity, concentric contraction of the visual field to 10 degrees and a high degree of hemeralopia. Since both eyes had hemeralopia the retinitis pigmentosa cannot be called unilateral though the fundus of the right eye appeared objectively normal. F. Nelson.

Kaplan, M., Morax, P. V., and Bernard, J. **The Tay-Sachs type of amaurotic family idiocy: a case report.** Ann. d'ocul. 181:32-35, Jan., 1948.

The patient was a practically blind, one and one-half year old boy of Oriental-Jewish extraction, whose father and mother were cousins. The direct and indirect pupillary reactions were diminished, but equal, and most of the other ocular reflexes were absent. The macular region was observed as a yellowish disc with a bright, red central depression; otherwise, the fundus was objectively normal. Chas. A. Bahn.

Kurz, O. **Differential diagnosis of lesions of the macula.** Ophthalmologica 114: 262-273, Oct.-Nov., 1947.

Three cases of lesion in the macula are reported in detail: one of central serous chorio-retinitis (corresponding to the central angiospastic retinopathy of Gifford and Marquardt), one of hypertensive retinopathy and one of a congenital familial anomaly of the macula. The importance of the distinction between cystoid macular edema and localized subretinal exudates is stressed. Examination of the macula by means of the slitlamp, the binocular corneal microscope and the fundus contact lens gives clues unobtainable by binocular ophthalmoscopy in mixed or redfree light.

Peter C. Kronfeld.

Lindner, K. **Bullous retinal detachment cured by waiting and operation.** Proc. Ophth. Soc. Vienna p. 23, June 29, 1942.

An almost total bullous retinal detachment of two or three weeks duration was found in the right eye of a 52-year-old woman. Only in the lower nasal quadrant was the detachment flat. A tear was found. Since the author felt that the prognosis was hopeless he waited four months before he decided to operate on the eye. The retina returned to its normal site and remained in place since, but the vision regained was only 3/24 as a result of the long delay. F. Nelson.

Matteucci, P. **Papilloretinitis of arterial hypertension and papilledema.** Riv. di oftal. 2:105-111, March-April, 1947.

One case of "cerebro-retinal" edema is reported. On the basis of this observation and of studies of retinal venous and arterial pressure studies on patients with

various types of arterial and intracranial hypertension, the author discusses the pathogenesis of hypertensive retinopathies. He also emphasizes the diagnostic value of the retinal venous pressure which seems to bear a close relationship to the intracranial pressure.

Francis P. Guida.

Michaelson, I. C. **Intra-mural new vessels in an occluded retinal vein.** Brit. J. Ophth. 32:164-166, March, 1948.

A 60-year-old woman developed an obstruction of a branch of a superior temporal vein near the optic disc. Five months later examination revealed numerous newly-formed collateral vessels between the affected and unaffected branches of the vein. Within the opacified walls of the obstructed vessel, two well formed veins were found extending into the distal column of blood. One of these vessels could be seen leaving the affected vessel and draining into an unobstructed vein.

Morris Kaplan.

Missiroli, Giuseppe. **Bilateral symmetrical paramacular tapetoretinal degeneration.** Boll. d'ocul. 26:655-660, Oct., 1947.

The only complaint of the patient, a 24-year-old female medical student, was that she became tired after reading. The parents were not related; there was no eye disease in the family and in two siblings. With correction of a medium degree of hypermetropic astigmatism, the patient has a visual acuity of 10/10. There was an absolute paracentral scrotoma for colors and a relative one for white in both visual fields which were peripherally normal. Color sense and adaptation were normal. In both retinas temporally from the macula lutea, there was an oval area of yellow-brown color, measuring 2 by 1½ papillary diameters, pigmented and sharply outlined; in the right retina this area was crossed by a retinal artery. For four years the lesions and the functional findings did not change; in the fifth year of observation, a slight but definite enlargement of both retinal lesions, to 3 by 2 papillary diameters, was found. The disease is one of the group of familial macular degenerations. The author suggests that the cases with paramacular localization may occur more often but are not described frequently because visual disturbances are missing; the present case would not have been detected were it not for the asthenopic symptoms caused by the astigmatism. (1 colored fundus picture, 6 references.)

K. W. Ascher.

Morgan, O. G. **A case of crush injury to the chest associated with ocular complications.** Tr. Ophth. Soc. U. Kingdom 65:366-368, 1945.

A small boy who was run over by a cart sustained minimal injuries to the chest. The following day he developed a typical picture of angiopathia retinae traumatica. He had a subconjunctival hemorrhage on the inner side of each cornea and three days later vision was reduced in the left eye to 6/12. The left fundus showed numerous whitish patches, some small hemorrhages along the main vessels and edema of the macula. The right eye showed a few whitish patches but no hemorrhages. The condition gradually cleared in three weeks and visual acuity was 6/6.

This must be an unusual complication of a minor chest injury. (1 colored plate.)

Beulah Cushman.

Rosen, Emanuel. **Solar retinitis.** Brit. J. Ophth., 32:23-35, Jan., 1948.

In the 23 cases described, exposure occurred for a few minutes to an hour and was not confined to direct gazing into the sun. Several cases of severe sun blindness were caused by watching the sun's reflection, as in a lake or in a bucket of water. In every case there were one or two easily

visible macular holes and heavy damage to vision. The destruction of the retinal tissue was irremediable. The ophthalmoscopic picture is quite characteristic; in the macula a deep crater, deep crimson in color, one-eighth disc diameter in width, the edges of which are sharply cut and irregular in shape, is surrounded by a soft cloud of pigment. (14 Figures.)

Morris Kaplan

Rosengren, B. **The operative treatment of retinal detachment.** Acta ophth. 25:111-126, 1947.

Among the factors accounting for the failure of operations for retinal detachment Rosengren considers errors in localization and faulty cauterization as insignificant, and believes that the majority of failures are due to the lack of contact between the retina and choroid. If the subretinal fluid is not withdrawn, healing is impossible. To maintain contact between the retina and choroid Rosengren injects air into the vitreous, and places the eyeball in such position that the hole is upward. The air bubble forces the retina against the choroid by pushing against it. The author advises bed rest until the elevation within the cauterized area has completely disappeared, that is for about five to six weeks. He keeps a binocular bandage for three to four weeks. The tabulated data on 100 patients show 81 cured. Reference is made to the author's former report on the technique of coagulation, in which he advocates nonperforating electrocoagulation with a ball electrode 1.25 to 1.00 mm. in diameter. (4 figures, 6 tables.) Ray K. Daily.

Verrey, F. **Myotonic dystrophy associated with degeneration of the macula.** Ophthalmologica 114:281-284, Oct.-Nov., 1947.

A typical case of myotonic dystrophy showed the following eye findings: bilateral ptosis, limitation of all ocular movements, slight reduction of corneal sensibility and fine, but typical lens opacities. The unusual finding was a bilateral degeneration of the macula (multiple yellowish dots within the retina) without gross visual impairment.

Peter C. Kronfeld.

Verrey, F. **Symmetrical involvement of the retinae in pigmentary degeneration.** Ophthalmologica 114:278-280, Oct.-Nov., 1947.

A white female patient, 51 years of age, complained of impaired vision in the dusk for the last ten years, and increasing reading difficulty for the last five years. Her vision was 20/20 in the right eye and 20/33 in the left. The fundus findings were those of retinitis pigmentosa confined to symmetrical sectors in the two eyes. The upper-temporal quadrants with portions of the adjacent quadrants had remained uninvolved, so that the lower halves of the visual field were almost normal. In the affected sectors the retinal vessels were much narrower than in the unaffected areas. Other members of the family could not be examined. Peter C. Kronfeld.

OPTIC NERVE AND CHIASM

Friedenberg, Sidney. **Tryparsamide optic neuritis treated by 2,3, Dimercaptopropanol** (B.A.L.). J.A.M.A. 135:1072, Dec. 20, 1947.

The author presents the first recorded case of tryparsamide optic neuritis successfully treated with 2,3, Dimercaptopropanol (B.A.L.). The arsenicals are thought to be toxic because they block the functioning of physiologically essential chain groups within the cells by combining with them. B.A.L. competes successfully for the arsenic with the sulfhydryl bond (the most vulnerable) by forming a stable compound with the arsenic which is rapidly excreted in the urine.

After tryparsamide injections the patient had loss of the inferior portions of the visual fields and general constriction. The last functions were recovered because of prompt B.A.L. therapy.

O. H. Ellis.

Igersheimer, Joseph. **Binasal hemianopsia.** Arch. Ophth. 38:248-258, Aug., 1947.

A case of binasal quatranopsia with central scotoma of the right eye in a 59-year-old man is reported. Exploratory operation showed a supraclinoid type of saccular aneurysm lateral to and apparently covered by the nerve. Diagnostic aspiration of blood from the aneurysm was done. Following the surgery there was marked loss of vision of the right eye but very considerable improvement in the vision of the left. The causes of binasal hemianopsia are discussed in some detail. The author concludes that the field of action in such cases is not the chiasm but the short portion of the intracranial part of the optic nerve in front of the chiasm. If the lesion is unilateral and the other optic nerve is also involved, this involvement can be explained only mechanically by pressure against the nerve, probably of sclerosed vessels, or by a local nutritional deficiency. The author believes, with Caramazza, that the presence of binasal hemianopsia combined with unilateral central scotoma points to a vascular disease, in the middle fossa and not a tumor of the pituitary body or a suprasellar tumor. John C. Long.

Jefferson, Geoffrey. (The Doyne lecture) **On compression and invasion of the optic nerves and chiasma by neighboring gliomas.** Tr. Ophth. Soc. U. Kingdom 65: 262-304, 1945.

The author describes in great detail his clinical data on eight patients with gliomas near the optic nerve and chiasm and discusses the significance of his findings to an understanding of the pathologic process and its clinical manifestation. Beulah Cushman.

Pallarés, J. J. **The occurrence of several cases of optic neuritis, of undetermined etiology, during an epidemic of neurotropic virus infections in Valencia.** Arch. Soc. oftal. hispano-am. 8:30-44, Jan., 1948.

From January to July, 1947, Pallarés saw four cases of isolated, unilateral, retrobulbar optic neuritis with an acute onset and terminal atrophy. Before the development of optic atrophy peculiar perivascular foci appeared at the point of emergence of the vessels from the papilla which seemed to be typical of this type of neuritis. Therapy was futile in three patients and the fourth improved on therapy with colloidal sulfur. Reference is made to Benedict's study of 225 cases of retrobulbar neuritis. Because the author's cases occurred following an epidemic of neurotropic virus diseases, it appears probable that a virus infection is the cause of the optic neuritis. Because of the perivascular foci it is suggested that the virus is transmitted along perivascular lymph spaces. (8 visual fields. 4 fundus drawings.) Ray K. Daily.

Rabadán Fernández, Pedro. **Posthemorrhagic, unilateral atrophy of the optic nerve.** Arch. Soc. oftal. hispano-am. 7: 1193-1198, Dec., 1947.

Complete and permanent loss of vision occurred in the right eye of a woman, 24 years old four days after a severe hemorrhage from the stomach. When seen five days later, she had no pupillary reaction to light, no light perception, the optic nerve was pale, the arteries narrow, and there was a slight peripapillary haziness. Two weeks later the optic nerve presented a picture of post-neuritic atrophy.

Ray K. Daily.

Vogelsanger, W. **A case of optico-chi-**

asmatic archnoiditis. Ophthalmologica 114:273-277, Oct.-Nov., 1947.

In a white man, aged 22 years, without any tangible antecedents, the vision of both eyes became rapidly reduced to light perception in small islands of the visual field. The ophthalmoscopic appearance of the discs and the results of a thorough general examination were normal. Within the next few weeks the peripheral vision improved spontaneously and only central scotomata persisted. The discs, however, became pale with distinct borders and normal vessel caliber. The gradual recovery of the visual field was interrupted by two fairly acute setbacks, one nine weeks and another 16 weeks after the onset of the visual disturbance. A few days after the latter the chiasma was explored surgically. A heavy arachnoiditic strand was found crossing both optic nerves from above just in front of the anterior angle of the chiasm. This strand was coagulated and severed. The author reports a very marked improvement in vision after the operation. After a few more spontaneous fluctuations the final vision was 20/20 in one eye and 20/200 in the other. Both discs remained snowy white.

Peter C. Kronfeld.

Werner, L. E. **Retrobulbar neuritis.** Tr. Ophth. Soc. U. Kingdom 65:376-393, 1945.

The syndrome of retrobulbar neuritis consists of: 1. rapid loss of vision in one or both eyes; 2. presence of central or paracentral color scotoma; 3. normal fundus in 85 percent of the cases and swelling of the disc in 15 percent; 4. pain on movement of the eyes and on pressure of the globe; and 5. occasional peripheral field defects.

The immediate treatment advised by the author is the daily intraorbital injection of 1 cc. of one-percent acetylcholine solution preceded by 0.25 cc. of novocaine with no adrenalin. Irrigation of the sphenoidal sinus, the removal of teeth that may have apical abscesses and the use of foreign proteins and sulfadiazine are considered necessary. The consultation with the neurologist can come later.

Beulah Cushman.

NEURO-OPHTHALMOLOGY

Esposito, A. C. **Acute syphilitic bilateral total ophthalmoplegia.** Arch. Dermat. and Syph. 55:686-690, May, 1947.

The author reports a case with diplopia, bilateral ptosis and bilateral third nerve paralysis with loss of pupillary reaction to light and in accommodation. The Wassermann reaction in the spinal fluid was positive and a tabetic type of gold curve was found. The patient responded to potassium iodide drops, bismuth subsalycilate and tryparsamide therapy.

Irwin E. Gaynon.

Focosi, M., and Levi, M. **A case of myasthenia gravis with predominantly ophthalmoplegic signs; diagnostic value of certain functional and laboratory tests.** Boll. d'ocul. 26:545-561, Sept., 1947.

Sometimes the differentiation of myasthenia gravis from chronic progressive nuclear ophthalmoplegia may become difficult. A 46-year-old man developed a partial paralysis of his left oculomotor nerve followed by ptosis of the right upper lid; later, his legs became weak and occasionally had slight cramps; there was no increase of symptoms during the day and the degree of the ptosis varied irregularly. Botulism and syphilis were excluded and the differentiation between myasthenia gravis and progressive nuclear ophthalmoplegia was undertaken by further study. Basal metabolism was plus 15 percent; lymphocytosis and eosinophilia were discovered in repeated blood counts. The beta-glycerophosphatase of the blood serum was markedly diminished; the blood serum contained

normal amounts of both calcium and potassium, and its inorganic phosphorus content was low. After oral administration of potassium chloride, the potassium content of the blood serum remained high for a longer period than in normal individuals; prostigmine administration had a favorable influence on all the muscle functions. The diagnosis of myasthenia gravis was accepted. K. W. Ascher.

Kravitz, Daniel. **Visual-field interpretations in chiasmal lesions.** Am. J. Ophth. 31:415-426, April, 1948. (10 figures, 6 references.)

Marín, Amat, M., and Marín Enciso, M. **Foster-Kennedy syndrome with unilateral exophthalmos in a child 3 years old.** Arch. Soc. oftal. hispano-am. 7:1190-1192, Dec., 1947.

A 3-year-old child, who had fallen on the floor, was brought for consultation because of exophthalmos of the left eye. She had a 6-mm. exophthalmos, hyperopia of 11 diopters in the left eye, and of 2 diopters in the right, atrophy of the right optic nerve and a choked disc in the left eye. X-ray examination of the skull revealed an osseous lesion in the roof of the left orbit in the region of the small ala of the sphenoid. A fracture of the small ala of the sphenoid and a congenital neoplastic or vascular lesion were considered in the diagnosis.

Ray K. Daily.

Mooney, A. J. **Visual manifestations of head injuries,** Tr. Ophth. Soc. U. Kingdom 65:394-404, 1945.

The author reviews 16 cases of injury to the optic nerve from road accidents. Fractures of the base of the skull involving the sphenoid bone and injuries of the external angular process of the frontal bone were common and were primary factors in lesions of the subchiasmal pathway. The visual nerve fibers are especially exposed to injury in the optic canal because of their close relationship to the bone in the case of fracture, and the limited area in which expansion can take place during hemorrhage into the vaginal space.

X-ray examination of the foramen was done routinely, but in no case did it reveal a lesion. Ocular paralysis co-existed with damage to the optic nerve in two cases only. If combined second, third, fourth and sixth nerve lesions co-exist it points toward basal hemorrhages with some infiltration into the optic canal. The weight of evidence suggested that severe lesions are due to laceration of the optic nerve and mild lesions to rupture of the nutrient vessels with or without bleeding into the sheath, although these conclusions are based entirely on theory.

Prognosis should be guarded. Improvement may take place in the field more than a year after the accident. If the margin of the defect in the visual field is shelving, the lesion is probably not stationary and improvement can reasonably be expected. A steep margin usually indicates a stationary and permanent lesion. If no perception of light is present two months after the accident, the disc pale, and the pupils inactive a bad prognosis can be given. Beulah Cushman.

Roessler, F. **Quadrant hemianopsia. (Observation with post-mortem findings).** Proc. Ophth. Soc. Vienna p. 17, May 18, 1942.

A 56-year-old man suffered a loss in three quadrants of both visual fields after sudden dizziness. Only the left lower quadrants were partly preserved. The patient died three days later of apoplexy. Post-mortem examination revealed thrombosis of the right and left arteria vertebralis, pronounced sclerosis limited to the posterior central arteries and cystic degenerations in both occipital lobes.

F. Nelson.

Rubino, A. **"Morgagni's syndrome" with upper quadrant bitemporal hemianopsia associated with partial retinitis pigmentosa.** Riv. oto-neuro-oftal. 22:237-252, July-Aug., 1947.

In a woman, 51 years of age, with obesity which started at the time of the menopause, hypertension, frontal headaches and other symptoms of the syndrome of Morgagni, radiographic evidence of an internal frontal hyperostosis of the skull were associated with a superotemporal heteronymous hemianopsia and a partial pigmentary degeneration in the lower nasal sector of the retina. The pigmentary degeneration of the retina is ascribed to a lesion of the "retino-hypothalamic" system. The bitemporal hemianopsia is a part of the Morgagni syndrome and must be considered an expression of a chiasmatic involvement.

Melchiore Lombardo.

Sedgewick, R. P. **Pure visual verbal agnosia with spatial disorientation.** Bull. Los Angeles Neurol. Soc. 13:64-66, March, 1948.

A patient had visual verbal agnosia, which is due to a subcortical lesion, but no agraphia, which is a cortical function. He could copy letters, but was unable to recognize them. He also had spatial disorientation, in that he had lost the power to revisualize objects, right homonymous hemianopsia, and retinal arteriolar sclerosis. At autopsy a softening of the brain in the distribution of the left posterior cerebral artery was found. O. H. Ellis.

Westerlund, E. **Ophthalmoplegia interna.** Acta ophth. 25:201-206, 1947.

The literature on ophthalmoplegia interna is reviewed, and four cases, occuring within a period of three months, are reported. The age of the patients was 11, 45, 47, and 24 respectively. The observation period was from three to five months. Two of the patients improved within this time, one recovered completely, and one showed a tendency to improvement. One patient complained of transitory headache. The disease in these patients was believed to be of undetermined infectious origin, as trauma, toxemia and lues could be excluded. Ray K. Daily.

14

EYEBALL, ORBIT, SINUSES

Campos, R. **Angioma cavernosa of the orbit with smooth muscle fibers.** Riv. di oftal. 2:81-104, March-April, 1947.

A woman, 53 years of age, had a slowly progressive unilateral exophthalmos. The first exploration of the orbit revealed a vascular tumor and brought about a transitory decrease in exophthalmos. Within a month the exophthalmos began to increase and vision began to fail. A superior orbitotomy allowed the removal of a retrobulbar tumor, the size of a pigeon's egg. Histologic examination revealed an angioma cavernosa in an advanced stage of fibrosis. In addition to the usual elements of blood-filled cavities, fibrous masses, lymphatic nodules, cellular infiltration, thrombosed vessels and hypertrophic walls, many strands of smooth muscles were found in a somewhat disorganized arrangement. Special mention is made of the infrequency of variations of the exophthalmos in angiomata cavernosa of the orbit. The origin of the smooth muscle and of the mechanism of formation of angioma is discussed. Francis P. Guida.

Carelli, P. V., and Cangelosi, J. P. **Angiosarcoma of the orbit.** Am. J. Ophth. 31:453-456, April, 1948. (3 figures, 13 references.)

Godtfredsen, Erik. **Studies on orbital tumors. Exophthalmos due to malignant tumors in the paranasal sinuses.** Acta ophth. 25:295-310, 1947.

Of 14 patients with paranasal sinus carcinomas penetrating into the orbit, 10 were over 60 years old, 3 were between 50 and 59, and one was a 3 year old boy. Eight of the patients were women. The origin of the tumor in eight was the antrum, in five the ethmoids, and the maxillo-ethmoid cells in one. The disease is characterized by early exophthalmos, with or without trigeminal neuralgia, dislocation of the eyeball upward and temporally, obliquity of the palpebral fissure, disturbances of motility, palpable mass in the orbit, and visual disturbances. In 10 patients the initial symptom was exophthalmos, associated in four with homolateral pain in the maxillary area. By the time the diagnosis was made all 14 patients had exophthalmos, and 9 had trigeminal neuralgia. The initial symptoms came from the nasal region in only one patient, and there were nasal symptoms in only five. Metastasis to the cervical glands were insignificant. Naso-pharyngeal tumors, which are frequently sarcomas, must be considered in the differential diagnosis. They occur in younger individuals and nasal symptoms, ophthalmoplegias, and metastasis to the cervical glands are pronounced. An early diagnosis is important, because the prognosis is good if operation or irradiation are instituted early. (7 illustrations.)

Louis Daily, Jr.

Godtfredsen, Erik. **Studies on orbital tumors. Nature and incidence of orbital tumors over a period of 15 years, (1932-1946).** Acta ophth. 25:279-293, 1947.

This is an analysis of the material of the Eye Department of Karolinska Sjukhuset, which is the largest university clinic in Sweden. There were 78 patients with orbital tumors, about 1 percent of admissions, and in 56 cases the diagnosis was verified histologically. Two-thirds of the tumors were primary orbital, originating in decreasing order of frequency from the lacrimal gland, nervous tissue, bone and vascular tissue. Two-thirds of the secondary tumors were extensions from the nose, and one-third was due to ocular neoplasm. Histopathologically half of the verified tumors were malignant. Because of the compression of the optic nerve and retinal vessels three-fourths were considered malignant biologically. Therapy is surgical and radiological, or a combination of both. It is emphasized that diagnosis and treatment call for close cooperation between ophthalmologists, roentgenologists, neuro-surgeons, oto-rhinologists, internists, and histopathologists. (1 table.)

Louis Daily, Jr.

Greear, J. N., Jr. **The use of buccal mucosa in the restoration of the orbital socket.** Am. J. Ophth. 31:445-453, April, 1948. (30 references.)

Inigo, L. **Ophthalmoeuliasis interna. Report of a case.** Arch. Soc. oftal. hispano-am. 8:45-63, Jan., 1948.

Ophthalmoeuliasis is the term applied to invasion of the eyeball by a parasite in its larval stage, and this, Inigo believes, is the first case of this type reported in Spain. An 11-year-old girl awakened during the night with an intense pain in the left eye, which radiated to the whole side of the head. The pain subsided within several hours, and she went back to sleep, but arose next morning with slight discomfort in the eye. During the next two months she developed a violent iridocyclitis with synechia, pain in the eye, and disturbance of vision. In the iridocorneal angle a whitish-yellow cylindroid body, about 7 to 8 mm. in length, and 1¼ mm. thick was found. The ocular tension was raised, and vision reduced to perception of large

objects. The parasite was extracted, and found somewhat adherent to the iris, and some iris pigment came away with it. The patient made a prompt and complete recovery within ten days. Examination of the cornea with the slit-lamp revealed a small punctiform corneal opacity, through the entire thickness of the cornea which was probably the point of entrance of the parasite. It was a larva of Hipoderma movis, which is abundant in the Iberian peninsula, and a frequent cause of diseases of cattle. Ray K. Daily.

Lavery, F. S. **Post-operative intraocular infection controlled by penicillin.** Brit. J. Ophth. 32:247, April, 1948.

A case of intraocular infection four days after an extracapsular cataract extraction is reported. Pus was present in the anterior chamber. Fifty thousand units of penicillin were injected subconjunctivally three times at 24 hour intervals, and massive doses were injected parenterally for four days. The eye improved rapidly, and the patient was discharged from the hospital with good light projection. Subsequently the eye was found to have a corrected vision of 6/6.
Orwyn H. Ellis.

Rebello Machado, Nicolino. **A case of bacteriemia with bilateral orbital cellulitis and thrombophlebitis of the cavernous sinus. Recovery.** Rev. brasil. oftal. 6:145-171, March, 1948.

The patient was a physician aged 37 years. The initial condition was an abscess of the epiglottis which occurred about the middle of June, and which was neglected by the patient. He first sought professional assistance after six days, when he was already in a state of advanced toxemia. Within two weeks he sustained an abscess of the left tonsil, which he himself opened. Next came a right peritonsillar abscess, and an arthritis of the left knee. There followed right exophthalmos, and during the next three weeks the left orbit became involved with the typical picture of thrombophlebitis of the cavernous sinus. The infective process is thought to have reached the lesser circulation by way of the lingual vein, the internal jugular, the brachiocephalic, and the superior vena cava. Significant details of the anatomy of the cavernous sinus are cited. The history of a chill with headache, septic temperature, swelling of the eyelids, and exophthalmos beginning on one side and extending to the other in a day or two suggests thrombosis of the cavernous sinus. Treatment in hospital included penicillin, streptomycin, Cibisol (a sulpha drug to which major credit is given), Heparin, and Dicumarol. Recovery was complete. (3 illustrations, references.)
W. H. Crisp.

Rosen, E. **An implant with bridges for attachment of muscles.** Brit. J. Ophth. 32:166-170, March, 1948.

The author designed an acrylic implant bearing six bridges to which the muscles can be attached. The implant is a truncated cone with a convex base; its anteroposterior diameter is 18 to 24 mm. and the diameter of the base measures 16 to 18 mm. After severing each muscle, plain 0000 gut sutures are placed in it and after the enucleation and insertion of the implant the muscle is brought through the bridge and sutured back upon itself. Tenon's capsule comes back into proper anatomical position and is left unsutured. The conjunctiva is then sutured in a horizontal line with very close approximation of interrupted sutures. The implant cannot be expelled and its mobility is unquestioned. The plastic bridges may be supplanted by metal bridges so that accurate X-ray study can be made of any orbital shift in the implant. (2 figures.) Morris Kaplan.

Rundle, F. F. **Some observations on exophthalmos.** West. J. Surg. 55:578-583, Nov., 1947.

The author describes the orbital contents, and lists the causal mechanisms of exophthalmos. In post-mortem examinations of a group of thyrotoxic patients with exophthalmos, fat deposition accounts for 70 percent of the total bulk increase and is mostly in the fibro-fatty tissue.

Clinically exophthalmos is only one sign of orbital overfilling. Lid protrusion is another and far more reliable sign, best determined not with the eyelids open, but lightly closed. A widened palpebral aperture is sometimes misleading. Examination with the lids closed is also helpful in determining unilateral lid protrusion. The occasional difficulty in diagnosing exophthalmos because of the wide variation in normal persons is mentioned. The best method is periodic, say monthly, measurements and plotting of the readings. (3 figures, 1 table, 1 chart, references.)

Bennett W. Muir.

Salgado Benavides, E. **Penicillin in the treatment of ophthalmitis neonatorum and septic endophthalmitis.** Arch. Soc. oftal hispano-am. 7:1121-1128, Nov., 1947.

Good results were obtained by the use of penicillin in the treatment of these infections. Large doses are needed and are administered locally and parenterally. The intravitreous injection of penicillin was considered dangerous and was not effective in controlling the infection.

J. Wesley McKinney.

Schultz, Abraham. **Bilateral chalcosis lentis with endophthalmitis of the right eye. Report of a case.** Am. J. Ophth. 31: 463-466, April, 1948. (1 figure, 7 references.)

Valière-Vialeix. **Myositis and subacute orbital cellulitis.** Ann. d'ocul. 181:1-31, Jan., 1948.

A 57-year-old man developed blepharoconjunctival edema with exophthalmus on the right side and subsequently on the left. Vision in the right eye was soon reduced to light perception, in the left, to 0.5. In both discs a glaucoma-like excavation was observed, though the ocular tension in both eyes remained normal and the field of the left eye was approximately normal. The motility of the left eye was slightly limited vertically and horizontally. The general well-being was normal, and bodily examinations and serological tests were essentially negative. A resection of the lateral orbital wall on the left side was first performed under local anesthesia. The external rectus muscle was much enlarged. Fifteen days later a fistula with suppuration developed. Under general anesthesia, a large orbitotomy was then performed. Lardaceous edema in the orbital cone was observed. The fistulous tract was curetted and a mass of inflammatory tissue removed. Healing followed with residual ptosis. Microscopic study of the inflammatory tissue revealed only the usual cellular changes of chronic inflammation. The inflamed lacrimal gland contained lymphoplasmocyte infiltrations along the blood vessels and gland acini. The inflammatory process involved especially the muscles and interfascicular septa. The symptomatology, pathology, and evolution of the condition are discussed at some length. The differential diagnosis involved: 1. malignant thyrotrophic exophthalmus; 2. Mikulicz's disease; 3. blood dyscrasias such as leukemia; 4. chronic and acute inflammatory orbital diseases such as chronic myositis and phlebitis. All these have been classified as inflammatory pseudo-tumors. Pathologically, they include inflammatory edemas as well as diffuse and local inflammatory cellular changes of different types and severities.

In the case reported, the diagnosis of subacute myositis and orbital cellulitis was based on the inflammatory and degenerative changes in the muscles and their sheaths. The etiology is not definitely understood. A pre-existing constitutional vascular degeneration in the orbit is presumed to have been followed by an inflammatory process due to an undetermined toxin. Chas. A. Bahn.

EYELIDS, LACRIMAL APPARATUS

Bangerter, A. **The treatment of stenosis of the lacrimal canaliculi.** Ophthalmologica 114:195-202, Oct.-Nov., 1947.

Both canaliculi of one eye of a young ex-soldier had become completely obliterated as an aftermath of a severe acute conjunctivitis. The author repaired this "stenosis" by making a direct anastomosis between the conjunctival and the lacrimal sac. The lacrimal sac was exposed through the usual incision for dacryocystorhinostomy. The sac was opened at the anterior junction of its medial and lateral walls. The latter wall was freed all the way back to the posterior crista. Through a conjunctival incision just anterior to the caruncle the tissues of the inner canthus were split into an anterior and posterior layer, until the previously freed lateral wall of the tear sac was exposed. A broad anastomosis between conjunctiva and tear sac was made by suturing the free anterior border of the lateral wall of the sac to the posterior lip of the conjunctival wound. A mucous membrane flap from the mouth provided the anterior wall of the anastomosis, having been sutured to the anterior edge of the medial wall of the sac and to the anterior lip of the conjunctival wound. A rubber drain was sutured and left in place for seven months, when it was replaced by a silver cannula. Ten months after the operation the cannula was removed. Two years later the patient reported no tearing or any other ocular discomfort. Peter C. Kronfeld.

Barri Rodríquez, Julio. **A contribution to dacryocystorhinostomy.** Arch. Soc. oftal. hispano-am. 7:1141-1148, Nov., 1947.

The author discusses the advantages of the crown-shaped burr for making the nasal opening rapidly without danger of injurying the nasal mucosa.

Gittler, R. **Successful treatment of blepharitis ulcerosa with albucid.** Proc. Ophth. Soc. Vienna p. 28, Oct. 26, 1942. 1942.

In a man, 43 years of age, severe ulcerous blepharitis responded neither to extraction of lashes, cauterization with silver nitrate nor X-ray treatment but healed within two weeks after intravenous injections of albucid. F. Nelson.

Godtfredsen, Erik. **Pathology of mucous and salivary gland tumours in the lacrimal gland and the relation to extra-orbital mucous and salivary gland tumours.** Brit. J. Ophth. 32:171-179, March, 1948.

The modern, revised view of the genesis of mixed tumors is that they are not mixed at all but rather come entirely from the ectoderm; the apparent mesenchymal elements of these tumors are not mesodermal but ectodermal products of the epithelial cells which to a great extent undergo metaplasia. These changes may present all transitional forms from benign to malignant. There are two main histopathologic types: the fibro-myxo-epithelioma and the basalioma both of which may be benign or malignant. The

former occurs more frequently than the latter and malignant ones are more frequent than benign. Treatment consists mainly in surgical removal and irradiation. However, the best 5-year-cure reported is 50 percent.

The author presents 10 case reports. Exophthalmos, ptosis, visual impairment, palpable cervical nodes and palpable tumor were the most common signs and symptoms. Five of the tumors were malignant although from a biological aspect all are malignant because the tumor proliferation has a delerious effect on the optic nerve or the retinal vessels. (2 figures.)

Morris Kaplan.

Redi, Francesco. **Plasma cell granuloma of the lacrymal passages.** Rassegna ital. d'ottal. 16:441-459, Nov.-Dec., 1947.

Three cases of plasma cell granuloma are described. Often these tumor masses are called plasmocytomas or plasmomas, which is incorrect, since these latter are pathologic neoplasms, which frequently metastasize to lymph glands and bones. As a result of this inexactness many plasmacellular granulomas are reported as plasmomas. Also occasionally included in the group are peritheliomas of the canaliculi. In the three cases described, the author suggests that the particular vascularization of the palpebral conjunctiva, the chemistry of the tears and the secretion of the various glands may play an important part in the etiology. It is also true that many cases described as trachoma of the lacrymal passages do not show the pathological changes characteristic of trachoma. (5 figures.)

Eugene M. Blake.

Sherman, A. E. **Choice of procedure in ophthalmic plastic surgery.** New York State J. Med. 48:861-868, April, 1948.

General principles of ophthalmic plastic surgery are reviewed: (1) the early accurate repair of lacerations about the orbit with careful closure of subcutaneous tissue and skin often makes later repair unnecessary, (2) the use of intermarginal lid adhesions for two to three months after burns of the eyelids may be sufficient to prevent ectropion, (3) correction of deformities from lacerations or burn should not be attempted from three to four months after the initial repair because scar tissue will by that time become compact and relatively avascular, (4) scar tissue should be thoroughly excised and the tissues approximated without undue tension, (5) eyelid structures should be used to replace eyelid structures, (7) simple procedures should be followed, (8) a well-placed pressure dressing is very important.

Two cases of neoplasms are shown in which the simple excision of the tumors, with undermining and careful closure of the surrounding normal tissues was adequate. Two cases of deformities of the medial canthal area are shown. The first was repaired by excising scar tissue, mobilizing the lid and suturing a small tongue of denuded tarsus in a pocket up to the medial canthal ligament, and the other by means of excising all scar tissue and the tear sac, freely mobilizing the entire medial canthal area, removing displaced bone, transposing Z-plasty flaps, and overcorrecting the deformity. The correction of an eyebrow deformity is demonstrated by a Z-shaped incision and interposition of flaps. In this patient iliac bone grafts were used for orbital rim defects.

The Wheeler secondary implant is discussed. The implantation of an acrylic wedge (about 2½ cm. by 1½ cm. by 0.8-0.4 cm.) on the orbital floor to elevate the eye in cases of depression and enophthalmos due to fracture of the floor of the orbit, is described. Cicatricial contraction of a portion of the eye socket is corrected by excision of underlying scar tissue, adequate enlargement of that por-

tion of the socket, and the use of a mucous membrane graft from the inner surface of the lower lip.

When there has been extensive loss of tissue so that the best result one could hope for would be immobile unnatural eyelids with a staring conspicous artificial eye, he prefers to remove the remains of conjunctiva and lacrimal gland, and to cover the orbit with a continuous layer of smooth skin. (26 photographs.)

Alston Callahan.

Weekers, L. **The operative technique of ptosis: diathermic coagulation.** Ann. d'ocul. 180:657-663, Nov., 1947.

In all cases of hypofunction of the levator, the Blaskovics operation is considered basic. As supplementary operations those of Motais and Machek may be advisable if additional superior rectus or orbicularis function is also needed. Skin excision may also be necessary. In the Blaskovics operation, the Agatston technique and diathermic coagulation of the tarsus are preferred. A 1-mm. electrode is used with a 4-mm. exposure and the current volume is adjusted at the time of operation. Diathermic coagulation is especially applicable in chronic inflammations of the palpebral connective tissues and the tarsus, such as trachoma. The term "blepharochalasis" is applied to several entities; one is characterized by epidermal relaxation followed by recurrent inflammation of the subcutaneous tissues and subsequent degenerative changes here and in the muscles. Depending upon the stage and severity, the operative procedures for the relief of blepharochalasis may include skin excision and the operations of Blaskovics or Machek.

TUMORS

Loewenstein, A., and Foster, J. **Two unusual sclerocorneal neoplasms.** Brit. J. Ophth. 32:1-12, Jan., 1948.

A small tumor appeared at the limbus in a 15-year-old boy and began to grow rather rapidly; it was yellow, painless and hard. Biopsy revealed a spindle cell sarcoma of a mature type, markedly vascularized and with giant cell formation in the vessel walls. A considerable number of large mast cells with big round nuclei was present. After the biopsy the remaining tumor grew faster than before and the eye was excised. The exact nature of the tumor could not be ascertained though it was felt to be a transmissible tumor, probably caused by a filterable virus. A second small tumor that arose from a degenerative pannus in a blind eye occurred in a 65-year-old woman.

The suggestion that a filterable virus was the etiologic agent is speculative and without proof, as the idea of animal inoculation was a fruit of the histologic investigation, when it could no longer be carried out. Such cases should in the future be investigated from the biologic viewpoint before the histologic. The amount of material required for injection into the anterior chamber of an animal is so small that it need not interfere with the usual histologic investigation.

Morris Kaplan.

Owens, N., and Stephenson, K. L. **Hemangioma: an evaluation of treatment by injection and surgery.** Plast. and Reconstruct. Surg. 3:109-123, March, 1948.

Only surface hemangiomas are considered, and they are described as tumors of the independently growing blood channels with their origin in embryonic rudiments of mesodermal tissue. A brief but interesting history of their treatment is presented and various methods of therapy

are mentioned. The incidence in the female is twice that in the male. Fifty-two percent of all hemangiomas occur in the area of the head.

Important diagnostic points are the discoloration, reexpansion after compression, increase in size if the patient's head is lowered, and enlargement of the mass if the jugular veins are occluded by pressure.

Injection therapy is indicated in areas where surgical excision would require the loss of a part such as around the eye, nose or lip, or the exenteration of the orbit. A cure resulting from sodium morrhuate injection accomplishes the desired results and saves the functioning part of the body. Of 39 patients treated by this method the youngest was six weeks of age and the eldest 35 years. Five typical cases are reported, in three of which there were involvements of the eye and adnexa. From 0.5 cc. to 4.0 cc. of sodium morrhuate was injected from a tuberculin syringe with a 25 or 26 gauge needle, the amount being determined by the clinical appearance and the response at the time of infiltration. Smaller doses are used in areas about the eye or lip or in a mucous-membrane-covered surface. At intervals of from ten days to five weeks the injections are repeated. The injection of sodium morrhuate causes thrombosis with secondary sclerosis, atrophy, and absorption of the vessels. To be effective it does not have to come in contact with the vessel lining. Complications of injection were central necrosis and ulceration, and in one case diffuse thrombosis. No allergic reaction accurred and the necrosis was not painful. The authors have injected this sclerosing solution into the conjunctiva, but have not used more than 2 cc. at any one time in this area.

Surgical removal is utilized in areas where the problem of the loss of the part of the body does not exist and in patients in which the injection treatment has not been successful. The location of the tumor should be carefully considered, particularly with reference to the availability of tissue repair, the ease of surgical excision and the possibility of complete eradication by one surgical maneuver. Of the 56 hemangiomas removed by excision from individuals of from six weeks of age to 50 years, four are reported in detail, but in none of these were the eye or adnexa involved.

A case report of massive ocular and adnexal involvement is included in which neither excision nor injection was attempted because of the size of the lesion. The authors advised against carbon dioxide snow, Xray or direct application of radium or radon to surface lesions. This type of therapy has not proved successful in regions having well differentiated endothelium. Alston Callahan

17

INJURIES

Cibis, P. **Lid formation and lid elevation by means of fenestrated implants made from "Supramid."** Klin. Monatsbl. f. Augenh. 112:232-238, 1947.

The author used a plastic lid support for repairs of defects of the lower lid. This support rests on the lower orbital rim by means of a base plate. A fenestrated frame is attached to this plate and serves as a support of the structures of the lower lid to the contours of which it conforms. The material is inserted through a lateral incision after the scarred area has been loosened and extensively undermined. The author presents pictures of several cases of anophthalmus and trauma to the lower lid after military injuries. The method proved cosmetically satisfactory and no disadvantages or complications were encountered. (11 photographs, 3 drawings.)
Max Hirschfelder.

Cibis, P. **Plastic lid repair by pedicu-**

lated skin flaps in combination with creeping flaps. Klin. Monatsbl. f. Augenh. 112: 238-243, 1947.

It is possible to transplant skin from distant parts by a repeated process of folding and subsequent stretching. This method was first used by Lexer in 1907 for repair of the eyebrow with skin from behind the ear. The author repaired traumatic defects of the upper and lower lid in the following way: he first implanted a pediculated flap from the forehead into the upper or lower lid. In a later operation he formed a double fold in line with the principles of the creeping flap. The fold was subsequently unfolded and stretched and served as material to repair the other remaining lid. The use of this type of flap from basal parts of pediculated flaps is recommended. (10 figures.)

Max Hirschfelder.

Leydhecker, F. K. **Experiments with a new assembly to prove the touching and grasping of metallic foreign bodies.** Klin., Monatsbl. f. Augenh. 112:255-258, 1947.

The article describes a relatively simple electric assembly which is used in connection with a forceps made of two electrically isolated prongs of different metals. The sound produced in a loudspeaker varies from a short knock at touch to a lasting signal, when the foreign substance is firmly grasped. Max Hirschfelder.

Lindner, K. **Saving of infected eyes with injured lenses.** Proc. Ophth. Soc. Vienna p. 25. June 29, 1942.

Lindner advocates as thorough removal as possible of lenses which have been injured by perforating trauma and from eyes that have become infected.

F. Nelson.

Neubert, F. R. **An attempt to treat a perforated eye with subconjunctival penicillin.** Brit. J. Ophth. 32:162-163, March, 1948.

This brief case report describes the unsuccessful use of penicillin in an eye with a severe perforation. A smear on the third day revealed the presence of penicillin-sensitive cocci. Subconjuntival injections of 50,000 units of penicillin in novutox and intra-muscular injections of 30,000 units were given. After three days the eye was much worse and was removed. The pathologic report indicated the presence of panophthalmitis. Morris Kaplan.

Papamatheakis, N. **Iridocyclitis caused by intraocular glass splinter.** Proc. Ophth. Soc. Vienna p. 38, Feb. 22, 1943.

Recurrent inflammation occurred some time after the eye had been injured in an accident. X-ray films revealed no intraocular foreign body, but 13 years later a very small glass splinter could be localized in the chamber angle at 6 o'clock and was removed under slit lamp control. Apparently even very small glass particles within the eyeball cannot be tolerated indefinitely. F. Nelson.

Paufique, L. **Anterior chamber puncture to facilitate scleral foreign body extraction.** Ann. d'ocul. 181:35-37, Jan., 1948.

Preliminary paracentesis temporarily reduces the ocular tension, and is therefore a valuable adjunct to numerous operations. First among these is the removal of posterior intraocular foreign bodies. Vitreous loss and other complications may thus be avoided or minimized, especially if section of the extraocular muscles is necessary. In the removal of a posterior intraocular foreign body, the transcleral route is generally preferred. This is especialy true if the foreign body is imbedded in the coats of the globe or if its removal predisposes to uveal or choroidal prolapse or retinal detachment. An illustrative case is presented. Chas. A. Bahn.

Thiel, R. **Electrodynamic power effects on nonmagnetic metals. A method to re-**

move nonmagnetic foreign bodies from the eye. Klin. Monatsbl. f. Augenh. 112: 258-267, 1947.

The theoretical background of this striking attempt to move non-magnetic metals by electric power lies in the utilization of so called "electrodynamic powers" and in the production of Foucault or eddy currents. Whereas it is difficult to abstract the theoretical parts of the article, the basis for the method may be described as follows. An alternating current of high frequency is sent through a primary coil. A Foucault current of opposite direction is created in a metal ring which lies in the electrodynamic field of this coil. A similar current corresponding in direction to that running through the metal ring is excited in a second nonmagnetic piece of metal which might well be an intraocular foreign body. As bodies containing alternating currents of equal direction attract each other, the second body, even though nonmagnetic, will move in the direction of the metal ring. Experiments in collaboration with the physicist Johann proved the correctness of this theoretical calculation. For practical use in ophthalmology one will need relatively high powers, and certain difficulties have yet to be solved. (6 references.) Max Hirschfelder.

Zwahlen, P. **Priscol in the treatment of ocular burns.** Ophthalmologica 114:241-245, Oct.-Nov., 1947.

In severe ocular burns the University Eye Clinic of Lausanne uses the following procedure in order to decide whether conservative or surgical treatment should be instituted. The burned conjunctiva is pricked with a fine needle. If this prick causes no bleeding or pain whatsoever, the author believes surgical treatment, that is, replacement of the burned conjunctiva by a mucous membrane flap after Denig, is indicated. If the needle prick causes bleeding or pain, the eye is treated conservatively. The author has obtained gratifying results with repeated instillations of a histamine derivative called Priscol.

Rodriguez, R., and Root, H. F. **Capillary fragility and diabetic retinitis with a note on the use of rutin.** New England J. Med. 238:391-397, March 18, 1948.

The literature on capillary fragility in relation to diabetic retinitis is reviewed.

Measurements of capillary fragility by the petechial index of Gothlin were done

in 156 diabetic patients. Forty percent of 100 unselected diabetic patients showed an increased capillary fragility. This abnormality was found in practically all patients with diabetic retinitis, whether or not hypertension was present. In 11 cases hypertension was present with increased capillary fragility, but no retinal damage was observed. In 56 selected cases of retinitis, no patients showed a normal petechial index; the petechial index was increased in 47, near the upper limit of normal in nine. The incidence of increased capillary fragility was related to the duration of the diabetes more clearly than to the age of the patient. Forty-one percent of 82 patients with retinitis were under 40 years of age, and increased capillary fragility was observed as early as the age of 21 years, but with long duration of diabetes.

Rutin was administered to 70 patients with retinitis and increased capillary fragility. The initial dose was 20 mg. three times a day, and this was increased to 40 to 60 mg. three times a day in 20 cases. (A dosage of 300 to 400 mg. daily may be used.)

Capillary fragility can be brought to normal with the use of rutin in sufficient dosage, but in no patient did the retinitis improve. Increased capillary fragility occurs in diabetic patients as an early evidence of generalized arterial disease and is closely correlated with the development of retinitis and nephritis.

Theodore M. Shapira.

Stuart, R. D., and McWalter, D. **Primary meningococcal conjunctivitis in children.** Lancet 1:246-248, Feb. 14, 1948.

Six sporadic cases of acute meningococcal conjunctivitis in infants and young children are described.

Meningococci were isolated from five of these infections and in four instances they belonged to group one.

In two instances meningococci were present in the nasopharynx of a close contact, and the probable source of infection was the respiratory tract.

Attention is drawn to a simple method for transporting specimens from an outlying clinic to a central laboratory, which overcomes the frequent difficulty of immediate culture. The possibility of confusion between meningococcal and gonococcal conjunctivitis is emphasized, and the importance of full bacteriological investigation is urged.

Theodore M. Shapira.

19

CONGENITAL DEFORMITIES, HEREDITY

Mata, Pedro, **Ocular manifestations of tuberous sclerosis.** Arch. Soc. oftal. hispano-am. 7:1176-1189, Dec., 1947.

An exhaustive description of the various manifestations of the disease, and brief reports of three cases are presented. A girl 16 years old, with a mental age of 9 years, had adenomas of Pringle, periunguinal tumors of Koenen, psychic disturbances, epileptic attacks, and typical retinal protuberances; cranial calcification was not demonstrable. Another patient, 17 years old, with Pringle's adenomas and mental retardation, died without developing retinal involvement. The third patient, 14 years old, had three typical retinal nodules, without other symptoms. (3 photographs, 2 fundus pictures.)

Ray K. Daily.

McCulloch, C., and McCulloch, R. J. R. **A hereditary and clinical study of choroideremia.** Tr. Am. Acad. Ophth. pp. 160-190, Jan.-Feb., 1948.

A genetic study was made of two families, with over 600 members, and 86 cases of this disease. In the female it is present in a latent form, causes no visual defects, and is essentially unchanged throughout life. In the males, however, the disease is progressive and begins at ages ranging

from 3 to 40 years. The first symptom is night blindness and in the very early stages, the fundus resembles the female type. The choroid is gradually absorbed with equatorial and peripheral field changes; central vision remains good. Mentality is not affected, but impairment of hearing is not infrequent. Choroideremia is a recessive sex linked character; the female is the carrier, the male has the progressive form of the disease. In the female, the differential diagnosis includes pigmentary retinal degeneration, diffused choroiditis and the salt and pepper type of chorioretinitis. In the male, the differential diagnosis includes pigmentary retinal degeneration, gyrate choroidal atrophy of Fuchs, diffuse choroidal sclerosis, choroidal atrophy in high myopia, and diffuse choroiditis (Oguchi's disease). The authors do not think choroideremia is a form of pigmentary retinal degeneration. Chas. A. Bahn.

McKernan, R. L. **Sturge-Weber Syndrome.** Tr. Ophth. Soc. U. Kingdom 65: 407, 1945.

The author advises that the name be changed to "angiomatosis ophthalmicus" because of the similarity in the distribution of the focal manifestations to herpes zoster ophthalmicus.

Beulah Cushman.

Posner, A., and Schlossman, A. **The role of inheritance in glaucoma.** Tr. Am. Acad. Ophth. pp. 145-158, Jan.-Feb., 1948.

In this study of 373 unselected patients with primary glaucoma 51, or 13.7 percent, knew of one or more relatives who had the disease. These 51 belonged to 30 families. The mechanics of dominant, recessive and sex-linked heredity in glaucoma is explained as are terms like penetrance and expressivity. In 20 of 25 sibships the penetrance was 80 percent. In evaluating the specific roles of the several types of heredity in the constitutional predisposition to potential and actual glaucoma, at least two factors must be considered. First, there is no sharp contrast between dominant and recessive genes, which means that in sporadic cases the exact mode of transmission is not yet understood. Second, primary glaucoma is essentially a bilateral, progressive, constitutional, degenerative disease which affects both the corneoscleral filterability and the intraocular vascular permeability. A more careful study of the pedigree of glaucoma patients is advised. Charts of ten glaucomatous families are presented with their pedigrees carried to the third and fourth generations.

Chas. A. Bahn.

Rieger, H. **A family with irregularily dominant hereditary retinitis pigmentosa of atypical character.** Klin. Monatsbl. f. Augenh. 112:203-213, 1947.

The author presents a family tree in which the mother, her offspring from two marriages and her grandchildren had atypical pigment degeneration of the retina. Not all the members were involved, but five had serious involvement of retina and choroid, resembling retinitis punctata albescens. Seven others had gross granular pigmentation of the fundus which is probably a more benign form of the same inherited process. The hereditary biological factors of this disease are discussed.

Max Hirschfelder.

Sauer, H. **Total atypical coloboma of iris and choroid and staphyloma verum in a child.** Proc. Ophth. Soc. Vienna p. 15, May 18, 1942.

A child was presented who had a normal right eye. In the left he had a large coloboma of the iris between 9 and 10 o'clock and another at 6 o'clock as well as a circumpapillary staphyloma verum.

F. Nelson.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Arjona, J. **Old age and the eye.** Arch. Soc. oftal. Hispano-am. 7:1097-1110, Nov., 1947.

The ocular changes characteristic of old age in the eyelids, conjunctiva, cornea, iris, lens, vitreous, retina, and sclera are briefly described. Several suggestions for the alleviation of ocular symptoms in senile patients are made.

J. Wesley McKinney.

Campbell, D. A. **Clinical report on miners' nystagmus.** Brit. J. Ophth. 32: 193-198, April, 1948.

The author presents a clinical survey of 44 certified cases of miners' nystagmus. The symptoms of active nystagmus, giddiness and photophobia were usually present. After medical supervision with rehabilitation and proper treatment, the average duration of disability was six months. These men are unable to return to work underground, but can fill good jobs if not required to work in poor illumination and in awkward postures. A plea is voiced for better working conditions underground, particularly in the matter of illumination. Orwyn H. Ellis.

Marshall, Don. **Military ophthalmology in the European theater.** Am. J. Ophth. 31:545-561, May, 1948. (13 figures, 12 references. Discussion by F. P. Calhoun, Jr. and Trygve Gundersen.)

Maxwell, Euphan, **A cross-sectional view of injuries in an ophthalmic practice in Eire.** Brit. J. Ophth. 32:134-153, March, 1948.

This very long article is a reminiscence of the author's many years of ophthalmic practice in Dublin. The review covers three-quarters of a century. Almost every conceivable complication of ocular injury was encountered and many of these are described. Morris Kaplan.

Nelson, H. A. **Eyes: compensation and medicolegal problems.** Tr. Am. Acad. Ophth. pp. 267-272, Jan.-Feb., 1948.

In medicolegal cases the doctor's function is to state his findings and conclusions without regard to the result. Efficient treatment of industrial diseases and injuries is obligatory. Necessary preoccupational and occupational examinations are strongly advised. The system used in Wisconsin is considered equitable to both employer and employee. A panel of physicians including ophthalmologists is selected by the State Medical Society, employers and insurance carriers. A choice of physician or eye specialist by the employee is made from this panel. Independent medical examiners are freely used by the state commission. Total loss of vision in one eye in Wisconsin entitles the victim to compensation of 250 weeks, enucleation, 275 weeks. The A.M.A. committee ratings are generally used. Permanent visual loss should not be estimated too quickly. Complicating conditions such as detached retinas, toxic cataracts and epidemic conjunctivitides must be evaluated individually on their merits. Intelligent coöperation among industrial physicians, employers and insurance carriers is strongly advised.

Chas. A. Bahn.

Sappington, C. O. **Medicolegal problems in industrial ophthalmology.** Tr. Am. Acad. Ophth. pp. 260-267, Jan.-Feb., 1948.

After a few general remarks a few case histories are reported, and a brief discussion of ophthalmic procedure in industry as an expert witness follows. Some twenty industrial chemical substances which may affect the eye internally are mentioned. Chas. A. Bahn.

Stern, E. S. **The psychiatric aspect of miners' nystagmus.** Brit. J. Ophth. 32: 209-224, April, 1948.

The author presents detailed reports of psychiatric examinations of miners with and without nystagmus. Miners' nystagmus is a psychosomatic affection which usually does not develop until the man has been working underground in the dark and with an upward gaze for at least 10 years, and more commonly for 30 years. The dangerous occupation of mining, coupled with economic anxiety, produces a varying degree of conversion into a hysterical state and the presence or absence of nystagmus itself is relatively unimportant. These people should be under psychiatric supervision, and the term "miners' nystagmus" should no longer be used. Orwyn H. Ellis.

DEATH

Dr. Louis Abraham Feldman, Brooklyn, New York, died February 2, 1948, aged 57 years.

ANNOUNCEMENT

CHICAGO CLINICAL CONFERENCE

The Chicago Ophthalmological Society announces its 2nd annual clinical conference to be given November 29 to December 4, 1948. Special attention will be paid to the pathologic and the clinical aspects of glaucoma and retinal diseases. Recent advances in general ophthalmic therapeutics will also be presented. The class will be limited to 50. For further information address: Miss Maud Fairbairn, 8 West Oak Street, Chicago 10, Illinois.

MISCELLANEOUS

IOWA POSTGRADUATE COURSE

The State University of Iowa, College of Medicine, gave a postgraduate course in ophthalmology on June 14, 15, 16, 17, 18, and 19. The course was under the direction of the staff of the department of ophthalmology: Dr. C. S. O'Brien, head of the department; Dr. J. H. Allen, Dr. P. J. Leinfelder, Dr. G. L. Walker, and Dr. Otis S. Lee, Jr.

The guest instructors and their subjects were: Dr. Moacyr E. Alvaro, "Hemostasis in Ophthalmology" and "Radiation Therapy in Ophthalmology"; Dr. A. D. Ruedemann, "Industrial Ophthalmology"; Dr. Paul A. Chandler, "Glaucoma"; Dr. Daniel B. Kirby, "Surgery of Strabismus," "Surgery of Glaucoma," "Surgery of Cataract," and "Complications in Eye Surgery"; Dr. Kenneth C. Swan, "Ocular Therapeutics."

SOCIETIES

AKRON GUEST SPEAKER

At the May 3rd meeting of the Akron Academy of Ophthalmology and Otolaryngology, Dr. E. Bruce Fralick, professor of ophthalmology at the University of Michigan, presented a very interesting paper on the "Surgical Anatomy of Glaucoma." Members of the Cleveland Club of Ophthalmology were guests of the Akron Academy.

CENTRAL ILLINOIS MEETING

The Central Illinois Society of Ophthalmology and Otolaryngology met on April 23rd, 24th, and 25th at the Orlando Hotel, Decatur. The guest speaker in ophthalmology was Dr. B. Y. Alvis, St. Louis, who discussed glaucoma and its various phases.

Two of the active members, Dr. Edgar T. Blair, Springfield, and Dr. G. E. Hartenbower, Bloomington, presented papers. Dr. Blair discussed "Gonococcal Conjunctivitis," and Dr. Hartenbower lectured on "Obscure Foci in the Throat."

The next meeting of the Society will be held at the Abraham Lincoln Hotel, Springfield, Illinois, November 12th, 13th, and 14th. The officers of the Central Illinois Society of Ophthalmology and Otolaryngology are: President, Dr. Clarence E. McClelland, Decatur; president-elect, Dr. Clifton S. Turner, Peoria; vice-president, Dr. Harold Watkins, Bloomington; secretary-treasurer, Dr. Philip R. McGrath, Peoria.

CHICAGO SOCIETY OFFICERS

The Chicago Ophthalmological Society has elected the following officers for 1948-49: president, Dr. Arlington C. Krause; vice-president, Dr. George P. Guibor; secretary-treasurer, Dr. J. Robert Fitzgerald; councilor, Dr. Cyril V. Crane; corresponding secretary, Dr. Richard C. Gamble.

READING MEETINGS

The 81st meeting of the Reading Eye, Ear, Nose, and Throat Society was held jointly with the Reading Dental Society. Harold M. Covert, D.D.S., chief of Oral Surgery Section, Allentown General Hospital, and Dr. Kerwin N. Marcks, chief, Department of Plastic and Reconstructive Surgery, Allentown General Hospital, presented a paper on "Diagnosis and Treatment of Mouth and Face Pathology."

On May 5th, the Study Club of the society was addressed by Dr. Ferris T. Ketcham on the subject "Pathologic Explanation of Common Ophthalmoscope Findings."

PERSONAL

APPOINTED SPECIAL LECTURER

Dr. Adalbert Fuchs has been appointed special lecturer in ophthalmology in the postgraduate division at New York University College of Medicine beginning October 1, 1948.

AMERICAN JOURNAL OF OPHTHALMOLOGY

VOLUME 31 AUGUST, 1948 NUMBER 8

THE CLINICAL COURSE OF GLAUCOMA*

A REVIEW OF 474 CASES FROM PRIVATE PRACTICE

ADOLPH POSNER, M.D., AND ABRAHAM SCHLOSSMAN, M.D.
New York

It is well known that the clinical course of primary glaucoma shows great variability from patient to patient. At one extreme, the disease is so mild that the diagnosis cannot be made with certainty except after long periods of observation. At the other extreme are those malignant cases which progress rapidly and inexorably to ultimate blindness within six months or a year. The majority of glaucoma patients fall somewhere between these two extremes.

The present study is a correlation of 474 glaucoma cases from private practice, of which 373 are primary glaucoma. Of these, 158 patients have been followed for 5 years or longer and 21 of these have been observed for 20 years or longer (fig. 1). Such cases, representing as they do, the life-cycle of the disease, can add greatly to our understanding of the nature of glaucoma. These studies are all the more valuable since they are based on carefully kept and richly annotated records which are the legacy of the late Dr. Mark J. Schoenberg. Shorter case histories have been included mainly to enhance the statistical value of this study.

The available material was correlated analytically to uncover the many variations in the symptomatology and course of the disease. An attempt was then made to synthesize these findings so as to achieve a better understanding of the many-faceted clinical picture of primary glaucoma. The ophthalmologist's experience with an individual case may be limited to only one stage in the life cycle of the disease. We hope that this paper will aid him in the evaluation of the past history of the case and in the formulation of a plan of treatment.

INCIDENCE

The exact incidence of primary glaucoma in the general population is unknown. It has been estimated that from 0.5 percent to 2 percent of all patients consulting ophthalmologists or clinics, suffer from glaucoma. According to Carvill[1] 1.33 percent of all the new patients attending the Massachusetts Eye and Ear Infirmary between 1928 and

1930 had glaucoma; 57 percent of these were primary. Lehrfeld and Reber[2] give the incidence of glaucoma at the Wills Eye Hospital between 1926 and 1935 as 0.78 percent. This figure includes both primary and secondary glaucoma. In our series the incidence of primary glaucoma among 12,000 case histories was 3.1 percent.

Classification

The most widely accepted classification divides glaucoma into three types: acute congestive, chronic congestive, and chronic simple. Other classifications were proposed at various times. Von Graefe[3] recognized acute and chronic inflammatory glaucoma as well as another disease which he called "amaurosis with excavation." The last named group probably contained many cases of chronic simple glaucoma in addition to those of glaucoma without hypertension. Heerfordt[4] divided glaucoma into "haemostatic" and "lymphostatic" forms; but this classification was not widely accepted because it contained etiologic implications which were not well founded. Elschnig[5] substituted the terms "compensated" and "incompensated" glaucoma for the chronic simple and congestive forms, respectively. This terminology is confusing, since most cases of chronic simple glaucoma are, in the physiologic sense, incompensated.

Raeder,[6] in 1923, proposed a classification of glaucoma based on the depth of the anterior chamber. More recently, this idea was elaborated by Barkan,[7] Sugar,[8] and Kronfeld[9] with the aid of gonioscopy. In this country the terms "narrow" and "wide-angle" glaucoma have almost supplanted all other terminologies. While every new line of approach in the study of glaucoma is a distinct contribution toward the ultimate solution of this baffling problem, we feel that the present state of our knowledge does not warrant the adoption of an etiologic classification.

The term "narrow-angle glaucoma" is based on the assumption of the iris block mechanism as the primary cause of this form of the disease. In "wide-angle glaucoma" the implication is made that the trabeculum-canal of Schlemm apparatus is, in some way, the primary offender. It is apparent that these two mechanisms are not mutually exclusive. Individuals who have eyes with narrow angles may develop disturbances in the trabeculum or elsewhere in the eye of a type similar to that found in the "wide-angle" glaucoma. A case of this sort cannot be classified except on the basis of its clinical picture.

We believe with Troncoso[10] that "shallowness of the angle should be considered as a predisposing and not . . . as the primary cause of hypertension." It is true that in some eyes with narrow angles, mydriasis may cause closure of the angle and thus precipitate an acute attack. Even here we do not know to what extent other factors are responsible for the rise of tension.

Bangerter and Goldmann[11] have called attention to the fact that, while 18 percent of normal eyes have narrow angles and 22 percent have wide angles, as many as 60 percent fall into an intermediate group. Since the incidence of glaucoma of all forms is 0.5 to 3 percent of all eye patients (the congestive type representing about one third of the total), a very small percentage of eyes with narrow angles develop glaucoma.

We have observed several cases with wide angles who were subject to acute attacks. The regular use of miotics does not necessarily prevent congestive attacks. On the contrary, we have gained the impression that, in some cases, the prolonged use of pilocarpine, while it lessens the frequency, increases the severity of attacks. Homatropine frequently fails to provoke an attack in the narrow angle type, and, furthermore, it occasionally produces a congestive attack in a case of chronic simple glaucoma with an intermediate or wide angle.[10] In two cases, whose angles are wide at present, the dis-

ease was ushered in with an acute attack. Ten-percent neosynephrine has been used by us even in chronic congestive glaucoma without increasing the tension. In fact, it may make the eye more responsive to the subsequent use of pilocarpine.[12] Hamburger[13] has made the same observation with regard to glaucosan. In certain cases, the pupil remains widely dilated following an acute attack, and yet the tension remains normal, either with or without the use of miotics.

We have adopted the classical nomenclature of acute congestive, chronic congestive, and chronic simple glaucoma, since it carries no etiologic implications and is based on the clinical course of the disease. The diagnosis of acute glaucoma was made when the patient had only one congestive attack, or a second one after many years. Recurrent ocular pain or congestion determined the diagnosis of chronic congestive glaucoma. A case was classified as chronic simple glaucoma even when colored halos and slight discomfort were occasionally present.

In our series of 373 cases of primary glaucoma, 152 were males and 221 were females (fig. 2). In terms of eyes, the total number

TOTAL NUMBER OF PATIENTS

TYPE	TOTAL	MALE	FEMALE
PRIMARY GLAUCOMA	373	152	221
SECONDARY GLAUCOMA	76	36	40
INDETERMINATE GROUP	25	12	13
TOTAL	474	200	274

Fig. 2 (Posner and Schlossman). Incidence of sex in the cases studied.

was 657 eyes (some cases were monocular), of which the males represented 262 and the females 395. The preponderance of women is much more pronounced in the congestive types, where the ratio is 64 male eyes to 171 female eyes (fig. 3).

In attempting to separate the chronic simple from the chronic congestive forms, it was often difficult to make a decision in borderline cases. In view of the fact that the subjective reaction to ocular disturbances varies widely with the psychic make-up of the individual, the use of subjective criteria, such as pain and congestion, may have led to the inclusion in the chronic simple group of some patients who actually suffered from chronic congestive glaucoma or a combination of the two forms. For example, some of the patients had no symptoms at first, but after treatment began to have ocular discomfort or to see occasional halos. The only patients whom we can classify with certainty as chronic simple glaucoma are those who never showed any symptoms except for the loss of field. It is interesting to note that in this group the sex distribution is equal (77 females to 77 males). Thus, even in the chronic simple form, the preponderance of females may be due to the inclusion of cases which have a congestive element in them. The higher incidence of congestive attacks in females may

EYES WITH PRIMARY GLAUCOMA

Fig. 3 (Posner and Schlossman). The congestive form shows a predominance of females over males, while chronic simple glaucoma without symptoms is equally distributed between the sexes. The slight predominance of females over males in the total group of chronic simple glaucoma indicates that some of these cases may exhibit a congestive element.

be related to their generally more labile vasomotor reactions.

Among the cases which were observed for five years or longer, many followed a clinical course which did not fit into any single category of our classification. Some of them behaved like chronic simple glaucoma but had one or more congestive attacks, either spontaneously while under treatment, or after the use of atropine or homatropine. In several cases the disease was initiated following the use of a mydriatic, either for refraction or in the treatment of a corneal ulcer; yet the subsequent course assumed the characteristics of chronic simple glaucoma. In other cases the disease began as asymptomatic glaucoma, but congestive attacks made their appearance after the prolonged use of miotics. In one case the acute attack occurred in connection with childbirth. Schmidt-Rimpler[14] has called attention to this group and has named it "glaucoma simplex with intermittent congestive attacks." We feel that the term is descriptive and we have adopted it in our classification. This group comprises 18 patients with a total of 24 affected eyes.

MIXED GROUP

FIRST EYE	SECOND EYE	No. OF CASES
CONGESTIVE	CHR. SIMPLE	18
CHR. SIMPLE & CONG. ATTACKS	CHR. SIMPLE	9
CHR. SIMPLE & CONG. ATTACKS	ACUTE CONG.	1
CHR. SIMPLE & CONG. ATTACKS	SAME	6
CHR. SIMPLE & CONG. ATTACKS	NORMAL	2

Fig. 4 (Posner and Schlossman). This "mixed group" of cases emphasizes the importance of an extended and careful study of the life history of a patient with glaucoma.

There were 28 cases in which one eye suffered from glaucoma of a type different from the other. In 18 of these, one eye had chronic simple glaucoma and the other congestive glaucoma. In 9 cases, one eye had chronic simple glaucoma and the other chronic simple glaucoma with congestive attacks. In one case, one eye suffered from chronic simple glaucoma with congestive attacks while the other had congestive glaucoma. This group of cases, together with the cases of chronic simple glaucoma with congestive attacks referred to in the previous paragraph, form a "mixed group" which is shown in Figure 4.

This "mixed group" of cases emphasizes the importance of an extended and careful study of the life history of a patient with glaucoma. In some instances, it may be necessary to defer classifying a case for several years until its true nature is revealed. At times, it may even be impossible to place a given case of glaucoma in any single category. This brings up the question, whether primary glaucoma should be considered as a single disease or as several diseases. It is possible that, with further advances in our knowledge, different cleavage lines will be used in the classification of glaucoma. In the light of our present information, however, the classification which we adopted is a practical one in that it offers the clinician a means of segregating his cases for therapeutic and prognostic purposes. In a future paper we hope to present some typical life histories of glaucoma patients, so as to give a more concrete basis for the evaluation of the various clinical pictures.

In following a case of glaucoma, it is important to obtain a detailed account of the patient's symptoms, and to record it, preferably in the patient's own words. The history may be the only clue to the diagnosis in many cases, especially in the congestive form during the glaucoma-free interval. These patients may present themselves immediately after a mild attack when the tension in the affected eye frequently drops to a lower level than that of the other eye. At this time, even provocative tests may give nega-

tive results. In this connection we would like to remark that pupillography may represent the only confirmatory evidence. One patient was carried for over a year by several ophthalmologists as a psychoneurotic, because the tension of his eye was always taken after a mild attack and found to be low normal.

Monocular cases

Our experience with the mixed group of glaucoma cases has forced the conclusion upon us that one cannot assume that both eyes will necessarily develop the same type of glaucoma or that they will show identical responses to miotics, surgery, or provocative tests. Even the gonioscopic appearance may be different in the two eyes. This lack of parallelism between the two eyes is graphically demonstrated by the comparatively large number of monocular cases which constitute 18 percent of the total (fig. 5). The incidence of monocular glaucoma was more than three times as great in the congestive (31 percent) types as in chronic simple (9.6 percent) type. The reasons for these differences are obscure, but some clinical evidence is available to permit a tentative explanation. Pupillographic studies have shown that even the monocular cases probably represent a binocular disturbance, since the pupillary reaction-curve is similar in the two eyes.[15] Mydriatics, acute disease, pregnancy, surgical procedures (ocular or general), emotional disturbances, trauma, excessive reading, movies, card playing, and occasionally even miotics may provoke a congestive attack. These precipitating factors probably act indirectly by disturbing the balance of the autonomic nervous system. It is possible that in chronic simple glaucoma the tension-regulating mechanism has achieved a certain degree of stability, although, of course, at a higher level, and hence is not apt to respond violently to disturbances of the autonomic nervous system.

In the congestive form, on the other hand, the tension-regulating mechanism is only occasionally embarrassed as a result of the aforementioned provocative factors. It may be assumed that there exists a threshold of vasomotor irritability which has to be passed before the disturbance of the equilibrium can provoke a congestive attack. This is independent of the tension because the degree of congestive symptoms need not be directly proportional to the height of the tension. Cases are observed in which the tension is over 70 mm. Hg (Schiøtz); yet congestive

MONOCULAR AND BINOCULAR CASES OF PRIMARY GLAUCOMA

66—70	2	3	2	7	11	18
71—75		2	1	3	9	12
76—80	8	2		10	1	11
81—85		1		1	1	2
86—90	1			1	1	2
TOTAL	40	71	36	157	208	365

Fig. 6 (Posner and Schlossman). The largest number of acute congestive glaucomas in any single 5-year period occurred between the ages of 76 and 80 years.

symptoms are entirely lacking. On the other hand, severe congestive attacks may be accompanied by tensions no higher than 35 mm. or 40 mm. Hg (Schiøtz).

Bloomfield[16] has shown that there is a deficiency of cholinergic substance in the aqueous of glaucomatous eyes. Pilocarpine, in addition to its effect on the tension, conserves this substance and raises the threshold of vasomotor irritability. Consequently, it lessens the frequency of attacks. The observation was made in 15 instances that the institution of treatment with pilocarpine was paradoxically followed by the appearance of acute attacks in previously asymptomatic forms of glaucoma. In some patients who

suffered from frequent mild attacks, miotic therapy decreased the frequency but increased the severity of the attacks to the extent that it was necessary to resort to surgical intervention.

This concept of a threshold explains the prevalence of monocular cases in congestive glaucoma. Even though the disturbance is present in both eyes (cf. pupillography) the threshold is exceeded only in one eye, in which case the other eye appears clinically normal. When the vasomotor imbalance becomes great enough to exceed the threshold, it probably acts like a trigger mechanism to set off a congestive attack. All this indicates that in chronic simple glaucoma the disturbance of the ocular and autonomic equilibrium is more stable, but at the same time more deeply rooted, than in the congestive forms.

Age incidence

The age of onset is shown in Figure 6. This table points out that 79 percent of cases began between the ages of 36 and 65 years. The drop in incidence in the higher age groups is less marked than appears in the figure, because of the progressive decrease in population in the higher age groups. In this connection, it may be significant that the largest number of acute congestive glaucomas in any single 5-year period occurred between the ages of 76 and 80 years. With this exception, the age incidence is approximately the same in congestive as in chronic simple glaucoma.

REFRACTIVE STATUS

−.75 to −1.50	13	20
+1.75 to +3.00	29	50
−1.75 to −3.00	11	21
GREATER THAN +3.00	38	44
−3.00 to −6.00	7	27
GREATER THAN −6.00		15

Fig. 7 (Posner and Schlossman). The spherical equivalents shown above were used in tabulating the refractive errors of 538 eyes.

Refractive status

The refractive errors of 538 eyes were tabulated in groups, using spherical equivalents as shown in Figure 7. In order to be able to compare the relative frequency of the refractive states with those found in the general population, the figure was arranged to conform with the scheme used by Jack-

REFRACTIVE ERROR IN DIOPTERS	CONGESTIVE		CHRONIC SIMPLE		TOTAL GLAUCOMA		NORMAL (JACKSON)	
	No.	%	No.	%	No.	%	No.	%
EMMETROPIA (−.50 to +.50)	44	23.3	114	27.8	141	26.2	—	12.4
HYPEROPIA above +.50	114	60.3	169	48.4	283	52.6	—	70.4
MYOPIA above −.50	31	16.4	83	23.8	114	21.2	—	17.2

Fig. 8 (Posner and Schlossman). Summary of refractive status as compared with Jackson's normals for the general population.

son.[17] He regards as emmetropic all errors between −0.50 and +0.50. Figure 8 shows that there were 52.6-percent hyperopic eyes and 21.2-percent myopic eyes in our cases of primary glaucoma. Jackson finds, for the general population, in the age group between 30 and 40 years, 70.4-percent hyperopes and 17.2-percent myopes. In the congestive group, there is a slightly higher percentage of hyperopic eyes than in chronic simple glaucoma, though the ratio of myopes to hyperopes still follows closely the normal distribution. It is apparent that a myope is just as susceptible to glaucoma as a hyperope. These conclusions agree with those of Loehlein[18] and Holst.[18a]

INCIDENCE OF HEREDITARY CASES

NUMBER OF EYES

CASES	CONGESTIVE AND MIXED	SIMPLE	TOTAL
OVERALL	235	422	657
HEREDITARY	35	53	88

Fig. 9 (Posner and Schlossman). All forms of glaucoma are represented in the hereditary group and they do not differ clinically from the nonhereditary group.

Of the 114 myopic eyes, 49 showed errors greater than −3.0D., and 15 of these had a myopia higher than −6.0D. These very high myopes were found only among patients with chronic simple glaucoma. Arnold Knapp[19] described 33 cases of glaucoma in high myopes and called attention to the fact that in these cases the tension tends to be low, even though the field deteriorates. Our experience corroborates his observations.

Hereditary glaucoma

Hereditary factors are present in many metabolic and nervous diseases, and glaucoma is no exception. The present study reveals 50 patients in 29 different families who had one or more relatives affected with primary glaucoma. This represents 13 percent of all cases of primary glaucoma. The total known number of affected patients in the 29 families is 100 (figs. 9 and 10). While in most families all of the members are affected with the same type of glaucoma, there are exceptions to this rule. All forms of glaucoma are represented in the hereditary group and they do not differ clinically from the nonhereditary forms.

Since 1842, when Benedict first called attention to the familial aspects of the disease, approximately 90 pedigrees have been reported in the literature. Because a large percentage of these deal with juvenile cases, and since hereditary tendencies are more conspicuous in the younger group (20 percent),[20] the impression was created that juvenile glaucoma is the only hereditary form. In our series there were only five patients (or 10 percent of the hereditary cases) in whom the disease began at the age of 35 or less.

In the families which were studied, the heredity seems to be of a dominant type. The incidence of hereditary glaucoma is likely to be even higher than our statistics indicate. It may even be possible that some sporadic cases are either mutations or the result of recessive inheritance. Only extensive genetic investigations could adequately explore the

HEREDITARY GLAUCOMA

NUMBER OF CASES IN EACH FAMILY	NUMBER OF FAMILIES	TOTAL NUMBER OF CASES IN ALL FAMILIES
2	10	20
3	8	24
4	6	24
5	1	5
6	2	12
7	1	7
8	1	8
TOTAL OF HEREDITARY GROUP	29	100

Fig. 10 (Posner and Schlossman). The total known number of affected patients in 29 families is 100.

hereditary mechanisms in this disease, particularly with respect to the possibility of a recessive form. A more detailed review of the subject will be published elsewhere,[21] and further investigations are now in progress.

It is important to be aware of the hereditary potentiality of glaucoma because it frequently enables the physician to make an earlier diagnosis. Through a study of hereditary glaucoma, one can obtain a great deal of insight into the early and the mild forms of the disease. If careful pedigrees were routinely taken on all glaucoma patients, the pooling of this data would materially advance our knowledge of the disease.

Juvenile glaucoma

Juvenile glaucoma cannot be sharply separated from adult glaucoma. This is borne out by the fact that the upper limit of the age of onset has been variously placed at between 30 and 40 years by different authors. The clinical picture of juvenile glaucoma does not differ fundamentally from adult glaucoma. We use the age of 35 years as the upper limit, as was suggested by Loehlein.[20] In our series there are 23 cases of so-called "juvenile glaucoma." There undoubtedly were cases which were not included in this group, merely because the glaucoma was not discovered until after the age of 35 years. It is obviously illogical to regard juvenile glaucoma as a separate disease. According to Anderson[22] 87 percent of hydrophthalmos cases are recognized during the first year of life; while Loehlein's figures show that 78.9 percent of juvenile glaucoma begins between 15 and 30 years of age. Of our cases 78 percent had their onset between the ages 26 and 35 years. This is in line with the statistics of Haag[23] who finds a progressively increasing incidence with increase in age. Because of the wide gap between the peaks of incidence (according to age) in hydrophthalmos and juvenile glaucoma, it is improbable that more than a small fraction of juvenile cases are related to congenital glaucoma.

Myopia is said to be much more prevalent in juvenile than in adult glaucoma. In our series there were only 6 myopes out of 23 and only 2 of them had a myopia higher than −3.0 diopters.

Mild vs. Severe glaucoma

A review of the cases which were followed for many years reveals a wide variation in the severity of the disease. While some cases end in blindness within a few years, others remain in the mild stage for 20 years and longer. The majority of glaucoma cases fall somewhere between these extremes. It seems absurd to refer to a case of mild glaucoma, which has lasted 20 years, as "preglaucoma" (Gradle),[24] prodromal glaucoma, or early glaucoma. From the clinical point of view, it is important to be able to prognosticate the probable severity and course in a given case. The criterion for placing a case in the mild group is the lack of deterioration of the field of vision over a period of several years. We had 40 such cases in our series. A number of these would never have been discovered had it not been for the fact that other members of the family suffered from the disease.

One illustrative case is that of L. C., whose father and brother suffered from primary glaucoma. A tentative diagnosis of glaucoma was made 25 years ago. She has symptoms of recurring mild ocular pain and blurring of vision. The only clinical evidence obtained has been the occasional elevation of tension to between 30 mm. and 35 mm. Hg (Schiøtz) and a pupillographic curve similar to that found in primary glaucoma. Even homatropine did not raise the tension during a glaucoma-free interval, but the Knapp adrenalin test[25] was positive. Fields and central vision have remained normal.

This type of case may be looked upon as a true compensated glaucoma, since the rise

of tension is not detrimental to the function of the eye; on the contrary, it may even help maintain its physiologic functions.

At the other extreme is a group of cases, generally of the chronic simple type, which do not respond to miotics, which show rapid deterioration of the fields and react unfavorably to any form of iris surgery. These are the malignant cases.* Fortunately, the incidence of this type of glaucoma is low. We had 11 such cases in our group. If such a case is suspected, it may be wise to resort to cyclodialysis, particularly if a filtering operation (involving trauma to the iris) has proved disastrous despite good surgical technique. As a general rule, if a case of glaucoma fails to respond satisfactorily to a mechanically well-executed filtering operation, it is advisable not to repeat the same type of surgery immediately. Whenever possible, it is better to wait, since the normalization of tension may be delayed as long as six months to a year. If the field continues to deteriorate, cyclodialysis should be the operation of choice.

*In the literature malignant glaucoma is usually referred to as synonymous with hemorrhagic glaucoma. We do not use this term in the same sense.

For the majority of the more typical glaucoma cases, Elliot's classification scheme[26] is of practical clinical value. He divides his cases into: (1) Early glaucoma, (2) established glaucoma, and (3) late glaucoma. Following a somewhat similar pattern, Kronfeld and McGarry[27] have divided their cases into four stages depending on the degree of field loss. They claim that this has prognostic value.

ASSOCIATED DISEASES

Tables 1 and 2 list the associated ocular and general diseases respectively. Among the former were 59 cases with cataract, 16 cases

of corneal opacity, 7 cases of diabetic retinopathy, and 7 cases of drusen in the macula. It is difficult to know whether any causal relationship exists or whether these conditions are merely coincidental.

Among the general diseases associated with glaucoma, there were 64 cases of essential hypertension, 31 cases of diabetes, 25 cases of arteriosclerosis (including coronary disease), 14 cases of gall bladder disease, 8 cases of obesity, 11 cases of allergy, 8 cases of asthma, 7 cases of hyperthyroidism, and 3 cases of migraine. Clinical, as well as pupillographic evidence, points to a probable etiologic connection between glaucoma on one hand, and hypertension, diabetes, and obesity on the other. Elwyn[28] has pointed out that in glaucoma, like in hypertension and diabetes, there is a disturbance of the regulatory center of the autonomic nervous system, probably in the hypothalamus.

Seven cases of nerve deafness were observed in association with the simplex form. Some of them had a long history of intermittent tinnitus. One patient gave a family history of deafness. We are unable to state definitely the relationship between deafness and glaucoma, but there may be a disturbance of the pressure equilibrium in the inner ear analogous to that present in the eye.

Although definite psychoneurosis was present in only 7 cases, many more patients showed emotional instability of a less pronounced degree. This is in accord with a currently accepted notion, emphasized by Schoenberg,[29] that psychosomatic factors play an important role in the pathogenesis and course of glaucoma.

Glaucoma without hypertension

The occasional finding of optic atrophy with cupping and field changes has given rise to speculation as to the relationship of such cases to glaucoma on the one hand and to the optic atrophies on the other. Thiel[30] has introduced the term "pseudoglaucoma" for these cases. He believes that the majority of them are related to calcification of the internal carotid arteries. Knapp[31] has reported 10 cases of this type. Sjogren[32] in a recent discussion of this subject prefers to confine the use of the term pseudoglaucoma to those cases in which the optic atrophy and cupping can be definitely ascribed to pressure upon the optic nerve or chiasm. He believes that glaucoma without hypertension is a type of chronic simple glaucoma, because of the many transitional and atypical forms of glaucoma found in association with this condition. We subscribe to his view. In our group of chronic simple glaucoma, there were two patients who had typical field defects and cupping of the nerve without hypertension.

We have had under observation over periods of many years eight patients who show deep cupping similar in appearance to that found in glaucoma but without field changes or elevation of tension. Such cases could also be included under pseudoglaucoma. It is interesting to speculate that an optic atrophy superimposed upon a deep physiologic cupping may give a picture indistinguishable from glaucoma without hypertension.

Indeterminate group

The diagnosis of primary glaucoma should be limited to those cases in which the cause is not known. As soon as an adequate cause is discovered, it is mandatory to reclassify the case as secondary glaucoma. In recent years there has been a tendency, however, to speak of glaucoma as secondary, whenever a coexisting ocular condition is found, without being too critical about the causal relationship. For example, glaucoma which follows cataract extraction is, as a matter of course, regarded as secondary. Careful analysis and prolonged observation of these patients revealed that 8 out of 19 cases in the aphakic group might actually have been suffering from primary glaucoma. The cataract surgery may have had no relation

to the development of the glaucoma or it may have hastened the onset in a predisposed patient.

F. G., a 66-year-old woman with high myopia, had a cataract extraction in her left eye at the age of 58 years. This was followed by glaucoma with deep cupping and loss of the nasal field. Five years later, the tension in the right eye was found to be elevated to between 33 and 36 mm. Hg (Schiøtz). A diagnosis of asymptomatic glaucoma simplex of the right eye was made. A positive lability test[33] was obtained recently. The patient was observed for eight years.

A. S., a 75-year-old woman, developed asymptomatic glaucoma 18 months after a Ziegler discission on her right eye at the age of 64 years. The tension was consistently between 40 and 50 mm. Hg. Pallor and cupping of the disc with progressive loss of field ensued. The other eye remained normal. However, paredrine used as a provocative two years after the onset of the hypertension in the right eye, raised the tension of the left eye from 20 to 35 mm. Hg. This patient was followed for 16 years.

The fact that the glaucoma in these two cases was asymptomatic and that chronic simple glaucoma or a tendency to it was demonstrated in the unoperated eye, leads one to suspect that the aphakic eyes were probably predisposed to glaucoma even prior to surgery. Without a long follow-up, the true nature of the glaucoma in some of these cases would probably not have been uncovered. Before committing oneself to a diagnosis of secondary glaucoma in an aphakic eye, one should always do a provocative test, preferably a lability test or a water-drinking test,[34] on the unoperated eye.

There is a great deal of confusion regarding the relationship between glaucoma and iridocyclitis. According to the prevailing dogma, any case of glaucoma which shows the presence of cellular elements in the aqueous or on the posterior surface of the cornea, no matter how few in number, is relegated to the class of secondary glaucoma. Yet, no one can explain satisfactorily in what manner a few cells in the aqueous or a few keratic precipitates can produce ocular hypertension in the absence of a plasmoid aqueous.

We reported nine patients who showed recurrent unilateral attacks of glaucoma with mild cyclitic signs.[35] These may be regarded as a clinical entity and they probably form an intermediate group which shows characteristics of both primary and secondary glaucoma. We have proposed the name of "recurrent glaucomato-cyclitic crises" for this syndrome.

There were two cases which showed iridocyclitis as a complicating incident in the course of primary glaucoma. On the other hand, there were 18 cases of chronic uveitis in which true secondary glaucoma supervened. Glaucoma with uveitis may be classified in the following manner:

1. Iridocyclitis, either precipitating an acute attack of primary glaucoma or incidental to the course of primary glaucoma.
2. The syndrome of recurrent glaucomato-cyclitic crises.
3. Iridocyclitis producing true secondary glaucoma as a result of changes in the filtration channels or by the osmotic effect of a plasmoid aqueous.
4. Late secondary glaucoma as the sequel to organic alterations produced by iridocyclitis, like iris bombé.*

Two cases of mild bilateral glaucoma were associated with nevus flammeus. In one case the nevus occupied the right arm and right half of the trunk but spared the face. There were some aneurysmal dilatations over the right disc. The other case showed a nevus flammeus of the face on the right side. Pupillography in both instances showed cen-

* We do not wish to imply that even in this condition the mechanical factors (anterior and posterior synechias) are alone responsible for the ocular hypertension. Weiss, in *Kurzes Handbuch für Ophthalmologie*, Vol. II, p. 67, makes note of the fact that there are cases of iris bombé which are not accompanied by glaucoma.

tral sympathetic disturbances, but not of the type found in primary glaucoma. The water-drinking test was positive in each case, the right eyes showing greater elevation of tension. Both patients responded well to 1-percent pilocarpine.

Usually the glaucoma associated with nevus flammeus is infantile or juvenile and limited to the affected side. Ehrlich[36] reports one case of bilateral glaucoma with unilateral nevus flammeus and refers to the only other similar case in the literature. The glaucoma in both of these cases was of a severe degree and of the juvenile type. In our two cases the glaucoma was bilateral and unusually mild. Even if vascular dilatations, as is generally assumed, were present in the uvea on the affected side, it is difficult to see how this could account for the bilateral mild glaucoma which was present in these cases. For this reason, we thought it best to set them apart from the general group of secondaries.

One patient had attacks of glaucoma associated with marked edema of the lids and conjunctiva since the age of 38 years. She also suffered from allergies, asthma, and hyperinsulinism. Attacks often occurred after menstruation. It is possible that this is a case of chronic congestive glaucoma with manifestations suggestive of allergy. We have classified this patient, for the present, as allergic glaucoma.

One patient, A. L., a man with myopia of −20D. developed retinal detachment of the right eye at the age of 18 years. This was followed seven years later by an asymptomatic glaucoma in the same eye. The tension of the left eye was normal at this time; but five years later, at the age of 32 years, it became elevated. The fundus shows no chorioretinal degeneration. Cyclodialysis has normalized the tension in the left eye for the past 1½ years. In this patient the glaucoma in the right eye might have been regarded as secondary to retinal detachment. However, the subsequent development of asymptomatic glaucoma of the simplex type in the other eye casts doubt on the original diagnosis.

Two cases of glaucoma were associated with retinitis pigmentosa. W. F., a 52-year-old man, has retinitis pigmentosa which was discovered in 1936 at the age of 41 years. Following a head injury, in 1940, he began to see halos around lights. The tension was moderately elevated in both eyes, but responded temporarily to pilocarpine. Two weeks after medication was instituted, an acute attack occurred in the right eye. Bilateral iridencleisis normalized the tension. The fields are those characteristic of retinitis pigmentosa. The second patient, N. F., a 38-year-old white woman, with retinitis pigmentosa, developed bilateral glaucoma of the chronic congestive type. Two of her sisters have retinitis pigmentosa, but only one of them has developed glaucoma. One brother and one sister are normal.

The association of retinitis pigmentosa and glaucoma was first noted by Galezowski in 1862.[37] Since then, numerous cases have been cited in the literature. Schmidhauser (cited by Leber[38]) found the incidence of glaucoma in retinitis pigmentosa to be 2.78 percent, while the incidence of glaucoma in all patients of the Tuebingen Clinic was 0.73 percent. Leber interprets this difference in incidence to mean that the association of the two diseases is not purely coincidental. Von Hippel[39] suggests as the cause for the glaucoma, an obstruction of the drainage channels by pigment. Blessig[40] reports a sibship of nine members of whom two sisters had chronic simple glaucoma alone, while two brothers and one sister suffered from pigmentary degeneration without ocular hypertension. The glaucoma associated with retinitis pigmentosa may be either of the congestive or the chronic simple variety. It behaves no differently from primary glaucoma. The data on this condition is insufficient for reliable statistical studies and the paucity of the anatomic material makes it difficult to determine the causal relationship between the two diseases.

The indeterminate group (fig. 11) was introduced here primarily because of the difficulty of classifying certain cases of glaucoma as either primary or secondary, even after prolonged and careful study. The

eight cases associated with aphakia, as well as the cases with allergic glaucoma and with retinal detachment, are probably primary glaucoma. The nine cases of recurrent glaucomato-cyclitic crises are probably an entity. They may be considered intermediate between primary and secondary glaucoma. The glaucoma associated with nevus flammeus is probably secondary. The cases with retinitis pigmentosa are difficult to classify. Even Thiel[41] admits that their pathogenesis is obscure.

Secondary Glaucoma

The 76 cases of secondary glaucoma are listed in Table 3. The most common cause was uveitis. Cataract extraction, including discissions, accounted for 11 cases. This number does not include the eight patients mentioned in the indeterminate group. There were nine cases of buphthalmos and one case of microphthalmos. Of the former, eight were males and only one was a female.

Two cases associated with detachment of the anterior layers of the iris are included. Schoenberg, in 1927, reported the first case in a man aged 51.[42] The second case is a 46-year-old man with high myopia, microcornea, and congenital lues. Detachment of the anterior layers of both irides was first noted at the age of 34 years. Four years later, he saw rainbows and the tension was found to be elevated. Subluxation of the left lens was present.

Vogt[43] notes the association between detachment of the anterior mesodermal layer of the iris, spontaneous subluxation of the lens, and glaucoma. He considers this condition to be due to senile degeneration of the mesodermal structures. However, both of our cases occurred in patients under 55 years of age. The glaucoma in these cases may be the result of analogous degenerative changes in the pectinate ligament.

As is evident from Table 3, secondary glaucoma is a heterogeneous group which is characterized by the association of ocular hypertension with some other ocular disease or abnormality. We need not necessarily assume a direct causal relationship between the two conditions in every instance. Very often the exact mechanism involved in the

production of hypertension is not known. Duke-Elder,[44] in his definition of secondary glaucoma, is careful not to imply a cause and effect relationship. The difficulty of deciding, in a given case, whether the glaucoma is primary or secondary is borne out by the fact that patients with primary glaucoma are no less subject to other ocular diseases than nonglaucomatous individuals (see fig. 4). Three cases of primary glaucoma developed thrombosis of the central retinal vein some time after the diagnosis of glaucoma had been made. Moreover, patients with other ocular diseases may, in the course of time, develop glaucoma.[45]

Comments

This study is an attempt to consider the glaucoma problem from a purely clinical point of view. The latest developments in research along experimental and physicochemical lines will be dealt with at a future time. The statistical and analytic study of our material reveals certain features which will be briefly reiterated in order to clarify a few more or less fundamental concepts.

When one compares an isolated case of acute congestive glaucoma which is cured by surgery with a case of asymptomatic chronic simple glaucoma in which the tension is within normal limits or only slightly elevated, one has the impression that here are two separate diseases. Analysis of a large number of cases, however, invariably reveals gradations in the symptomatology and course to such an extent, that one is unable to draw a sharp line of demarcation at any point in the series. Furthermore, there is a mixed group of cases in which one may find either a congestive glaucoma in one eye and chronic simple in the other or a chronic simple glaucoma with acute exacerbations in one or both eyes. One is forced to accept the inevitable conclusion that, in the present state of our knowledge, primary glaucoma should be regarded as a single clinical entity. It is possible that further investigations will reveal primary glaucoma to be more than one disease; but the criteria for such a classification will not be the same as those generally used at present. We have utilized the conventional nomenclature because it is useful from a clinical point of view, and because it does not carry any etiologic implications.

Further evidence for assuming a unitary concept of primary glaucoma is found in a study of hereditary cases. In the same family tree, one may find examples of congestive and chronic simple glaucoma. Pupillography,[46] which is a means of studying the state of the central autonomic nervous system through the pupillary response, shows the same type of curve in congestive and chronic simple glaucoma.

On the other hand, there are some points of difference between the two forms of glaucoma which may be used as arguments for regarding them as separate entities. The prevalence of females over males is greater in congestive than in chronic simple glaucoma. Also, there are more hyperopes and monocular cases in the former than in the latter. The shallow anterior chambers and narrow angles predominate in the congestive forms.

Glaucoma should be regarded as a constitutional disease in the sense of a dysfunction of the central regulatory mechanism[28] of the autonomic nervous system similar to the group of metabolic disorders such as diabetes, hypertension, and obesity. It is possible that this dysfunction constitutes the primary, or at least the predisposing cause, while the various anatomic and physicochemical conditions of the eye are modifying or precipitating factors.

The fact that congestive glaucoma occurs in a small percentage of eyes with narrow angles and may occur also in eyes with wide angles tends to indicate that the angle plays a secondary role in the etiology of the disease. It should be remembered that the width of the angle and the depth of the

anterior chamber are intimately related to the architecture of the remainder of the eye, such as the shape of the ciliary body, the mode of attachment of the iris root, and the position of the anterior surface of the lens. Thus, while eyes with narrow angles are more prone to develop the congestive form of glaucoma, the causal relationship between the angle and glaucoma has not been established. In fact, Busacca[47] has questioned the entire concept by pointing out that the angle is not a static structure but that its width varies from time to time.

It is common experience to find that the tension varies with different individuals within wide limits, but that it is fairly constant for each individual. Generally, both eyes have the same tension. This corroborates the hypothesis of a central regulatory mechanism for the intraocular pressure. A significant difference of tension between the two eyes is more important as presumptive evidence of glaucoma than an elevation of tension which is equal in both eyes. Downey[48] has recently emphasized this diagnostic point. At least four of our patients had a continuously elevated tension above 35 mm. Hg without showing any deterioration of field or ophthalmoscopic changes for from two to three years. It appears that in some cases, pathologically increased tension does not produce any interference with function. It may be assumed that intraocular pressure is kept at a definite level which is optimal for the maintenance of the normal function of that eye. The level varies with each individual. We do not know why these variations are present; nor do we know what constitutes the upper limit of normal for any given eye. Consequently, the assumption that a tension above 30 mm. Hg is abnormal need not hold for all cases. There are normal individuals whose tension is around 30 mm.; yet these patients show negative responses to provocative tests and never develop glaucoma. In the early stages of glaucoma, the ocular hypertension may be a necessary compensatory mechanism, serving a useful purpose in that it helps to maintain normal metabolic conditions in the eye. For example, sclerosis of the choriocapillaris or impaired permeability of the lamina vitrea may interfere with the nutrition of the neuroepithelium. It was shown by Evans[49] and Berens and Posner[50] that there is a circulation of intraocular fluid from the vitreous into the retina and optic nerve. Increase in intraocular pressure would tend to favor the flow of fluid into the retina and thus supplement the nutrition of the retina.

As long as this mechanism is adequate to maintain the normal function of the retina and the field does not deteriorate, one may regard the glaucoma as being in a compensated phase. As soon as field loss sets in, the limits of compensation have been exceeded. It may be interesting to speculate, in the light of this hypothesis, why the central area and the temporal periphery of the visual field are the last to be destroyed. The increase in intraocular pressure, while helping to maintain the function of the neuroepithelium, exerts a deleterious effect on the retinal circulation. Consequently, the relatively avascular areas of the retina (macula and nasal periphery) survive longer than the more vascular zones. This relationship is more fully discussed elsewhere.[51]

The following case is suggestive of the role which ocular hypertension may play in maintaining the normal metabolism of the lens. Since 1942, H. F., a 57-year-old chemist, has had an almost continuous right ocular hypertension, usually above 40 mm. Hg (Schiøtz). Up to the present, his visual acuity has remained 20/15 and his fields have shown no changes other than downward enlargement of the right blindspot. The tension of his left eye has consistently remained around 22 mm. Hg. Recently, he developed a posterior cortical cataract in his left eye, while his right lens has remained normal. The general impression that surgical intervention in a glaucomatous eye (with the subsequent reduction of tension) often hastens the development of a cataract, may

have a basis in an interdependence between the ocular tension and the metabolism of the lens.

The concept that a diseased process is an expression of an imperfect or inadequate attempt at compensation for another disturbance is in line with the principles of general pathology which have been excellently formulated by Aschoff.[52]

Earlier in the paper it was shown that the characteristics of congestive glaucoma as clinically observed may be better interpreted by assuming the existence of a threshold of vasomotor irritability which determines the ease with which a congestive attack becomes manifest. This may vary with different patients and at different times. It is not known why the threshold is more easily exceeded in some cases than in others, but a few clues are suggestive. In congestive glaucoma the ratio of male to female eyes was 1:26 while in asymptomatic chronic simple glaucoma, it was 1:1. Women, especially in the menopause, show greater vasomotor instability than men. The relationship of congestive glaucoma to vasomotor phenomena is further demonstrated by the prevalence of congestive attacks in association with allergy. Nine out of 11 patients with allergy had congestive glaucoma; 2 had chronic simple glaucoma.

We have considered the increase in tension as a compensatory mechanism which is controlled by the central autonomic nervous system. The nature of the primary affection in the eye is not known. It may be related to senile or nutritional changes. There is ample evidence that disturbances other than ocular hypertension play a role in the causation of the clinical picture of glaucoma. In the first place, the height of the tension bears no definite relationship to the severity of the field loss. Secondly, many patients who have been normalized by surgery or miotics, continue to have progressive deterioration of the visual field. While the aforementioned considerations are indicative of the presence of a factor other than hypertension, additional evidence may be adduced from a consideration of cases of glaucoma without hypertension. Magitot[53] divides this group into three categories:

1. Myopic glaucoma with low tension.
2. Mild intermittent unilateral glaucoma.
3. Field changes and excavation of the disc either with or without calcification of the internal carotids.

Sjogren[32] does not draw a sharp line between glaucoma with and without hypertension, but rather stresses the numerous transitional forms which are frequently observed. He believes that the basis of glaucoma lies in a circulatory disturbance independent of the intraocular pressure which constitutes only one symptom of the disease. Although our series includes only two cases of glaucoma without hypertension, there are others in whom the elevation of tension was never marked and who, nevertheless, showed extensive field loss. This is particularly true of the cases of chronic glaucoma associated with high myopia.

We feel that, although the tension undoubtedly plays an important role in glaucoma, there may be other factors which contribute to the causation of the disease. The following possibilities are suggested.

1. Disturbance of central autonomic nervous system (may include psychosomatic factors).
2. Vasomotor instability.
3. Hereditary factors.
4. Arteriosclerosis (a) General, and (b) Local.[54]
5. Blood pressure.[55]
6. Metabolic disturbances: diabetes, obesity, endocrine.
7. Relation of intracranial to intraocular pressure.[56]
8. Degenerative changes in the nervous tissue. (a) Lacunary degeneration in the brain and nerve;[32] and (b) Schnabel's cavernous atrophy.
9. *Local factors:*

a. Anatomic (Schlemm's Canal, chamber

angle, retinal circulation, choroid, and so forth).

b. Nutritional.

c. Congenital.

d. Physicochemical:

(1) Increased capillary permeability.

(2) Diminution in cholinergic substance.[16]

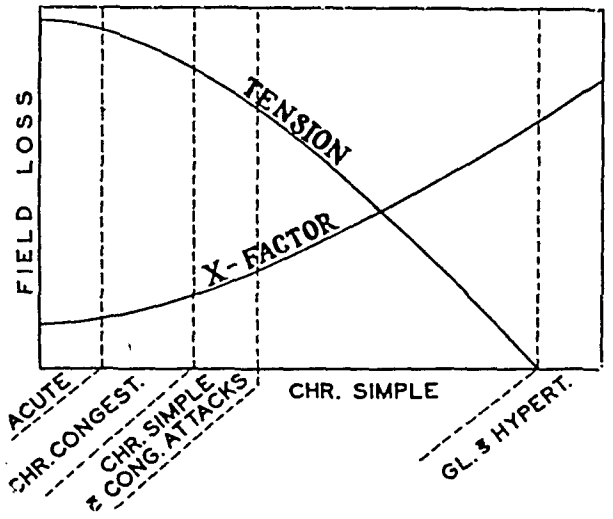

Fig. 12 (Posner and Schlossman). SCHEMATIC REPRESENTATION OF THE ROLES PLAYED BY OCULAR HYPERTENSION AND THE X-FACTOR* IN THE PRODUCTION OF FIELD LOSS IN PRIMARY GLAUCOMA. Glaucoma is shown as a single disease with varying clinical pictures. A representative sample of cases forms a continuous series in which the field loss appears to be dependent upon the aforementioned variables. In acute glaucoma, the duration and height of the ocular hypertension play the predominant role. In chronic congestive and chronic simple glaucoma with congestive attacks, the X-factor plays a more important role. In chronic simple glaucoma, the field change is dependent partly on the X-factor and partly on the hypertension. In this group there are cases with relatively low degrees of hypertension in which the progressive field loss suggests that the X-factor plays a predominant role. This group merges into glaucoma without hypertension where the X-factor is obviously the chief cause of the field loss.

* Sum total of all other disturbances.

In Figure 12 we have attempted to visualize graphically how the field changes may be regarded as a function of the tension and the sum total of the other factors, which we call the "X-factor" for the sake of simplicity. In acute congestive glaucoma, the tension factor plays the predominant role and the field changes appear to depend directly on the height and duration of the hypertension. In glaucoma without hypertension, on the other hand, the X-factor is chiefly responsible for the loss of field. The vast majority of the cases fall somewhere between these two extremes. In chronic simple glaucoma without symptoms, the visual field changes show less relation to the tension than in the chronic congestive form, while the mixed group which contains elements of both may be placed between chronic congestive and chronic simple glaucoma.

The hypotheses expressed in this paper represent the conclusions drawn from the material available for our study. They are offered with the hope of stimulating further investigations along these and other lines of thought.

SUMMARY

The present study is a correlation of 474 cases of glaucoma from private practice, of which 373 are primary; 158 patients have been followed for five years or longer.

In this series there are 71 eyes with acute congestive, 140 eyes with chronic congestive, and 422 eyes with chronic simple glaucoma. Twenty-four additional eyes showed chronic simple glaucoma with congestive attacks (Schmidt-Rimpler). In the congestive form the ratio of male to female eyes was 1 : 2.6. In glaucoma simplex there was only a slight preponderance of females over males, while in asymptomatic glaucoma simplex, the ratio was 1 :1. The incidence of monocular cases was three times as great in the congestive types as in chronic simple.

In 60 percent of the cases of primary glaucoma, the onset was between 41 and 60 years of age. Considering refractive errors between +0.5D. and −0.5D as emmetropia, there were 141 emmetropic, 283 hyperopic, and 114 myopic eyes. The ratio of hyperopes to myopes is similar to that found in the general population.

Fifty cases showed hereditary tendencies. The pedigrees studied exhibited dominant

inheritance. In 23 patients, the onset was below 35 years of age. These juvenile cases differed in no way from the rest of the group. Forty patients followed a very mild course and many of them would have remained unrecognized were it not for the attention paid to heredity.

Besides the cases of primary glaucoma, there were 25 which could not be definitely classified as either primary or secondary. Of this group, nine had the syndrome of recurrent glaucomato-cyclitic crises (recurrent attacks of unilateral glaucoma with mild cyclitic signs). Eight patients with aphakia had glaucoma which probably was primary. Bilateral mild glaucoma with unilateral nevus flammeus was present in two cases and two patients had retinitis pigmentosa associated with glaucoma.

In the light of present knowledge, primary glaucoma is regarded as a single disease in which the primary or predisposing cause consists of a dysfunction of the central regulatory mechanism, while the various anatomic and physicochemical conditions of the eye are modifying and precipitating factors.

A case of mild glaucoma without field loss is considered to be in a compensated phase, in the sense that the hypertension may serve a useful purpose. The prevalence of monocular cases in the congestive group, and the action of miotics in modifying the congestive attacks, may be explained by assuming the existence of a threshold of vasomotor irritability which must be exceeded before a congestive crisis manifests itself. In addition to ocular hypertension, there are other factors which influence the course of glaucoma. In the various forms of glaucoma, the tension and the other factors (X-factor) play a varying role in determining the progress of the field changes.

SOME PROBLEMS IN THE CALIBRATION OF TONOMETERS*

JONAS S. FRIEDENWALD, M.D.
Baltimore, Maryland

The present study was undertaken at the request of the Committee on Standardization of Tonometers of the American Academy of Ophthalmology and Otolaryngology and has been supported by a special grant from the Academy. Laboratory space for the work was provided by the Wilmer Institute and some of the human eyes used in the calibration measurements were supplied by the Eye Bank Associates, Inc. The present report concerns some of the preliminary aspects of the work and an attempted analysis of the factors that must be taken into consideration in such calibrating measurements.

The reasons for undertaking this work were many. In the first place, the magnificent study of Schiøtz in this field has never been comprehensively checked by any other investigator and, as will appear in the analysis below, Schiøtz's study is open to certain possible criticisms, the significance of which could be evaluated only by fresh experimental data.

In the second place, the Committee on Standardization of Tonometers has adopted certain specifications for the construction and dimensions of the Schiøtz tonometer. These specifications were based on a careful analysis of Schiøtz's own description of his instrument. It was found necessary, however, to specify some characteristics in respect to which Schiøtz's description is ambiguous. Choice in respect to such specifications has been guided by actual measurements on instruments certified by Schiøtz himself, but since some variation in the instruments was found there remained slight uncertainty as to how closely these modern specifications duplicated the instrument which Schiøtz used as a reference standard and which he used in his calibration experiments. Some of Schiøtz's calibrating measurements lend themselves readily to accurate reproduction and by this means the present standard instrument could be compared with that of Schiøtz.

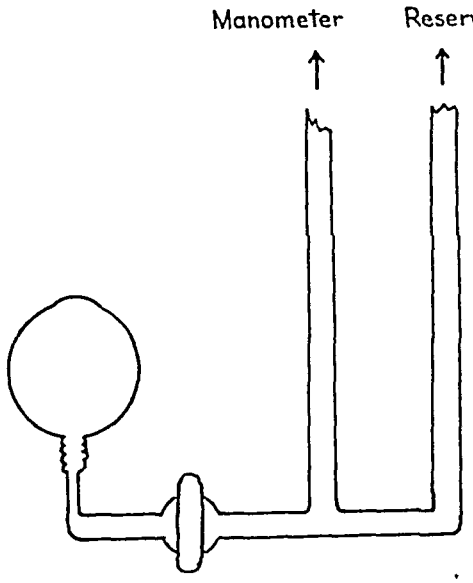
In the third place the calibration experiments of McLean have led to a somewhat different estimate of the average normal intraocular pressure than had been reached by Schiøtz. The resulting disagreement between the Schiøtz and McLean scales has been a constant source of confusion. The present undertaking afforded an opportunity to test simultaneously a reference-standard Schiøtz, McLean, and also Gradle tonometer on the same set of eyes. While all sources of systematic error may not have been excluded in these measurements, it is to be expected that calibration scales based on these measurements would yield concordant clinical readings on the same eye with the three different instruments. For these measurements, a reference-standard Schiøtz instrument was contributed by the Sklar Company. This instrument was specially machined to correspond as closely as possible to the specifications of the Committee on Standardization of Tonometers. A similar reference-standard McLean tonometer, measured and adjusted by Dr. McLean, was contributed by Dr. McLean, and a reference-standard Gradle tonometer was contributed by the American Optical Company. Parallel measurements were made with all three instruments. The present report, however, concerns only those made with the Schiøtz.

I. OPEN MANOMETER READINGS

It will be recalled that in his calibrating experiments Schiøtz attached eyes to a manometer by a cannula inserted through the

* Presented at the 83rd annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June, 1947. From the Wilmer Ophthalmological Institute of The Johns Hopkins University and Hospital.

optic nerve (fig. 1). Introducing any desired pressure into the eye, he then rested the tonometer on the cornea and recorded the tonometer scale reading. Two sets of readings were made. In one set which he called the "open manometer" readings, the stopcock between the cannula and the manometer was



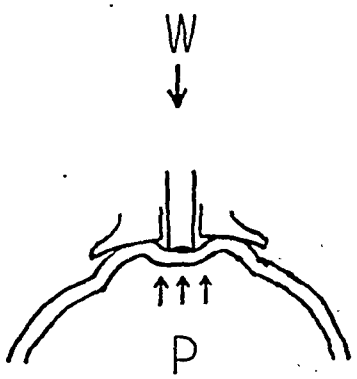


Fig. 1 (Friedenwald). Diagram of apparatus used by Schiøtz in calibrating his tonometer.

left open. These readings served to correlate the scale reading with the intraocular pressure in the eye while it carried the weight of the tonometer. In the second set of readings, which Schiøtz called "closed manometer" readings, a desired pressure was introduced into the eye, the stopcock then closed, and the tonometer applied. The closed manometer readings were the ones actually used for calibration purposes but the open manometer readings were useful to Schiøtz as a preliminary guide.

The open manometer readings showed, according to Schiøtz, much less experimental scatter from eye to eye than did the closed manometer readings, and this is indeed to be expected since variations in ocular rigidity would have much less effect on the former than on the latter readings. A repetition of the Schiøtz open manometer measurements could, therefore, afford a very good check in respect to whether the present reference-standard instrument does in fact closely resemble the original Schiøtz in certain important characteristics. Open manometer readings were, therefore, made on pig, cat, rabbit, and human eyes. Ten to 20 eyes of each species were used. Corneal curvatures were measured with a keratometer on all except the pig eyes, and cat and rabbit eyes were chosen whose corneal curvatures closely approximated the average normal human corneal curvature of 7.8- to 7.9-mm. radius.

In order to compare these various sets of data with each other and with the original observations of Schiøtz, some empyrical formula needs to be fitted to the data. The following argument was followed in arriving at such a formula. When the tonometer plunger comes to rest at a given scale reading, the downward force of the weight of the

$$W = PA$$

Fig. 2 (Friedenwald). Forces supporting the tonometer when it rests on the cornea.

plunger must be balanced by an upward force of the intraocular pressure acting over the area of indentation (fig. 2). This equality of the upward and downward forces can be expressed by the equation formulated by Fick and Maklakow:

$$W = PA$$

provided the weight W, pressure P, and area A are given in appropriate units. Thus if the

weight is given in grams, the area in square centimeters, the pressure must be expressed in grams per square centimeters. Now, if it should turn out that for a given tonometer scale reading, that is for a given depth of indentation, the area was constant then, by plotting our data with W/P as ordinate and scale readings as abscissa, all of the data for a given species of animal should fall on the same curve. The results of such a plot of the data obtained on cats, pigs, and human eyes is shown in Figure 3 in which Schiøtz's original data on human eyes are also shown. Each point plotted represents the average scale reading obtained on 7 to 20 different eyes with a given plunger load and intraocular pressure. It will be seen that the data do in fact fall on straight lines with no significant variation in respect to plunger weight. It follows that, for a given scale reading, the area of indentation is the same irrespective of whether this indentation is produced by a small plunger load at a low intraocular pressure or by a larger plunger load at a higher intraocular pressure. A straight line may be fitted to these data according to the formula

$$\frac{W}{P} = a + bR.$$

By the method of least squares, the values for a and b can be determined. For instance in the data on the cats' eyes a = 0.0795, b = 0.0091.

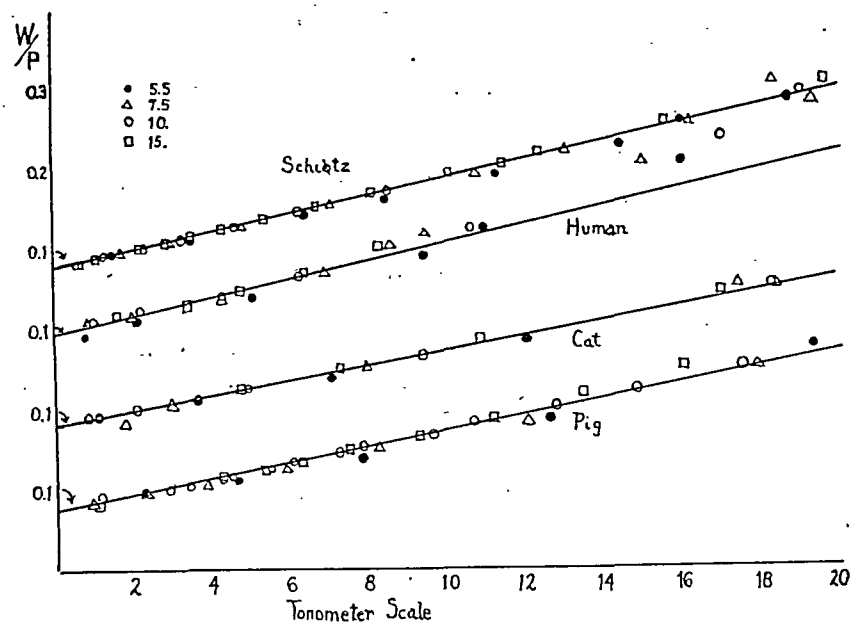

Fig. 3 (Friedenwald). Plot of open manometer data on human, pig, and cat eyes compared with Schiøtz original data on human eyes. The ordinate scale for each successive set of readings is shifted by 0.1 unit.

Applying the same analysis to the data obtained on the different species tested, and also to the data of Schiøtz's original measurements on human eyes,[1] one obtains a set of closely similar values for the coefficients a and b as shown in Table 1. The deviations between these different calculated values of the coefficients are probably statistically significant, but it is to be doubted whether they represent biologically significant differences. Thus, while there are differences between the values obtained on the four species, the values obtained from Schiøtz's data are identical with those I have obtained on the pig and differ slightly from those that I have

obtained on human eyes. Moreover, taking eyes with the same corneal curvature—cat, rabbit, and human—the corneal thickness is greatest in the cat, least in the rabbit. The coefficients, however, do not lie in any reasonable relationship to corneal thickness. In the calculations later in this paper I have used the coefficients derived from the measurements on cats' eyes, because these lie near to the average values for the whole series, and because the technician who made these particular measurements did so with unusual care and reliability.

TABLE 1

ANALYSIS OF DATA ACCORDING TO THE FORMULA $W/P = a + bR$

	a	b
Human	.085	.012
Human (Schiøtz)	.075	.0105
Pig	.075	.0105
Cat	.0795	.0091
Rabbit	.080	.0086
Average	.079	.0101
Value Chosen	.0795	.0091

In view of the close agreement between Schiøtz's open manometer data and those which I have obtained on these four species, it may be concluded that in respect to those aspects of tonometer construction which are involved in this type of reading, the present reference-standard instrument is a good reproduction of Schiøtz's original instrument.

The close agreement of the open manometer readings in the four different species requires some further comment. It is to be remembered that the pig's cornea is about 2-mm. thick, the rabbit's only about ½ mm., while the cat and human corneas fall between these extremes. Moreover, while the cat and rabbit eyes were chosen to have corneal curvatures closely approaching the average human, the radius of curvature of the pig's cornea is approximately 12 mm. If there were an appreciable resistance of the cornea to indentation one would expect an appreciable difference in the readings made on thick as against thin corneas. The fact that no difference was found which could be related to corneal thickness indicates that corneal resistance to indentation is negligibly small.*

One other aspect of these measurements should be noted. From the analysis above it is seen that the ordinates in these curves represent the area of the plunger indentation. Now, when the plunger is just flush with the foot plate, that is, for zero indentation, it must be supported by an area of cornea equal precisely to the area of cross section of the plunger. This area can readily be calculated and amounts to 0.0707 cm.^{2} One can inquire at what tonometer scale reading does the ordinate have this expected value.

As seen in Figure 4 which represents an enlargement of the type of curve plotted in Figure 3, the scale reading for zero indentation is not at zero on the tonometer scale but at minus one. The explanation of this apparent anomaly is quite simple. The radius of curvature of the tonometer foot plate and of the foot of the plunger are both 16 mm. When the instrument is put upon a test block of 16-mm. radius, the scale reading is minus one. Schiøtz, however, thought that the plunger would sink slightly into the corneal epithelium, deforming the epithelium before an actual indentation of the corneal stroma would take place. He estimated the depth of this epithelial deformation as 1/20 mm., or one tonometer-scale unit, and moved the zero of his tonometer scale one unit to the right to allow for this presumed effect. The results of the measurements with the open manometer show that this shifting of the zero

* The foot plate of the Schiøtz tonometer having a radius of curvature of 16 mm. is considerably flatter than even the pig's cornea. Similar measurements with the Gradle and McLean instruments, with their much more concave foot plates, yielded marked discrepancies between the open manometer readings on pigs as compared with the other species, but these tonometers also gave close agreement of open manometer readings on cats, rabbits, and humans.

by Schiøtz was not justified. I am not suggesting that the scale should be shifted back, since its present location has the merit of a familiar convention, but the erroneous location of the zero has bearing on some theoretical analyses of tonometric readings.

II. Closed manometer readings

The technique used by Schiøtz in his closed manometer readings has been briefly described. The eye is supported by being fastened on a cannula inserted through the optic nerve and the tonometer indents and distorts the cornea much as it does in ordinary clinical measurements, but since the full weight of the tonometer as well as that of the eye itself is supported by the cannula an additional indentation and distortion at the posterior pole results (fig. 5). The stresses placed upon the eye under these circumstances are very different from those imposed by the tonometer in vivo when the eye is supported by the orbital cushion. Schiøtz was himself aware of this discrepancy in his calibrating readings and attempted to avoid this in a later series of measurements in which eyes were studied postmortem without enucleation by inserting a fine cannula into the anterior chamber at the limbus. He found, however, that it was almost impossible not to distort the cornea by such a limbal cannula and that this method led to a very wide scatter in the experimental readings.

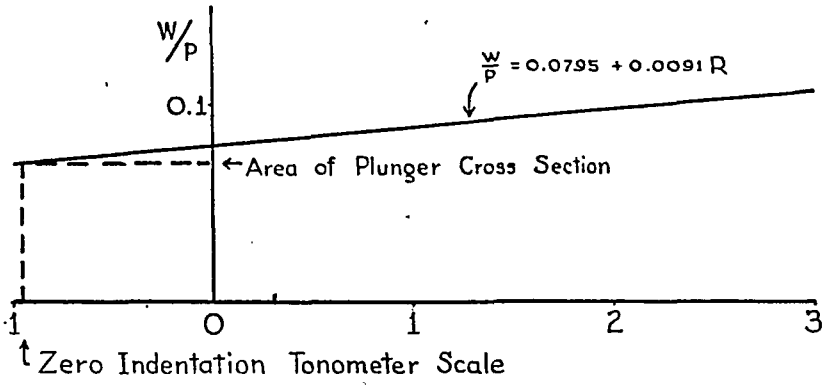

Fig. 4 (Friedenwald). Plot of open manometer data showing location of scale reading for zero plunger indentation.

In order to eliminate these difficulties and to support the test eye in a manner similar to that which occurs in the living patient, a somewhat more complicated apparatus has been developed (fig. 6). As in Schiøtz's original measurements, the eye is attached to a cannula inserted through the optic nerve, but this cannula is connected with a manometer through a universal joint and does not support the eyeball. A membrane is tied onto the cannula and arranged in such a fashion as to form a closed chamber, an artificial orbit, supporting the eyeball. This closed chamber is filled with fluid not con-

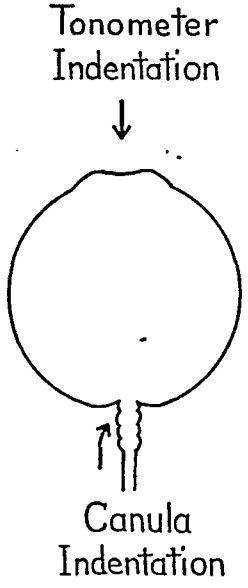

Fig. 5 (Friedenwald). Distortion of eyeball in Schiøtz's closed manometer readings.

nected with the manometric system, and the eyeball floats on this fluid chamber. When the tonometer rests on the eye, the globe is depressed slightly, the membrane stretches, and the pressure in the artificial orbit rises.

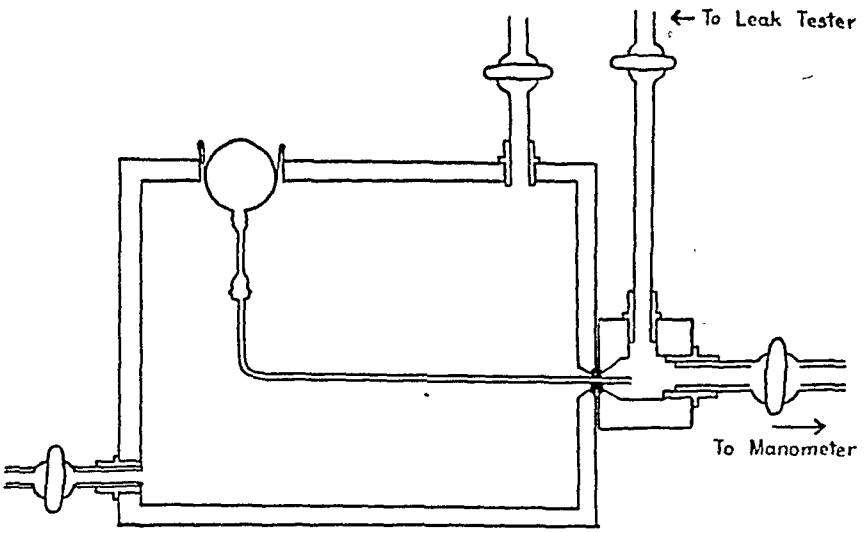

Fig. 6 (Friedenwald). Apparatus for closed manometer readings in which the eye is supported on an artificial orbit and indentation of the posterior pole by the cannula is avoided.

Only eyes that were quite fresh and free from disease or deformity were used for these measurements. After the cannula has been attached, it is necessary to aspirate some of the vitreous in order to insure a free flow of fluid in and out of the eye through the cannula. Only those eyes were used for closed manometer measurements in which a free connection was established with minimal manipulation. Finally, after the eye was attached in the calibrating apparatus it was tested for leaks and was rejected if at a pressure of 40 cm. of water more than one cubic millimeter of fluid leaked out per minute. Among the 30 human eyes which were obtained for this study, only four were found satisfactory by these very rigid requirements. The results of the closed manometer readings on these four eyes are given in Table 2.

The measurements on these four eyes do not, of course, suffice for calibration of the Schiøtz tonometer. They do, however, suffice to show that this method of calibration is unreliable. The first inkling that this was so was obtained by comparing the scale readings obtained with two different plunger loads at the same intraocular pressure. For instance at 30-cm. water pressure the av-

erage reading with the 5.5 weight was 4.7, while at the same pressure the average reading with the 10 weight was 8.9. Comparing these readings with similar pairs of readings that I had obtained some years ago on 500 normal human eyes,[2] it became evident that the rigidity of these dead eyes differed somewhat from that in the living. It was not apparent from these measurements whether the rigidity was the same throughout the set of measurements or whether it changed progressively. If the former were true, then correction factors might be calculated and an adequate calibration scale obtained provided a sufficient number of eyes were tested. If the latter were true, then the effort at direct calibration would have to be abandoned and some indirect procedure substituted. In order to find out what ocular rigidity corresponded to each one of these readings, it was necessary to get additional data as to the volume of fluid displaced by the tonometer foot plate and plunger when they were resting on the cornea.

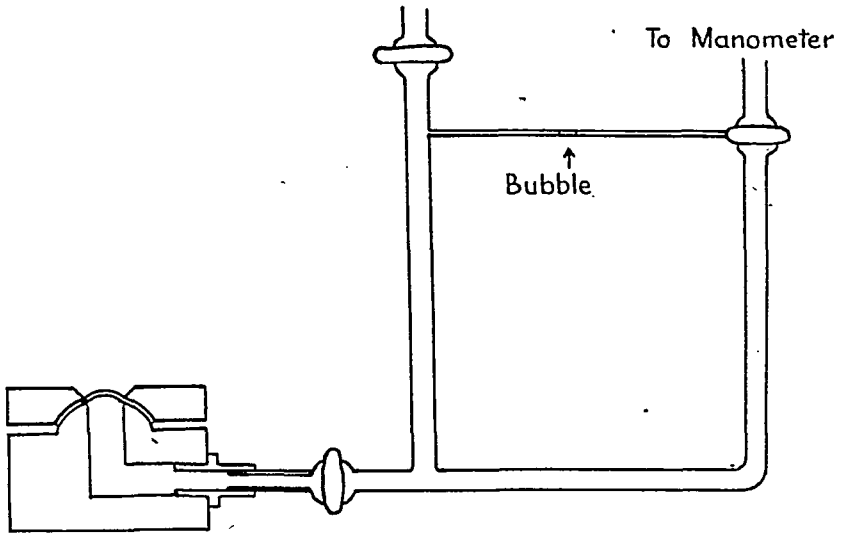

Fig. 7 (Friedenwald). Apparatus for measuring the volume of fluid displaced when the tonometer rests on the cornea.

III. Volume of indentation

To obtain the necessary data a new set of chambers was designed into which the anterior segment of an eye could be clamped leaving the cornea exposed (fig. 7). The chamber was connected with a manometer and reservoir through a calibrated capillary tube into which a bubble was introduced. With the pressure set at a desired level, the tonometer was lowered on to the cornea and the movement of the bubble recorded. Measurements were made on cat, rabbit, and human eyes at various pressures and with each of four different plunger loads.

Before analyzing the results of these measurements, the question of their reliability needed to be answered. It appeared possible that although the tissues were clamped into place with great care, the cornea might nevertheless be pulled or distorted in such a way as to make the readings unreliable. As a check against this possibility, we recorded the tonometer scale reading at each measurement and compared these, pressure for pressure, with our previous open manometer readings on whole eyes. The result showed that the open manometer readings were not distorted by this new method of attaching the eye to the manometer.

Each set of readings with a given plunger load on a set of eyes of the same species was found to fit quite satisfactorily an empyrical formula of the type:

$$P^N V = K$$

or the equivalent

$$\text{Log } P = B - \frac{1}{N} \text{ Log } V.$$

The numerical coefficients of these equations, N and K for the first, or N and B for the second, varied with the plunger load.

$$B = \frac{1}{N} \text{ Log } K.$$

Comparing eyes of the same species with different corneal curvatures, it was found that for a given pressure and plunger load the volume of the displaced fluid was greater the more deeply curved the cornea. This was to have been anticipated as may be seen from Figure 8, since, if the area of contact is the same in each case, more fluid will be displaced the higher the corneal dome.

Comparing eyes of the same corneal curvature but of different corneal thickness, for instance cats versus rabbits, it was found that the greater the corneal thickness the greater the volume of fluid displaced. This might also have been anticipated as may be seen from Figure 9 since, if the area on the inner surface in which the intraocular pressure supports the tonometer is the same in each case, more fluid will be displaced when the inner surface of the cornea is more deeply curved.

Comparing human eyes with those of rabbits and cats, it was found that the data on the human eyes agreed quite closely with those obtained on rabbits of the same corneal curvatures. Consequently the coefficients for the empyrical equations expressing the relation of pressure to volume of fluid displaced were first calculated from the rabbit data and then adjusted slightly to fit the human data. The combined results of these experiments and those with the open manometer correlate the tonometer scale reading with the intraocular pressure of an eye carrying the tonometer and the volume of the displaced fluid.

Fig. 8 (Friedenwald). *Schematic illustration of the relation between corneal curvature and volume of fluid displaced.* In each diagram the area of contact between tonometer foot plate and cornea is the same, but the cornea on the right is more deeply curved than that on the left.

Fig. 9 (Friedenwald). Schematic illustration of the relation between corneal thickness and volume of fluid displaced. In each diagram the curvature of the anterior corneal surface is the same and the area of the indentation of the posterior corneal surface is the same, but the cornea on the right is thicker, its posterior surface more deeply curved, and the volume of displaced fluid consequently greater.

These direct measurements of the volume of the displaced fluid may be compared with the indirect estimate which I made of the same volume in a study reported a number of years ago.[2] It is found that the volume actually measured is somewhat greater than that previously estimated. The reasons for this discrepancy are embedded in the various approximations used in the earlier calculations. No account was taken in those calculations of the fact that the curvature of the inner surface of the cornea differs from that of the outer surface. Furthermore the volume of the plunger indentation and of the foot-plate indentation were calculated inde-

pendently although the former influences the latter. Comparing the volumes of displaced fluid at the same intraocular pressure for two different plunger loads, there is quite good agreement between the two estimates, indicating that the earlier calculation of the volume of indentation produced by the plunger were reasonably accurate and that most of the errors in the earlier estimate concern the volume displaced by the tonometer foot plate.

With these new data we can now return to the closed manometer measurements on the four eyes reported above. For each reading we know the initial intraocular pressure. From the tonometer scale reading and the open manometer data we can calculate the pressure in the eye with the tonometer resting upon it. From this pressure and the known plunger load we can, with the aid of the new data, calculate the volume of fluid displaced. Knowing the initial and final pressure and the volume displaced one can, as has been shown elsewhere,[2] calculate the coefficient of rigidity. These calculations are shown in Table 2. It will be seen that, far from being constant during the experiment, the coefficient of rigidity of these eyes rose as the intraocular pressure was increased and as the experiment proceeded. It is evident that these dead eyes do not recover, as do living eyes, from the effects of transitory stresses. There is no reason even to believe that the ocular rigidity which characterized the very first reading in the series corresponded to that normally present in vivo. It is to be concluded, therefore, that the direct manometric calibration of tonometers on dead eyes is impossible and that errors due to abnormal rigidity are present not only in the closed manometer readings which I have just reported but also in the similar readings used by Schiøtz in his original calibrating measurements.

IV. Discussion

The situation, however, is by no means hopeless. The open manometer measurements and the measurements of the volume of displaced fluid are both unequivocally free from errors due to variations in ocular rigidity. From these data one can calculate calibration curves for any assigned value of ocular rigidity. Moreover, by finding out what are the most frequently paired readings obtained with different plunger weights on normal human eyes in vivo one can calculate the average normal ocular rigidity. Data on which such a calculation can be based are found in the report of paired readings with two plunger weights on each of 500 normal human eyes which I have previously reported.[2] I have calculated the average normal ocular rigidity from these clinical data using the current more reliable experimental data for open manometer pressures and volume of displaced fluid.

The calculations involved in the procedure are long and laborious and have not yet been completed, and I am not as yet prepared to present new calibration curves. I wish to confine the present report to the problems encountered in calibration experiments rather than to the final conclusions. Nevertheless, certain trends are already clearly visible in those parts of the calculations that have so far been completed. It seems clear that the calibration scales of Schiøtz and also of McLean are both too high and that the average normal intraocular pressure is probably between 18 and 19 mm. Hg rather than between 22 and 24 mm. Hg, as thought by Schiøtz or 27 to 28 mm. Hg, as thought by McLean.[3]

The best estimate that I am able to make for the coefficient of ocular rigidity of the average normal living eye has the value 0.0245 corresponding to an increase of 5.8 percent in the intraocular pressure for a displacement of one cubic millimeter of fluid. If one compares this average normal ocular rigidity with the values found on dead eyes in Table 2, it is seen that these eyes start out more flaccid than normal and become progressively more rigid during the course of the experiment passing through the normal range and finally reaching supranormal values. It should be noted that in these experi-

ments excessively high pressures were avoided. The highest pressure used was 75 cm. H_2O, that is, 55 mm. Hg. The cause of the abnormally low rigidity in dead eyes is not clear. One might have expected that with the loss of the compressible vascular bed, the enucleated eye would have a higher rather than a lower rigidity than in vivo.

If eyes with abnormally low rigidity are used for calibration measurements, then the scale determined by these experiments will give too high a pressure reading for eyes of normal rigidity. Conversely, if eyes with abnormally high rigidity are used for calibration, then the scale determined by these measurements will give too low a pressure reading for eyes of normal rigidity. Since the enucleated eyes used in closed manometer experiments start out with abnormally low rigidities and end up with abnormally high rigidities, a scale determined from such measurements will deviate from the true value in both directions. It is natural in such measurements to start with low pressures and proceed to higher ones. It would appear that this was the procedure used by Schiøtz and that in the region of normal pressures determined with the 5.5 weight his scale gives too high a pressure value, while at the upper limit with the heavier weights the scale is too low. McLean, on the other hand, who had only one plunger weight to deal with, and who was most meticulous in avoiding high intraocular pressures until the end of his experiments, appears to have done most of his measurements on eyes that were still in the abnormally flaccid state. His scale appears, therefore, to err throughout on the high side, though percentually the deviation decreases in the upper ranges.

It is perhaps of interest to note that Verhoeff on the basis of his experience with the Souter tonometer has for years maintained that the average normal intraocular pressure is not above 20 mm. Hg. The Souter tonometer, although afflicted with very large and erratic reading errors, is, at least theoretically, an instrument in which variations in ocular rigidity do not significantly affect the reading.

It should be pointed out that tonometric calibration based on the indirect method which I have outlined involves the use of a theory as to the role of ocular rigidity in the tonometric reading for which there is both a priori and experimental support, but which is, nevertheless, assuredly subject to further refinement and correction. In view of this, the calibrations that can be achieved by this method, although having a high probability of correctness, cannot be regarded as final even within the limits of error of the experimental data used for the calibration.

Finally, lest there be any misunderstanding, it must be clear that, no matter what the calibration scale in terms of millimeters of mercury, a tonometer scale reading under 3 with the 5.5 weight still means an abnormally high pressure or rigidity.

BETA IRRADIATION AS A POSSIBLE THERAPEUTIC AGENT IN GLAUCOMA*

AN EXPERIMENTAL STUDY WITH THE REPORT OF A CLINICAL CASE

GEORGE M. HAIK, M.D., LOUIS A. BREFFEILH, M.D., AND AELETA BARBER, M.A.
New Orleans, Louisiana

Whatever the special etiologic factors may be in a given case of glaucoma, the condition is always the result of an increase in intraocular pressure. The increased tension is itself the result of (1) the production of an abnormal amount of intraocular fluid, or (2) decreased absorption of a normal amount of fluid, or (3) blockage of normal intraocular channels of drainage.

Medical and surgical therapeutic methods, none of which have given uniformly satisfactory results, have up to this time been chiefly aimed at increasing the rate of flow through drainage channels. Recently cyclodiathermy[1] has been employed, with the objective of decreasing the production of intraocular fluid by destruction of the secretory process of the ciliary body. The theory is sound, but the method is attended with too much risk to warrant its routine use. It may cause damage to the lens, the cornea, the iris, the retina, or the sclera. Loss of vitreous, hemorrhage into the anterior chamber, and scleral slough are always possibilities, and all may be associated with irreparable impairment of vision.

It occurred to us that the effect aimed at by the use of diathermy in glaucoma, that is, destruction of a portion of the ciliary body, with a resulting decrease in the production of aqueous and, in turn, a decrease in intraocular pressure, might be brought about without injury of the lens or other ocular structures by the use of irradiation. The considerable experimental work done up to this time on the effects of beta irradiation on the eye, as well as the clinical use of the method, has apparently been limited to the lids, the cornea, and the conjunctiva.[2-4] In Warren's[5] excellent review of the effects of irradiation on the tissues no mention is made of irradiation of the ciliary body, nor has an independent search of the literature revealed any such studies. The experiments reported herewith were therefore undertaken, for the purpose of determining (1) the effect of irradiation with beta rays on the ciliary body and (2) the degree of destruction which could be brought about in that structure without injury to the lens.

MATERIALS AND METHODS

The materials used in this study consisted of 18 adult rabbits, each weighing 5 pounds or more. Two animals (nos. 3B and 12) died of intercurrent disease early in the experiment, and another (no. 3), which developed cataract and exophthalmos 5 days after the first treatment, was discarded, since these are not the usual results of irradiation.

Treatment consisted of the application of 50 mg. of radium, in an applicator devised by Iliff, over the ciliary body of the left eye, for 30-minute periods. One group of animals received one treatment. Three other groups received, respectively, 2, 3, and 4 treatments, at 7-day intervals. All applications were made under anesthesia obtained by subcutaneous injections of nembutal. The rabbit was placed on the table, with the head to the side, and the applicator was so suspended that it was in direct contact with the eyeball. Its weight kept the eyelids open without difficulty, and the position of the eye was such that the rays passed into the ciliary body through the sclera.

Three animals (nos. 7, 14, and 16), which

* From the Departments of Ophthalmology and Pathology of the School of Medicine of Louisiana State University and the Charity Hospital of Louisiana. Presented as an exhibit at the Southern Medical Association meeting in November, 1947.

had had, respectively, 3 treatments, 2 treatments and 1 treatment, each, were preserved for further study. No gross changes have been observed in their eyes to the date of writing (20 weeks). The remaining 12 animals were killed at intervals of from 5 to 42 days after the first treatment. Paraffin sections of the eyes were made in 3 cases (nos. 5, 10, and 11), but the decision to employ this method proved unfortunate, since it did not permit satisfactory preparation of the lens. In the other 9 animals the eyes were prepared by the celloidin technique and were stained with hematoxylin and eosin. In each instance the untreated right eye was used as a control.

Results

Gross Findings

All the animals which received 2, 3, and 4 treatments developed severe mucopurulent conjunctivitis with necrosis of both the palpebral and the bulbar conjunctiva, obviously as the result of failure to protect these tissues from the rays. The results were what might have been expected and probably could be obviated by proper screening.

There were no gross changes and no ophthalmoscopic abnormalities in the iris or the lens in any case. The control eye was negative in every animal.

Fig. 1 (Haik, Breffeilh, and Barber). Section of left-eye ciliary body of rabbit No. 15, which received one application of 50 mg. of radium for 30 minutes and was killed 21 days later. The ciliary processes show edema, and there are slight endothelial changes in the walls of the capillaries.

Microscopic Findings

Group I. The 4 animals in the group (nos. 10, 11, 17, and 15) each received one treatment consisting of the application of 50 mg. of radium for 30 minutes. They were killed at 5 (no. 10), 9 (nos. 11 and 17) and 21 (no. 15) days after the first treatment. A 5th animal (no. 16) which was given the same treatment was preserved for further observation. The lens was lost in 2 animals (nos. 11, 10) as the result of preparation by paraffin section.

In animal No. 11, which was killed at 9 days, the ciliary body was swollen and showed marked infiltration of both acute and chronic inflammatory cells, with some necrosis. Degeneration of the ciliary epithelium and dispersion of pigment were also noted. The reaction in this eye was comparable to that observed after 3 treatments (50 mg. of radium for 90 minutes) and 4 treatments (50 mg. of radium for 120 minutes).

Animal No. 17, which was also killed 9 days after treatment, and animal No. 15, which was killed 21 days after treatment, both showed only slight edema of the ciliary processes and some scattering of pigment (fig. 1). The endothelial cells in the walls of the capillaries were clumped and swollen. The nuclei of the fibers of the lens were slightly scattered from the normal equatorial bow in both animals, and the fibers appeared hydropic.

Group II. The 5 rabbits in this group (nos. 5, 8, and 13) received 2 treatments

each at 7-day intervals (a total of 50 mg. of radium for 60 minutes). They were killed, respectively, 12, 15, and 28 days after the first treatment (5, 9, and 21 days after the last treatment). All the specimens presented the usual features of inflammation. The stroma of the ciliary body (fig. 2) was edematous, with early hyalinization. The epithelium was vacuolated and clumps of pigment could be seen in the stroma. Capillaries in the ciliary processes showed evidence of stasis. A few blood vessels in the stroma had thickened walls and the endothelium was irregular. There was no evidence of healing.

Fig. 2 (Haik, Breffeilh, and Barber). Section of left-eye ciliary body of rabbit No. 8, which received two applications of 50 mg. of radium at 7-day intervals for a total of 60 minutes and was killed 16 days after the first treatment. The ciliary processes show stasis, and there is early hyalinization of the stroma.

The sclera was somewhat less cellular than normal in all 3 rabbits but otherwise showed no changes. The lens in animal No. 5, which was prepared by paraffin section, was lost. The lenses in the other rabbits (nos. 8 and 13) were definitely damaged (fig. 3). The nuclei of the fibers were disarranged and the fibers were swollen and in some areas were liquefied. Cataractous changes were observed in both of these eyes.

Fig. 3 (Haik, Breffeilh, and Barber). Section of ciliary body of left eye of rabbit No. 4, which received four applications of 50 mg. of radium at 7-day intervals for a total of 120 minutes and was killed 16 days after the first treatment. The stroma of the ciliary body is smooth and hyalinized, and the epithelium is replaced by a layer of flat cells.

Group III. The 3 rabbits in this group (nos. 7, 9, and 6) received three treatments each at 7-day intervals (a total of 50 mg. of radium for 90 minutes). Rabbit No. 7 was kept for further study. Rabbits No. 9 and No. 6 were killed, respectively, 23 and 35 days after the first treatment (9 and 21 days after the last treatment). The inflammatory changes in both these specimens appeared more chronic than the changes observed in the animals in Group II, and in both there was slight evidence of healing. There was

Fig. 4 (Haik, Breffeilh, and Barber). Section showing ciliary body of normal control.

marked hyalinization of the stroma of the ciliary body and the blood vessels were seen only in faint outline. There was hemorrhage into the ciliary processes.

Changes in the lens (fig. 4) were more marked in these specimens than in the specimens in Group II. Vacuolation of fibers and fragmentation of nuclei in the treated eyes of both animals were observed, and cataracts were present in both.

Group IV. The 3 rabbits in this group (nos. 2, 1, and 4) each received four treatments at 7-day intervals (a total of 50 mg. of radium for 120 minutes). They were killed, respectively, 26, 30, and 42 days after the first treatment (5, 9, and 21 days after the last treatment). The changes observed in the treated eyes of rabbits No. 2 and No. 1 were similar to those described for the specimens in Group III, that is, obliteration of blood vessels, slight healing of the ciliary body, and cataracts. Rabbit No. 4, however, which was killed 21 days after the fourth treatment and 42 days after the first treatment, showed entirely different findings (fig. 5). There was considerable advance in the reparative process. The ciliary epithelium was completely absent over the area treated and was replaced by a thin, flat membrane. No blood vessels could be identified, and the stroma was smooth and hyalinized.

The lens (fig. 6) was cataractous, with necrotic nuclei and vacuolated, hydropic fibers. The sclera in the treated area appeared less cellular than in the untreated eye, and only a few scattered leukocytes could be seen. Early organization was apparent in the subconjunctival tissues. The

Fig. 5 (Haik, Breffeilh, and Barber). Section of lens of left eye of rabbit No. 8. The lens shows early cataractous changes in the fibers at the equator.

fact that this animal was an albino rabbit accounts for the lack of pigment in the specimen.

Control Specimens. None of the untreated right eyes used as controls showed any microscopic changes (figs. 4 and 8).

Discussion

The experiments reported in this communication were planned in the light of the changes in the vascular endothelium, leading to proliferation and various degrees of occlusion of the lumen, which have been reported after beta radiation and which are most marked in the endothelium.[2-4] The object of the study was to determine whether

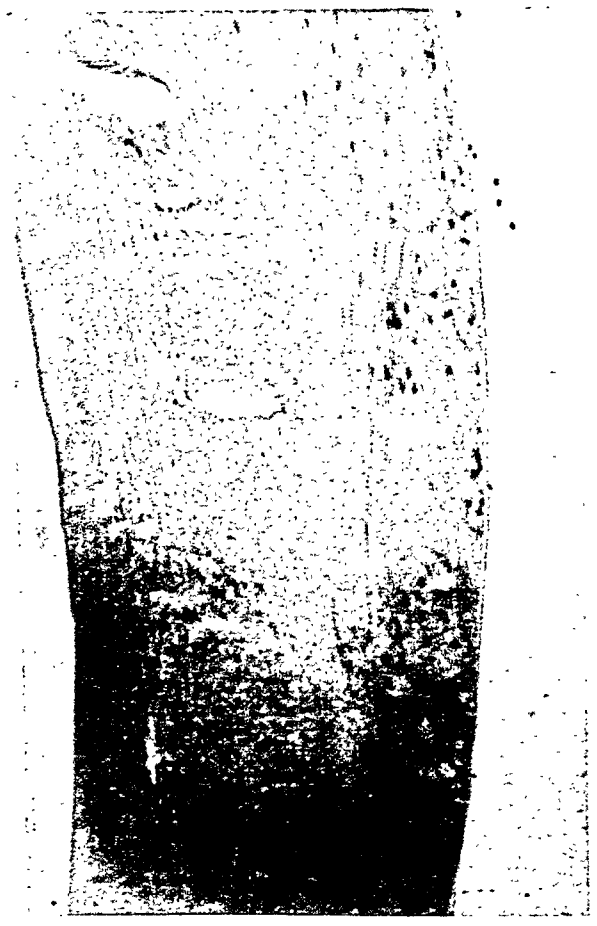

Fig. 6 (Haik, Breffeilh, and Barber). Section of lens of left eye of rabbit No. 9, which received three applications of 50 mg. of radium at 7-day intervals for a total of 90 minutes and was killed 23 days after the first treatment. The lens shows scattered nuclei and swollen fibers in the equatorial region.

Fig. 7 (Haik, Breffeilh, and Barber). Section of lens of left eye of rabbit No. 4. The lens is cataractous, with necrotic nuclei and vacuolated, hydropic fibers.

it was possible, by the use of such radiation, to reduce the aqueous production in the rabbit's eye by bringing about obliteration or partial occlusion of the capillaries in a portion of the ciliary body. An excessive dosage was deliberately used, to permit a study of the type and rate of the healing process.

In one animal (no. 11) the application of 50 mg. of radium for 30 minutes resulted in excessive destruction of the ciliary body. In 2 other rabbits (nos. 17 and 15) which had the same amount of treatment, there was only slight damage to the endothelium of the ciliary blood vessels. In the animals treated by two applications of 50 mg. of radium for 30 minutes per treatment definite obliteration of the vessels of the ciliary body resulted. When four treatments were given (50 mg. of radium for a total of 120 minutes), healing, as evidenced by hyalinization

Fig. 8 (Haik, Breffeilh, and Barber). Section showing lens of normal control.

of the ciliary stroma, was observed 21 days after the first treatment and was quite complete at 42 days. The cumulative effect of the dosage of radium did not seem to alter the histologic details to any great degree.

In planning these experiments, the observations of previous workers on other tissues were used as a starting point. According to Linser (cited by Warren[6]), maximum effects of irradiation are observed in the blood vessels by the 8th posttreatment day and the process of repair is well advanced by the 20th day. In our own experiments, although the reaction in the eye after irradiation is less marked than the reaction in other parts of the body, the peak of vascular dilatation was reached on the 9th day and healing was evident by the 3rd week after the last treatment, which are comparable intervals. Edema and inflammation of the palpebral and bulbar conjunctiva reached a maximum at about 10 to 12 days and healing was evident by the 3rd week after the last treatment.

The significant time interval, however, seems to be related to the number of days after the first treatment rather than after the last. Animals No. 13 and No. 4 were both killed 21 days after the last treatment. The ciliary body and the lens showed an equal degree of damage in both specimens, but the degree of healing differed. In animal No. 4, which was killed 42 days after the first treatment, there was definite evidence of healing, but in animal No. 13, which was killed 28 days after the first treatment, there was no evidence at all of healing. The reparative process therefore seems to require more than 28 posttreatment days, and the cumulative effects of radium seem to have little influence on the results.

Rabbits No. 11 and No. 17, both of which were killed 9 days after the first (only) treatment, showed no changes in the lens, and animal No. 15, killed 21 days after the first (only) treatment, showed only a slight change. All the other rabbits, regardless of the amount of treatment which they had received or the time at which they were killed, showed definite cataractous changes. To make this method practical, therefore, it will be necessary to establish the minimum dose of radium which will secure the desired vascular obliterative changes in the ciliary body without, at the same time, damaging the lens. It will also be necessary to develop an applicator which will permit the emanation of pure beta rays while at the same time excluding gamma rays, which are damaging to the lens. At the present time no such applicator exists.

Case report

In the following case the application of radium was a last resort. The method was resorted to because it was impossible to accomplish with it any more harm than had already been accomplished by the disease process.

A 4-year-old boy with congenital bilateral buphthalmos was first seen in the Charity Hospital of Louisiana Eye Clinic November 14, 1946. An iridotasis was performed on the left eye on November 18th and on the right eye on November 25th. Massive prolapse of the ciliary body occurred into the operative wound on the right side, the cornea became hazy, and there was marked injection of the ciliary body. Enucleation was therefore carried out on December 16. The specimen showed hydrophthalmos, dislocation of the lens, and detachment of the retina and choroid as the result of hemorrhage, chronic uveitis, and glaucomatous cup. Carcholin therapy was instituted, and the child was followed in the clinic until the end of May, 1947.

When he was next seen, in August, 1947, the tension in the remaining (left) eye was 55 mm. Hg (Schiøtz). It varied between 30 mm. and 49 mm. until October 2nd. On this date, 50 mg. of radium was applied to the nasal side of the limbus and 50 mg. to the temporal side, each application lasting 10 minutes; the Iliff applicator was used. A similar application was made on October 6th. The day after the second application the tension (Schiøtz) was 25 mm. Hg. On October 11th, it was 35 mm.; October 12th, 19 mm.; October 13th, 24 mm.; October 14th, 30 mm.; October 17th, 35 mm.; October 19th, 40 mm.; and October 21st, 40 mm. On October 21st, 50 mg. of radium was applied for 10 minutes at the 9-o'clock position. Between that time and the present writing (December 9, 1947) the tension has varied between 25 and 55 mm. It was above 40 mm. on only 7 of the 29 readings. It was consistently higher for a week after miotics were discontinued (November 20th), then showed a somewhat lower trend, although readings were still between 30 and 40 mm.

Vision at the time of the first application of radium had decreased to 3 to 4 feet. There has been no additional loss to date.

Whether irradiation will accomplish anything in this case it is impossible to say. To date, however, there have been no evidences of harmful effects, the only reaction following irradiation being a slight, transitory reddening of the eyelids. The most encouraging feature of the case is that since the application of radium there has been no progression of a condition which was progressing before treatment was instituted and the natural tendency of which is toward progression. A long period of observation will be necessary before definite statements can be made concerning results, and at the present time there would be no justification for using this method in any case which was not as clearly hopeless as this one was.

Summary and Conclusions

A series of experiments has been described, in which beta irradiation was applied to the ciliary body of rabbits in varying amounts over varying periods of time, in an endeavor to determine the practicability of treating glaucoma by obliteration of the vascular supply of the ciliary body, with the objective of bringing about a decrease in the production of intraocular fluid.

While vascular changes were achieved in the majority of cases, damage to the lens also resulted in almost every instance in which the desired changes were achieved.

The method proposed thus seems theoretically sound. To make it practical, however, a dosage of radium must be established which will achieve the desired changes in the ciliary body without at the same time damaging the lens. This objective could probably be accomplished if an applicator were available which would permit the emanation of beta rays but would screen out gamma rays.

A clinical case is presented in which irradiation was employed because the state of the eye was already practically hopeless. The treatment has apparently produced no ill effects but the therapeutic results are still inconclusive.

FLARE-UP OF TRACHOMATOUS PANNUS DUE TO ARIBOFLAVINOSIS*

J. LANDAU, M.D., AND H. J. STERN, M.D.
Jerusalem, Palestine

Pannus is an essential manifestation of trachoma. Appearing at a very early stage of the disease it is decisive in the differential diagnosis. It represents the progress by continuity of the disease from the conjunctival lesion into the subepithelial tissue of the bulbar conjunctiva and the cornea. In one

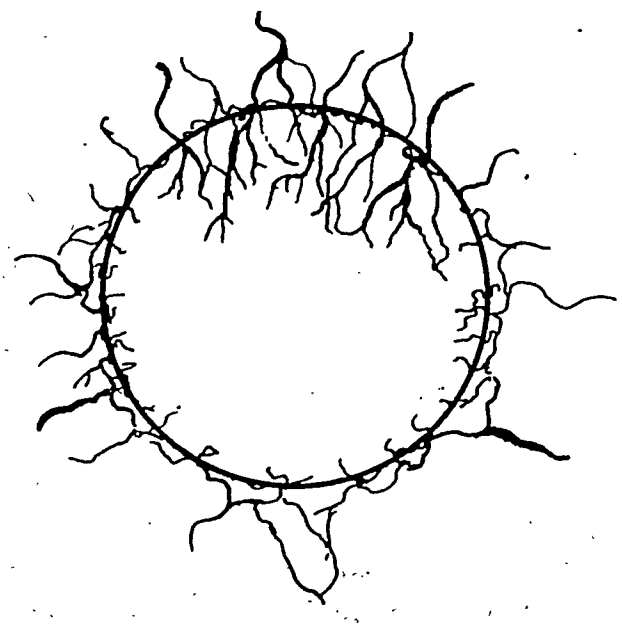

Fig. 1 (Landau and Stern). Trachomatous pannus and ariboflavinosis.

form or another it remains recognizable throughout the whole life of the patient.

Treatment of pannus in active trachoma coincides with the treatment of the palpebral conjunctiva. Once the conjunctival lesions enter the cicatrizing stage, the vessels of the pannus become thinner, anemic, and eventually almost invisible unless the slitlamp is used.

There are cases, however, in which a marked discrepancy exists between the aspect of the cornea and the palpebral conjunctiva. The latter may be entirely smooth and well cicatrized, and yet a marked pannus, that is, hyperemic blood vessels, may extend over the cornea. The patients complain of watering, itching, and burning, and sometimes exhibit even marked photophobia. This condition often proves very difficult to treat. Operations like peritomy and peritectomy suggested for such cases have been abandoned because their results are decidedly unsatisfactory.

When some cases of this kind were examined carefully with the slitlamp, it was found that the cornea was vascularized not only in its upper half, as in classical trachomatous pannus. The typical aspect of grayish infiltration in the corneal epithelium was present only in the upper part but fine blood vessels of 1 to 3 mm. in length could be seen encroaching upon the clear cornea from the limbus over the entire circumference, similar to the limbal "flush" described in ariboflavinosis (fig. 1). This peculiar finding induced us to attempt to influence the con-

* From the Eye Department of the Hadassah University Hospital.

dition with riboflavin and other components of the vitamin-B complex in a number of cases.

Ten cases have been observed so far, and the history of a typical one follows. The relevant data of the other cases are presented in Table 1.

Report of a case

Case 6. J. K., a woman, aged 45 years, suffered during childhood from trachoma which had healed with corneal opacities. In the right eye vision was reduced to counting of fingers at 1 m. For the past few weeks she complained of photophobia and burning in both eyes. The corneas presented an acute trachomatous pannus and, in addition, a typical ariboflavinotic corneal vascularization. The pannus reached the pupillary region in the left eye, and visual acuity amounted to 6/36. The patient received 5 mg. of riboflavin twice daily by mouth. One week later, considerable improvement was noted. Vision in the left eye was 6/18 and the corneal vessels became much thinner. After another week of treatment, the subjective symptoms vanished, the corneal vessels were greatly constricted, and the pannus assumed the aspect usual in inactive trachoma. With a vision of almost 6/12 the patient declared that she had not felt so well for a long time.

TABLE 1

DATA ON 10 CASES OF TRACHOMATOUS PANNUS TREATED WITH RIBOFLAVIN

No.	Sex	Age	Trachoma Stage	Trachom. Pannus	Ariboflavinotic			Diet	Treatment	Time (days)	Result	Visual Acuity
					Corneal Vascularization	Cheilitis	Glossitis					
1	f	19	IV	+++	++++	—	—	good	Riboflavin 2×5 mg. daily	7	very good	
2	f	42	IV	+++	+++	+	+	very poor	Riboflavin 2×5 mg. Bevitex 1.5 g. Yeast 3 g.	14 14 14	very good	
3	f	18	IV	++	+	—	—	poor	Riboflavin 2×5 mg. daily	18	very good	
4	f	44	IV	+	+++	—	—	very poor	Riboflavin 2×5 mg. daily	7	very good	
5	f	42	IV	++++	++++	—	+	very poor	Riboflavin 2×5 mg. daily	7	very good	
6	f	45	IV	++	+++	—	—	poor	Riboflavin 2×5 mg. daily	9	very good	O.S., 6/60 *improved to* O.S., 6/12
7	f	14	IV	+++ O.D. ++ O.S.	+	—	+	poor	Riboflavin 2×5 mg. daily	4	very good	O.D., 6/24 *improved to* O.D., 6/18
8	m	62	IV	Total	Pannus	++	++	very poor	Betotal 2 cc. i.m. daily	6	good	
9	m	58	IV	Total	Pannus	++	++	very poor	Betotal 2 cc. i.m. daily	6	good	
10	f	22	IV	+++	++	—	—	good	Betotal 2 cc. i.m. daily	4	very good	

None of the patients received any kind of local treatment.
"Betotal" ampules (2 cc.) contain 3.0 mg. Vitamin B_1, 1.5 mg. B_2, 20 mg. nicotinic acid, 2.0 mg. B_6, 3.0 mg. calcium pantothenate and 400 mg. crude liver extract.
"Bevitex" tablets contain 3.3 mg. B_1, 2.0 mg. B_2, 20 mg. nicotinic acid, 0.4 mg. B_6, 3.0 mg. pantothenic acid.

Comment

All cases responded very well to medication with riboflavin alone or with vitamin-B complex in the form of yeast or proprietary preparations. The total B complex has lately been given preference because ariboflavinosis must be regarded as an expression of a relative deficiency in the other constituents of the B complex, as well. The normal dietary sources of riboflavin (meat, bread, dairy products) contain considerable amounts of thiamine, nicotinic acid, and so forth, and

it is correct to assume that an insufficient intake of riboflavin also entails a diminished intake of the other members of the group. The complex deficiency may remain subclinical with the exception of the riboflavin deficiency, because the eye seems to be a particularly sensitive indicator of a disturbance in cell metabolism. The corneal tissue, devoid of blood vessels, can be assumed to suffer first when the absence of riboflavin prevents the proper synthesis of the respiratory enzymes. It was, therefore, decided also to administer B-complex preparations, after the first cases that had received riboflavin alone had shown the prompt response described above.

To explain the therapeutic success with vitamin-B complex in such "intractable" pannus in cases of completely cicatrized trachoma, it must be remembered that the blood vessels constituting the pannus do not leave the cornea entirely once the trachoma has become inactive. Although contracted, they still exist and remain visible, with the slit-lamp, as minute channels with a sluggish, much reduced circulation. If a riboflavin deficiency occurs at this stage of trachoma, the well-known response of the cornea sets in—the limbic plexus becomes flushed and fine capillaries encroach upon the cornea, most probably in order to relieve the disturbance of the respiratory process of the corneal cells. In trachoma IV, where the disease has ceased to be active but where the vessels of the pannus are still present, the limbic vessels in this region do not seek new pathways to invade the cornea, having at their disposal the old channels of the trachomatous pannus. The vessels become engorged and present the picture of an active trachomatous pannus—with this difference that, in addition, newly formed vessels have invaded the cornea in the rest of its circumference, hitherto devoid of vessels.

Adequate provision of riboflavin will then, of course, exert its beneficial effect on the newly formed vessels as well as on the old pannus. The ocular signs of ariboflavinosis are relatively frequent among the patients of our out-patient department who come from the poorer classes and whose diet is frequently grossly deficient.

An additional factor may play a rôle in the flare-up of a pannus in clinically cured trachoma. The corneal tissue of an eye which has undergone trachoma is rarely entirely normal and may be subject to occasional breakdowns as shown by the frequent recurrences of corneal infiltrations in some cases of inactive trachoma. An analysis by Feigenbaum* in 1921, of 3,389 cases of Koch-Weeks conjunctivitis of which about one third were also affected with trachoma, may be quoted in order to illustrate this fact. The frequency of involvement of the superficial corneal layers was 3.1 percent in patients free from trachoma, and 13.1 percent in trachomatous patients, which, according to the author, clearly points to a less favorable state of the corneal tissue in trachoma. It is conceivable that the corneal tissue of such eyes is more sensitive to a lack of riboflavin.†

† We are indebted to the Winthrop Products, Inc., New York, and Teva, Ltd., Jerusalem, who kindly furnished the riboflavin (Ribotone and Betotal, respectively,) used in these trials.

MIKULICZ'S DISEASE AND SYNDROME*

PARKER HEATH, M.D.
Boston, Massachusetts

Mikulicz's disease and syndrome constitute problems of considerable clinical interest. Patients afflicted usually consult an ophthalmologist. The report by Haltenhoff,[1] an ophthalmologist, 1889, mentions a report by Gallasch,[2] 1874, of this syndrome in relation to leukemia. Mikulicz,[3] in 1888, presented a case at a medical meeting and first published his article in 1892. Following his description, the disease has come to bear his name. E. Fuchs,[4] 1891, published a case as lacrimal lymphosarcoma; and Zirm,[5] 1892, reported the syndrome, presumably caused by erysipelas. Following these pioneers, numerous reports have been published from all over the world.

The Mikulicz report described bilateral, painless, swollen upper eyelids associated with a nodular form of tumor of the lacrimal glands, unattached to the skin, and with a similar involvement of the parotid and submaxillary glands. There were no signs and symptoms associated with general health. The process remained local, ran a fairly long course, and regressed. Microscopic examination of sections of the glands showed masses of small round cells, lymphoid in character, fine reticulum, increase of fibrous stroma, and the remaining acini unchanged.

REPORT OF A CASE

A report of a case (WA 783,394) apparently showing a primary lesion in the lacrimal gland, the pure "Mikulicz" type, follows:

History. The patient, a Negro, aged 19 years (fig. 1), was admitted to the Receiving Hospital October 10, 1941, and was discharged November 17, 1941. For three months he had a painless and gradually increasing swelling of the left upper lid and slight protrusion of this eye. Two weeks before admission the right eye began to assume a similar appearance and course. He entered the Hospital because of disfigurement.

Eye examination. There was no diplopia. There was some reduction of tears. Examination of the left eye showed proptosis (fig. 2) and the appearance of an inward deviation. There was a fixed tumor mass, the size of a hickory nut, in the upper outer aspect of the orbit. The lacrimal gland area of the right eyelid showed swelling and a movable tumor the size of an almond. Conjunctivas and the movements of the extraocular muscles were normal. The pupils were equal and reacted to light and accommodation. There was no fever.

Fig. 1 (Heath). *WA 783,394.* Pure type of Mikulicz showing bulging of lids associated with nodular growth and the illusion of convergent squint with ptosis.

* Presented at the 83rd annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June, 1947. From Wayne University and Receiving Hospital, Detroit, Michigan, Departments of Pathology and Ophthalmology.

Fig. 2 (Heath). *WA 783,394.* Lateral view showing proptosis of the left eye.

Laboratory tests. O.T. (old tuberculin) test, in a dilution of 1:10,000, was negative at 48 hours. Blood Kline test negative. Hemoglobin, 14 gm.; erythrocytes, 4 M; white blood cells, 6,800; neutrophiles, 78; lymphocytes, 18; urea, 21. Urinalysis was negative, except the first specimen which showed a 3+ albumin (possibly a contamination).

X-ray examination. Orbit: October 10th and 15th, showed no orbital bone destruction. Chest: October 10th, showed no areas of infiltration. Hands: October 10th, showed no pathologic condition of the bones.

Surgery. On October 22nd, a biopsy of the left lacrimal tumor was done. On November 4th, the left lacrimal gland was removed through the conjunctiva, and on November 11th, the right gland was removed through the skin (fig. 3).

Microscopically, the sections of the tumor showed a moderate number of nests of epithelioids and lymphoid follicles with open centers, and occasional giant cells. There was no caseation and a marked fibrosis replaced reticular and acini tissue. A well-advanced lymphogranulomatosis was present in the stage of healing by sclerosis and scar formation (figs. 4 and 5).

Additional case histories

Following are some brief case histories illustrating Mikulicz's syndrome with different etiologies, namely, tuberculosis and sarcoid, syphilis, gout, and rheumatism, and giant-cell follicular hyperplasia. Other etiologies could be added, such as leukemia, lymphosarcoma, uveoparotid fever, and, relatively rare, Hodgkin's disease.

Case 1

History. R. E., a Negro, aged 21 years, was admitted on August 13, 1929, to the Receiving Hospital, and discharged on October 13, 1929. He had a progressive painless enlargement of the parotid and submaxillary glands of one year's duration, with progres-

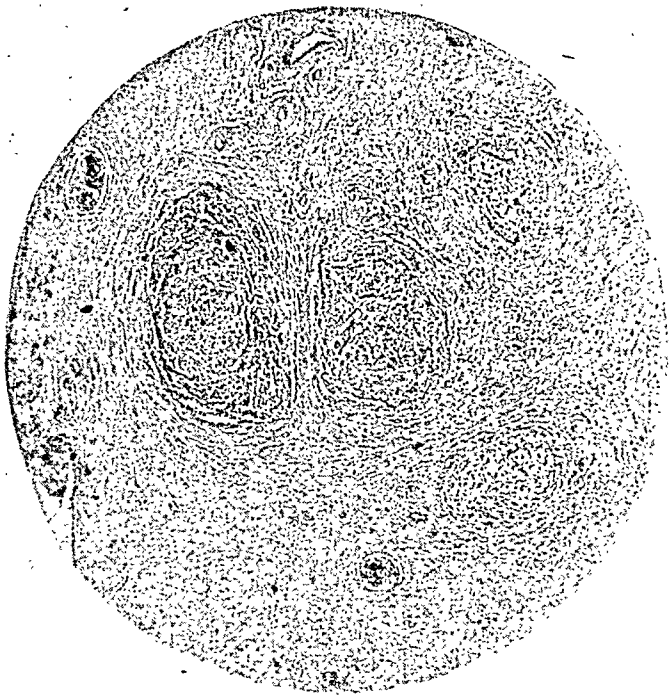

Fig. 4 (Heath). *WA 783,394.* Low-power view of tissue removed from the orbit, showing typical follicles with the exaggerated scar formation and atrophy.

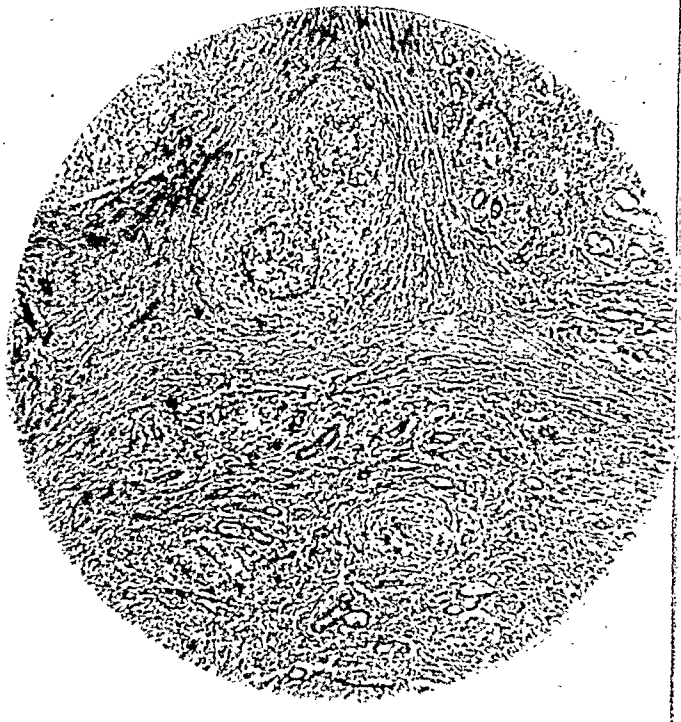

Fig. 5 (Heath). *WA 783,394.* High-power view showi nest of lymphocytes, epithelioids, occasional giant cells, granuloma, without caseation and marked fibrosis. A parently healing by sclerosis and scar.

Fig. 6 (Heath). *Case 1.* Front view showing marked enlargement of the parotid and submaxillary glands in a tuberculous lymphadenitis.

Fig. 7 (Heath). *Case 1.* Lateral view of tuberculous lymphadenitis showing preauricular and submaxillary and less obvious ocular and lacrimal gland involvement.

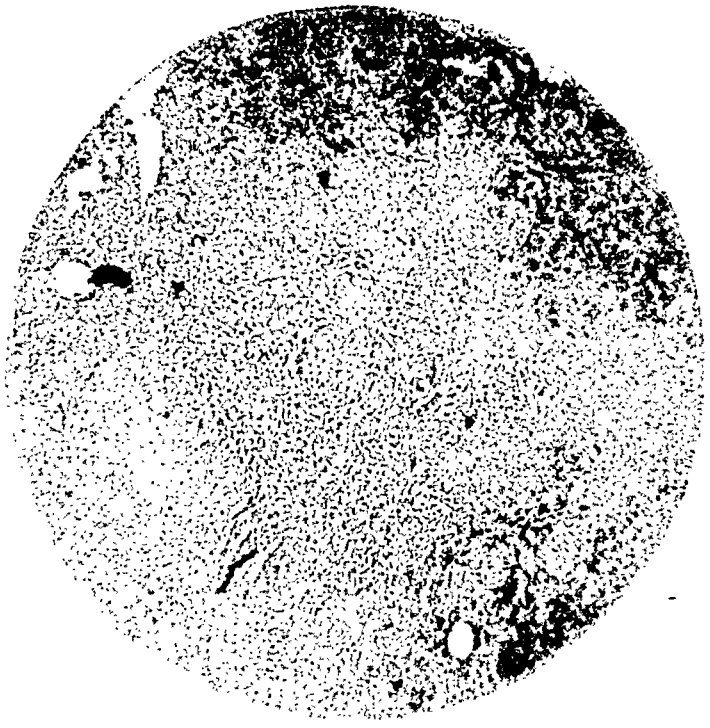

Fig. 8 (Heath). *Case 1.* Microscopic section through the biopsy material showing typical lymphadenitis, tuberculous type, with giant cells and caseation.

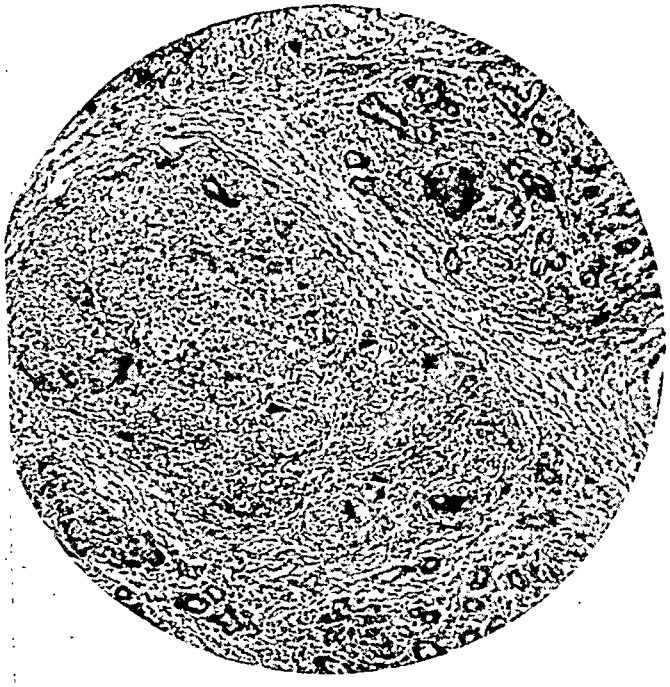

Fig. 9 (Heath). *Case 2.* Low-power view of biopsy of imal gland showing sarcoid, lymphogranulomatosis and iaumann bodies. No caseation. Moderate fibrosis and iphatic nodules

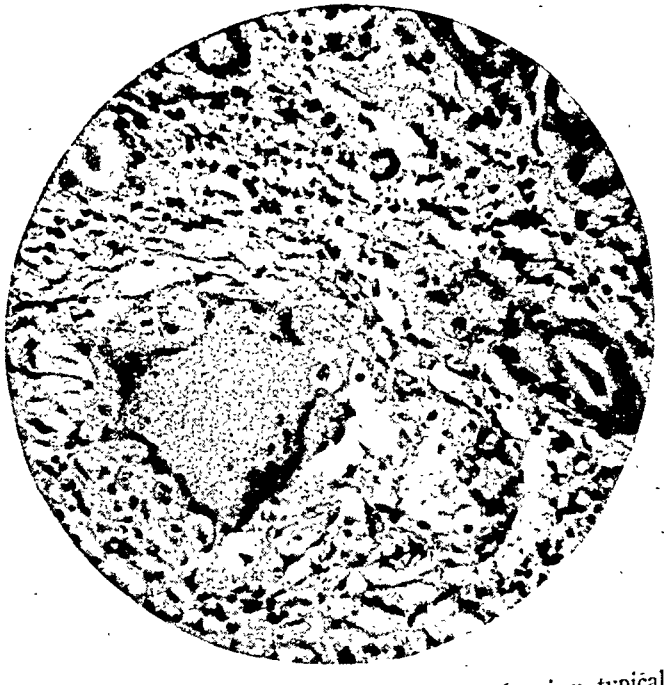

Fig. 10 (Heath). *Case 2.* High-power, showing typical structure of giant cell and follicle.

sive weakness (figs. 6 and 7). On March 22, 1929, he had been admitted to the hospital with a complaint of progressive enlargement of the neck glands over a 5-year period. There was associated redness of the eyes. Examination revealed parotid and submaxillary enlargement associated with cervical lymphadenopathy. The patient refused biopsy, and was released.

Physical examination. On August 13, 1929, there was bilateral massive enlargement of the submaxillary and parotid glands, indurated and well circumscribed, as well as edema of the upper lids (fig. 8).

X-ray examination on March 22, 1929, showed minimal infiltration of the right upper lobe of the chest. On August 13th, the films showed massive bilateral tuberculosis with cavitations.

Course. Rapidly downhill.

Autopsy. Extensive bilateral pulmonary tuberculosis with apical cavitations. Tuberculous parotitis. Cervical adenitis.

CASE 2

History. E. A., a Negro, aged 29 years, was admitted to the Receiving Hospital on September 1, 1946, and was discharged on October 7, 1946. His chief complaint was conjunctivitis, edema of the upper lid, and nasal obstructions of one month's duration. P.H. was essentially negative.

Physical examination. Temperature was 99°F.; pulse, 64; blood pressure, 112/84 mm. Hg. Examination of the eyes showed congenital nodular conjunctivitis and associated firm, bilateral enlargement of lacrimal glands—palpable, nontender. There was preauricular tenseness over the parotid region. There was granular infiltration of nasal mucosa.

Laboratory tests. W.B.C., 8,850; differential—neutrophiles, 70; lymphocytes, 20; monocytes, 8. Repeated sputum examinations were negative for acid-fast bacilli. Serology: Positive Wassermann.

Course. A biopsy of lacrimal gland was illustrative of sarcoid (figs. 9 and 10). The patient improved.

CASE 3

History. I. H., a Negro, aged 34 years, was admitted to the Receiving Hospital on March 22, 1938, and was discharged on April 11, 1938. His complaint was enlargement of the lacrimal and parotid glands and conjunctivitis, low grade.

Physical examination. There was bilateral, firm painless enlargement of the lacrimal and parotid glands with mild inflammation. The right pupil failed to react to light and accommodation. There was a perforated nasal septum and ulceration of palate.

Laboratory tests. Serology was positive.

X-ray studies. Chest negative.

Course. Antisyphilitic treatment. Rapidly improved.

CASE 4

History. E. C., a Negress, aged 15 years, was admitted to the Receiving Hospital on February 24, 1947, and was discharged on March 8, 1948. She had stiffness of joints, fatigue, anorexia, and skin rash on abdomen and left ear. She had a history of fairly typical rheumatic fever beginning January, 1944, with associated remissions and exacerbations. In January, 1946, she was admitted to the University Hospital, and after two subsequent admissions, a diagnosis of sarcoidosis was made on lymph-node biopsy. The nodes decreased in size, but three weeks prior to admission to the Receiving Hospital, the patient showed exacerbation of symptoms associated with generalized lymphadenopathy.

Physical examination. The temperature was 99.6°F.; pulse, 120; blood pressure, 106/70 mm. Hg; respiration, 24. Positive findings included: (1) Enlarged nodes of rubbery consistency, submental, cervical and pre- and postauricular and axillary positions. (2) Abdomen—Large hyperpigmented erythematosquamous eruptions with indefinite

borders. (3) Bilateral lacrimal and parotid enlargement.

Laboratory tests. Hematology: Hemoglobin, 10 gm.; W.B.C., 17,700; neutrophiles, 86; lymphocytes, 9. Toxic alteration of neutrophiles. Bone marrow negative.

X-ray examination. Bones of hands showed periarticular demineralization.

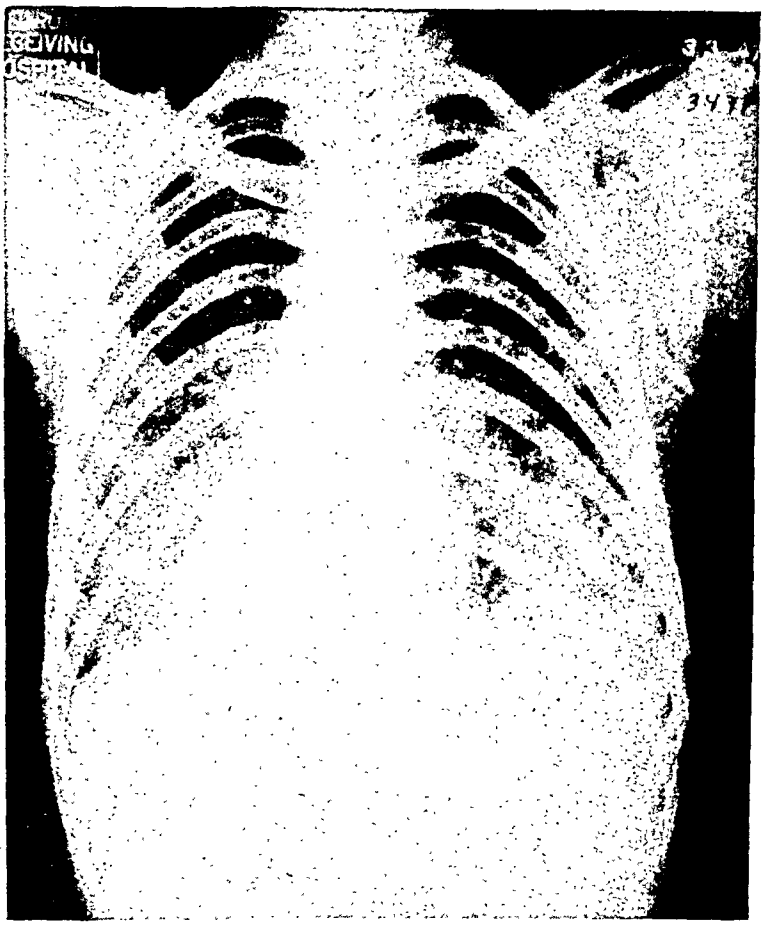

Fig. 11 (Heath). *Case 4.* Shows typical lung field and a diffuse fibrosis as seen in sarcoid.

Chest: Lung fields showed reticular pattern of opacity in all lobes, but heaviest in the bases; relatively little hilar adenopathy (fig. 11).

Lacrimal gland biopsy. Moderate interlobular and periductal fibrosis, illustrative of gout.

CASE 5

History. J. F., a Negress, aged 43 years, was admitted to the Receiving Hospital on June 15, 1946, and was discharged on July 8, 1946. She suffered from malaise and polyarthritis. There was edema of the lacrimal, parotid and salivary glands, of six weeks' duration, and conjunctivitis of one week's duration. P.H. was essentially negative.

Physical examination. Temperature, 99° F.; pulse, 88; respiration, 22; blood pressure, 140/95 mm. Hg. There was bilateral swelling of the lacrimal gland. Funduscopic examination revealed early arteriosclerotic vessel changes.

Laboratory tests. Serology was negative. Hematology and blood chemistry within normal limits. Sedimentation rate elevated.

Course. The patient refused biopsy. She was placed on salicylate.

Discharged markedly improved. Illustrative of rheumatism.

CASE 6

History. L. W., a Negro, aged 27 years, was admitted to the Receiving Hospital on December 14, 1936, and discharged on December 22, 1936. He had had progressive enlargement of the inguinal lymph nodes for one year, with parotid and submaxillary gland enlargement for three months (fig. 12).

Physical examination showed temperature, pulse, and respiration to be normal. Blood pressure was 130/90 mm. Hg. There was mild conjunctivitis and bilateral, painless, soft enlargement of parotid and submaxillary glands, as well as generalized lymphadenopathy.

Laboratory tests. W.B.C., 5,450; lymphocytes, 34. Serology negative. Sputum negative.

X-ray examination. Chest revealed advanced bilateral tuberculosis.

Course. Biopsy of epitrochlear node revealed acute noncaseating adenitis and giant-cell folliculosis. Biopsy of submaxillary gland refused. The patient was discharged on release. There was no follow-up. This case illustrates giant follicular hypertrophy.

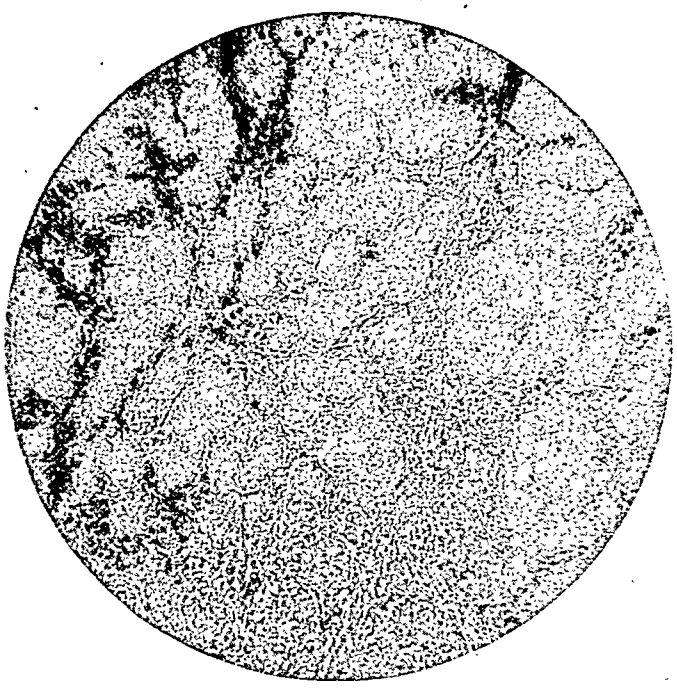

Fig. 12 (Heath). *Case 6.* Low-power view showing giant cell follicular hyperplasia.

COMMENT

Possible confusion in diagnosis is illustrated by the cases cited. There are many agencies causing physical signs of the syndrome, especially if the swelling is bilateral and includes the lacrimal, parotid, and maxillary glands (table 1).

The physiology and environment of the lacrimal gland renders it susceptible to deterioration from the edema and swelling resulting from any injurious agency. The gland has a fair blood supply and long periods of activity, a tight compact lobular structure surrounded by fibrous and lymphoid tissue. The gland is contained in a rather rigid environment between bony fossa, globe, and orbital septum, all limiting expansion, except at the price of pressure, atrophy, and fibrosis.

Microscopic studies of a biopsy material, made at only one stage sometimes, confuse unless the whole process has been followed from early through to the late stages. The structure of the gland and the lymphoid tissue present favors an inflammatory response by formation of granulomas. The structural and environmental factors mentioned above lead to early atrophy and fibrosis and the development of a lacrimal cicatrix. The clinical and morphologic findings, therefore, are often confusing.

One enters the realm of lymphomatous lesions ranging from benign simple hypertrophy and hyperplasias—transitional stages

TABLE 1

AGENCIES CAUSING LACRIMAL GLAND TUMEFACTION

Congenital hypertrophy	Infections in gland, as sarcoid, tuberculosis, syphilis, leprosy, virus (as mumps)
Simple hypertrophy (exaggerated physiology)	Rickettsia (as Q fever)
Trauma (including surgical)	Tularensis, oculoglandular fever
Foreign body	Uveoparotitis
Mechanical block (scarring and shrinking of conjunctiva, salivolithiases, calculus)	Extensions from skin as erysipelas from conjunctiva, keratoconjunctivitis
Chemicals and drugs (iodine, lead)	Leptothrix, sporothrix, blastomycosis, dachryoadenitis
Gland hypersensitivities and allergy	Neoplasms, as sarcoma, mixed cell, cylindroma, lymphoblastoma, and so forth
Metabolic diseases (gout, rheumatoid)	Leukemia
Parasitic (?trichinosis)	Hodgkin's disease
Blood dyscrasias	
Any acute xanthematous infection	

—to various forms of neoplasm. The lymphatic, hematopoietic, reticular tissues are difficult to classify.

Invasion of the gland by small lymphocytes is interpreted by some as a hyperplasia of the lymph elements and by others as a reaction of chronic inflammation. Others have noted that Mikulicz's disease in some cases is only a stage progressing from lacrimal lymphomas to ultimate concomitant, general lymphatic and hematopoietic involvement (Howard)[6]. Others present evidence against the theory of progression from Mikulicz's disease proper to pseudoleukemia to leukemia (Schaiffer and Jacobson)[7].

The evidence of a chronic, benign (over 10 to 15 years), clinical course is strong for a purely local disease. Other evidence is to be had from a study of biopsy material showing a limited lymphoid reaction and an early cicatrix, and a different, less sensitive response to radiation therapy from that of malignant lymphoma as has been pointed out by Leucutia and Price.[8]

Classification

Publications by Jackson, Parker, and Bethea,[9] and by Callender,[10] 1943, from material of the Lymphatic Tumor Division of the American Registry of Pathology give useful classifications. Gall and Mallory,[11] 1941, published a survey of "Malignant Lymphoma" offering a classification on a cellular basis, correlated with the clinical course. A general study of lymphatics, and so forth by Drinker[12] is useful. V. Brunn[13] classified with two main classes—those with and those without blood changes. Howard[6] concluded that Mikulicz's disease is not an entity. Thursfield's[14] classification provides for eight groups:

I. Congenital, familial or hereditary
II. Mikulicz's disease proper
III. Mikulicz's disease proper with involvement of lymphatic apparatus
IV. Leukemia
V. Tuberculosis
VI. Syphilis
VII. Gout
VIII. Sialodochitis fibrosa

Schaiffer and Jacobson[7] classify as follows:

I. Mikulicz's disease
A. Familial
B. Mikulicz's disease proper
II. Mikulicz's syndrome
A. Leukemia
B. Tuberculosis
C. Syphilis
D. Lymphosarcoma
E. Toxic
1. Lead
2. Iodides, and so forth
F. Gout
G. Febris uveoparotidea subchronica

Discussion

It is not the purpose of this paper to report the clinical findings related to a cellular classification of tumors of the ocular adnexa (McGavic[15]). Our purpose is to call to the attention of ophthalmologists some diseases of the lacrimal gland and related lymphadnexa. These lesions have features in common other than their location. We list in Table 1 some causes of lacrimal disease. It is clinically possible to find these causes. Lacrimal gland disease is probably more important than the frequency of its treatment suggests. Clinically, one rarely directly attacks the gland. To disentangle etiologic possibilities requires a number of studies. One may employ history, inspection, palpation, X-ray films, blood studies, examination for parasites, paper-strip studies of tears, intravital dyes, corneal studies of an associated keratitis, study of conjunctiva and smears, inspection of the lacrimal drainage apparatus, and the use of biopsies.

Tuberculosis as a rule shows caseation necrosis, loss of reticulum, smaller (Langhans) giant cells, infiltrative loss of acini, fibrosis different in character from sarcoid, and characteristic progress in the involve-

ment of other organs. The organisms may be stainable.

Sarcoid, in nearly half of the tissue sections, shows large foreign-body giant cells with inclusions (Schaumann bodies). The reticulum is present with a more normal appearing fibrosis and, as a rule, no coagulation necrosis. Other parts of the body may show sarcoid lesions—skin, viscera, lungs, bone, and so forth, and the whole process may characteristically be held in abeyance for irregular intervals.

Syphilis shows lymphocyte infiltration about vessels, the granuloma are firmer, less diffuse, and more vascular. Other over-all changes of syphilis will be present.

The clinician has to determine whether the nodule in the lacrimal gland is a self-limiting or an expanding inflammation, or neoplastic in character. Leinfelder and O'Brien[16] report the rarity of simultaneous involvement of orbits and lids in other forms of tumor.

Sarcoid and tuberculosis differentiation may be seen in Table 2. The lesions illustrated here, of the Mikulicz "pure type," are partly healed and illustrate a predominance of fibrosis and atrophy of the normal gland structure. The follicles in other patients studied late in the disease may be very rare, and giant cells still more rarely seen. The cracking phenomenon is seen hardly at all and then is only partially represented. At times a foreign body giant cell is found in the midst of, and in spite of, an extensive fibrous environment.

Early lesions show polymorphic granulomas, lymphocytes about the vessels, some

TABLE 2

DIFFERENTIATING TUBERCULOSIS AND SARCOID

Tuberculosis	Sarcoid
More of a proliferative endarteritis	A reticulo-endothelial system disease
Lesions usually move along to either healing or breakdown	Spontaneous regression common, periods of abeyance. Lesions may remain unchanged
Dissemination obvious, course relatively visible	Clinical manifestations variable, depend on organ involved
Distribution is wide; most rarely in striate muscles. Shows zonation	Descrete lesions. May occur in striate muscles
Does not enter through vessel walls. May be found on endothelial side	May enter vessel walls and go through to endothelium
Giant cells common, of Langhans type. No Schaumann bodies. More giant cells, in lymph relatively; more rare in lungs	Giant cells common, of foreign body type. Schaumann bodies common, 30 to 40 percent. Less in lymph; more common in lung
Caseation necrosis is the rule	Caseation rare
Cavity formation characteristic	In lung, cystlike spaces and emphysema
Concentric growth characteristic	Concentric growth absent
Epithelioids and eosinophiles not characteristic	Epithelioids common; eosinophiles in 10 percent
No reversal of albumin-globulin ratio	Reversal of albumin-globulin ratio
Healing is concentric, fibrous	Healing is fibrous, diffusely laid down
Reticulum lost	Reticulum present
If tuberculin test is negative, lesions may show stained organisms	If tuberculin test is negative, lesions do not show acid-fast organisms

instances of phagocytosis, red and giant cells, and sometimes eosinophiles. The acini are compressed and/or disorganized; the reticulum is compressed. Some authors distinguish two forms of lesion—lymphomatous and granulomatous. However, the characteristics of each may be found in the same tissue.

Summary

A report is given of a case of "pure" Mikulicz's disease. Similar lacrimal gland enlargements due to different agents—tuberculosis, sarcoid, gout, syphilis, and giant follicular hyperplasia—are reported. Attention is called to confusion in diagnosis. A table is supplied listing some factors and causes of tumefaction of the lacrimal gland.

Resemblances between the lesions of "pure" Mikulicz's disease and sarcoid are described. A comparison between tuberculosis and sarcoid pathology is outlined.

Conclusions

A considerable number of agents may cause tumefaction of lacrimal and accessory lacrimal glands. The differential diagnosis is made by studying the state of the general health of the patient, by following the course of the disease, and by making local ocular studies and biopsies. Confusion exists, especially between tuberculosis and sarcoid. This usually can be resolved. So-called "pure" Mikulicz's disease probably is a granulomatous response of lymphatic tissue of the reticuloendothelial system to a stimulus. This stimulus may be infectious, parasitic, or chemical. Many lacrimal gland reactions are reversible while others resolve by fibrosis to a lacrimal cicatrix. If the latter is extensive enough, the cornea inevitably suffers.

OPERATIVE FAILURES FOR CHRONIC SIMPLE GLAUCOMA*

A HISTOLOGIC STUDY

BRITTAIN F. PAYNE, M.D.
New York

A study of eyes removed after operative failures for chronic simple glaucoma shows that ideal surgical relief has not been devised as far as the laboratory is concerned. The examination of approximately 100 operated eyes with glaucoma at the New York Eye and Ear Infirmary showed at least three characteristics: (1) Adhesions between the iris and the cornea; (2) closure of new filtration channels with fibrosis; and (3) inflammation of the uvea.

Synechias between the anterior surface of the iris and the posterior surface of the cornea are composed of such dense connective tissue that permanent separation by operation is almost impossible. The artificial filtration channel or channels become closed by the proliferation of connective tissue, despite an iris inclusion in the operative wound. Progressive iridocyclitis usually requires enucleation.

Operations for glaucoma which illustrate the general microscopic findings of all globes sent to the laboratory for study are iridectomy, iridencleisis, and trephination. These eyes show in common the following characteristics.

1. Pathologic changes in the corneal epithelium.
2. Thinning of the cornea and sclera.
3. Inflammation at the limbus.
4. Shallowness of the anterior chamber.
5. Adhesions of the iris to the cornea and lens.
6. Inflammation of the iris and ciliary body.
7. Changes in the crystalline lens.
8. Pathologic depression of the optic nerve.
9. Atrophy of the ganglion cells of the retina.
10. Unusual findings in the vitreous body.

The object of this paper is to show the causes of failures in the usual operations performed for the relief of chronic simple glaucoma. In order to show the histologic changes in the disease, it is necessary to review briefly the microscopic anatomy of the normal globe.

THE NORMAL EYE

The eye is composed of a comparatively avascular fibrous tunic consisting of the cornea and sclera, both a millimeter or less in thickness, enclosing the uvea and the transparent contents of the globe. The

Fig. 1 (Payne). Normal globe. (A) Iris angle.

* Presented at the III Pan-American Congress of Ophthalmology, Havana, Cuba, January 4 to 10, 1948. From the Department of Pathology, New York Eye and Ear Infirmary and the New York University College of Medicine.

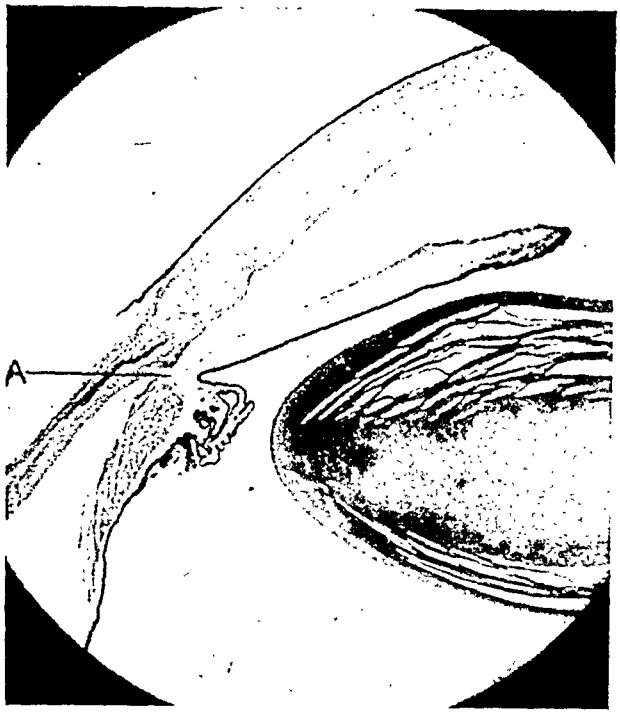

Fig. 2 (Payne). Normal angle of the iris (A) enlarged.

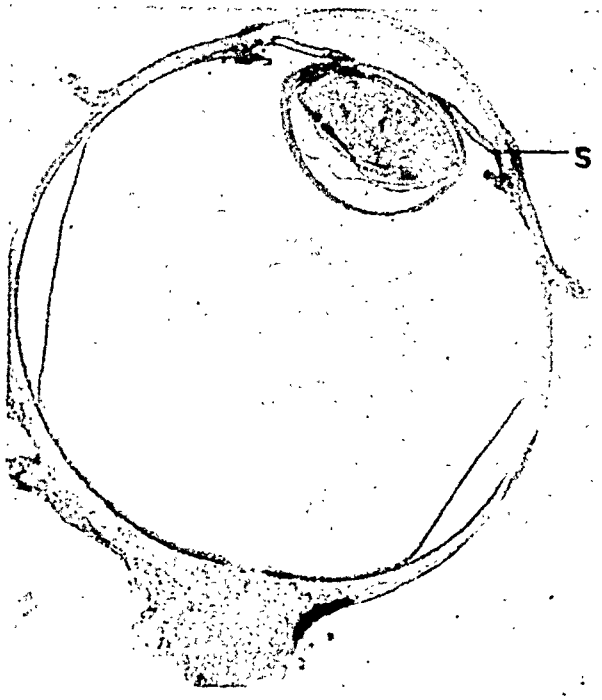

Fig. 3 (Payne). Subacute glaucoma with shallow anterior chamber and peripheral anterior synechias.

lamina cribrosa is a continuation of the sclera to form a meshwork across the optic canal.

A section of the cornea shows that it consists of five layers and from without inward they are: the epithelial layer, Bowman's membrane, the stroma, Descemet's membrane, and the endothelium. The normal cornea contains no blood vessels nor medullated nerve fibers. Corneal epithelium is unique in that it is visible throughout its five layers, including its most superficial squamous cells. Bowman's layer is a thin, homogenous, acellular layer lying immediately internal to the epithelium and serving as a basement membrane for it. It gradually fuses into the underlying stroma and becomes one of its components. The stroma consists of layers of specialized connective tissue, so interlaced that clean separation is impossible, and it forms nine tenths of the thickness of the cornea. Descemet's membrane has an inner cuticular and an outer elastic component and is quite resistant to trauma or disease. The innermost endothelial lining consists of a single layer of flattened cells which become quite thin over the pectinate processes and the anterior surface of the iris.

The limbus corneae

The limbus is a concentric segment measuring 0.75 mm. anteroposteriorly at the junction of the cornea and sclera, and containing characteristics of each. The fibrous tunic is reduced in thickness in this area by the indentation of the scleral sulcus externally and the scleral-furrow internally. The external sulcus is filled in with fine, loose aerolar connective tissue permeated by blood vessels which end in small capillary loops at the corneal margin. The surface is covered with thickened stratified squamous epithelium, which is arranged in folds and is undergoing transition to bulbar conjunctival epithelium. The scleral furrow or the internal depression of the limbus is filled in with a meridional meshwork of endothelial-covered strands known as the ligamentum pectinatum. Schlemm's canal is in close relation to the outer bounds of the furrow. Anterior ciliary veins connect with the drainage channels which transport aqueous from the anterior chamber.

The sclera

The sclera is that portion of the fibrous tunic which extends from the limbus corneae to the optic canal. It is composed of dense connective tissue and varies in thickness from 1 mm. at the posterior pole to 0.5 mm. beneath the insertions of the extraocular muscles. For descriptive purposes, the sclera has three layers: the loose, mildly vascular episcleral connective tissue; the dense, almost avascular, areolar connective tissue forming the middle and greater thickness of the structure; and the inner or "lamina fusca" which is only differentiated from the middle layer by chromatophores in its interspaces.

The lamina cribrosa is a weblike continuation of scleral fibers across the optic canal. It contains collagenous and elastic fibers intermingled with glial components. Normal horizontal sections through the optic nerve show that there is continuity in curvature of the cribriform plate corresponding to that of the sclera. It is evident that it is the weakest portion of the fibrous tunic and will be first to become distended by pressure from within the globe.

The uvea

The uvea consists of the choroid ciliary body and iris. The choroid may be described as the vascular layer lying just internal to the lamina fusca of the sclera. It is composed of three ill-defined series of blood vessels as follows: An outer layer of large-sized blood vessels, a middle layer of intermediate-sized vessels, and an internal layer composed of a single row of capillaries adjacent to the lamina vitrea of the choroid. Interspersed between these various layers of blood vessels are chromatophores and a fine reticulum of connective tissue and endothelial elements.

The ciliary body is composed essentially of the same layers as the choroid, but differs in that the ciliary muscle is interposed. The ciliary muscle is made up of three parts; an inner circular series of fibers connected with outer meridional fibers by a series of radiating fibers. The ciliary muscle gives size and shape to the ciliary body. Internal to the muscle layers are the continuations of the vascular choroidal layers with the exception of the choriocapillaris. The pigment epithelium is a continuation of the pigment epithelium of the retina and the ciliary epithelium is the same as the retina reduced to a single layer of the nonpigmented cells.

The principal blood and nerve supply is from the long posterior ciliary vessels and nerves.

The iris may be divided into an anterior or mesodermal portion and a posterior or ectodermal derivative. The former consists of three ill-defined layers: the endothelium, the anterior border layer, and the vessel layer. The posterior portion of the iris is composed of a dilator pupillae and the pigment epithelium of the iris. The anterior endothelium is peculiar in that its surface is abruptly broken at the margins of the crypts and aqueous is permitted to come into direct contact with the stroma. The anterior border layer is characterized by a slight condensation of the fibrous tissue beneath the endothelium. The number of chromatophores contained in this layer determines the color of the iris, the more chromatophores, the darker the iris. The vessel layer of the stroma of the iris is composed of delicate, loose connective tissue supporting numerous blood vessels, which appear to have thickened walls. No elastic fibers are found in the iris except in the walls of the blood vessels and at its union with the ciliary body. The constrictor and dilator pupillae muscles are derivative of the pigment epithelium and the latter forms the outer lead or the ectodermal portion of the iris. The constrictor is easily seen in most preparations but the dilator is thin and obscured by the pigment epithelium or the inner leaf of the iris. The circulation is through the radicals from the greater arterial circle, which lies in the anterior part of the ciliary

body and is supplied by the long posterior and anterior ciliary vessels.

The retina

The retina is a thin transparent structure composed of nine layers, the outermost being the rods and cones and the innermost being the internal limiting membrane. It lies in apposition but not attached to the pigment epithelium, a single layer of cells separating it from the choroid. The retina is anchored only at the ora serrata and around the margin of the optic disc. It has a dual blood supply, the inner five layers receiving nutrition from the central artery and accompanying vein. The outer four layers are supplied by the choriocapillaris. The optic nerve begins with the papilla, a flat round projection just inside the globe measuring 1.5 mm. in diameter. It lies 1 mm. below and 3 mm. nasally to the posterior pole of the eye and corresponds to the intraocular portion of the nerve. The elevation is caused by an accumulation of nonmedullated nerve fibers from the ganglion cells of the retina. A central depression lies on the surface. It is in this depression that the central retinal vessels emerge. The fibers arrange themselves in the interstices of the cribriform plate and just posterior to it they assume medullation and become arranged into bundles. Posterior to the globe, the nerve is covered by the pial and dural sheaths, with the arachnoid lying between. At approximately 15 mm. posterior to the globe, the central retinal vessels enter the nerve at right angles and proceed forward in its center to appear in the depression of the papilla. The bundles are so arranged that regular rows of nuclei from the septa follow a course parallel to the long axis of the nerve. The blood supply is from the vessels of the sheaths, the central vessels, and the circle of Zinn.

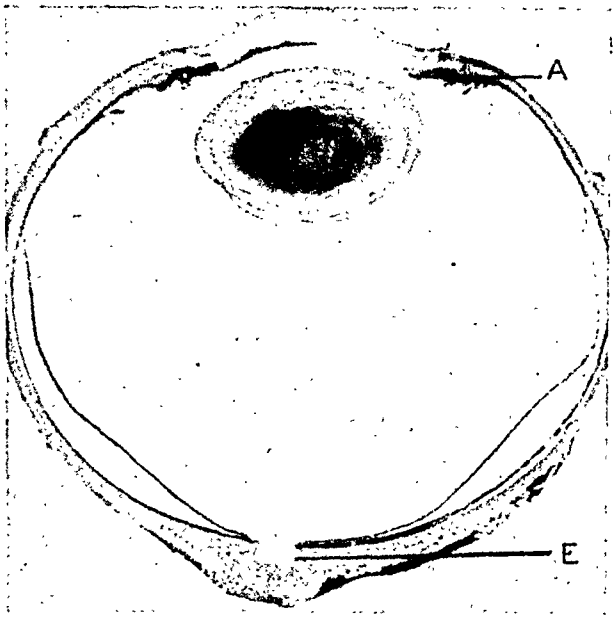

Fig. 4 (Payne). Iridectomy operation (A) shows stump of iris extending toward apex of cornea, adhesions remain.

Contents of the normal globe

The contents of the globe are aqueous humor, the crystalline lens, and the vitreous body. Under normal conditions, the aqueous does not appear in sections. The lens is often distorted in the process of fixation and staining. The vitreous may be displaced or compressed. In the presence of glaucoma, all three of these elements may show definite findings which contribute to the pathologic picture. The aqueous may show albuminous changes with cells and fibrin in suspension, the lens may be pushed forward and swollen, and the vitreous may contain fragments of pigment and other evidences of degeneration.

Iridectomy operations

An eye (fig. 4) demonstrating most of the usual microscopic findings after unsuccessful iridectomy operations shows generalized thinning of the fibrous tunic with edema and absence of the corneal epithelium. The operative wound is closed by dense connective tissue in which some of the iris pigment remains. The stump of the iris extends toward the center of the cornea and is adherent to it, showing that the synechia is just as extensive as it was before the operation was performed. In other words, the normal iris angle is not restored

and the adhesions are not relieved.

Further study of the specimen shows considerable edema and round-cell infiltration at the limbus which extends into the operative wound. The cornea is somewhat thinner than normal and the epithelium is undermined in the periphery, swollen and absent over the center. Bowman's membrane is intact except in the region of the limbus, where pannus is beginning to form. A membrane is forming on the anterior surface of the iris, and the endothelium is covered with a thin layer of round cells, fibrin, and pigment particles. The sclera is thinner than normal and shows little of importance. The iris is characterized by atrophy, broad anterior peripheral synechias, and chronic inflammation. The iris stump extends far anterior to the filtration angle which has been closed by adhesions. The membrane forming on the anterior surface of the iris, and contributing to the adhesions, has firmly sealed any possible connection with the normal drainage spaces. The ciliary body shows atrophic and inflammatory changes, and the choroid is flattened to a mere line by pressure and fixation. The retina shows destruction of the ganglion cells, edema, and cystic degeneration. The crystalline lens has been removed but its enlarged and forward displaced capsule remains. A fragment of iris lies on the anterior surface of the lens. Careful study of this specimen indicates that the iridectomy failed to create a new drainage channel and the synechias were undisturbed. The presence of inflammation contributed to the loss of the eye.

Fig. 5 (Payne). Iris inclusion (A) in operative wound; (L) crystalline lens; (S) anterior synechias.

Iridencleisis operation

An eye (fig. 5) removed after an unsuccessful iris inclusion operation shows atrophic uveal tissue in the operative wound, a shallow anterior chamber, and definite lens changes.

The fibrous tunic is distended and thinner than normal. The epithelium shows signs of edema and bullouslike formation near the operative wound.

A more intensive examination of the sections shows that the iris is included in the bleb and that filtration is possible. There is sufficient space between the conjunctival flap

and the iris for aqueous drainage. Unfortunately, the iris shows signs of chronic inflammation and firm diagonal adhesions, which unite the root of the iris to the base of the flap. Instead of acting as a filtration "wick," the iris forms a firm band which dams the aqueous behind it. There is no relief from increased intraocular pressure, which accounts for distention of the globe and formation of bullae on the cornea.

vessels with extravasations into the loose connective tissue. A small hemorrhage lies adjacent to the ciliary body. Diffuse lymphocytic infiltration and fibrotic changes complete the picture. The iris on the side opposite is drawn taut by its adhesion to the displaced lens. It is atrophic and diffusely infiltrated with lymphocytes. The ciliary body shares in the atrophic changes just mentioned.

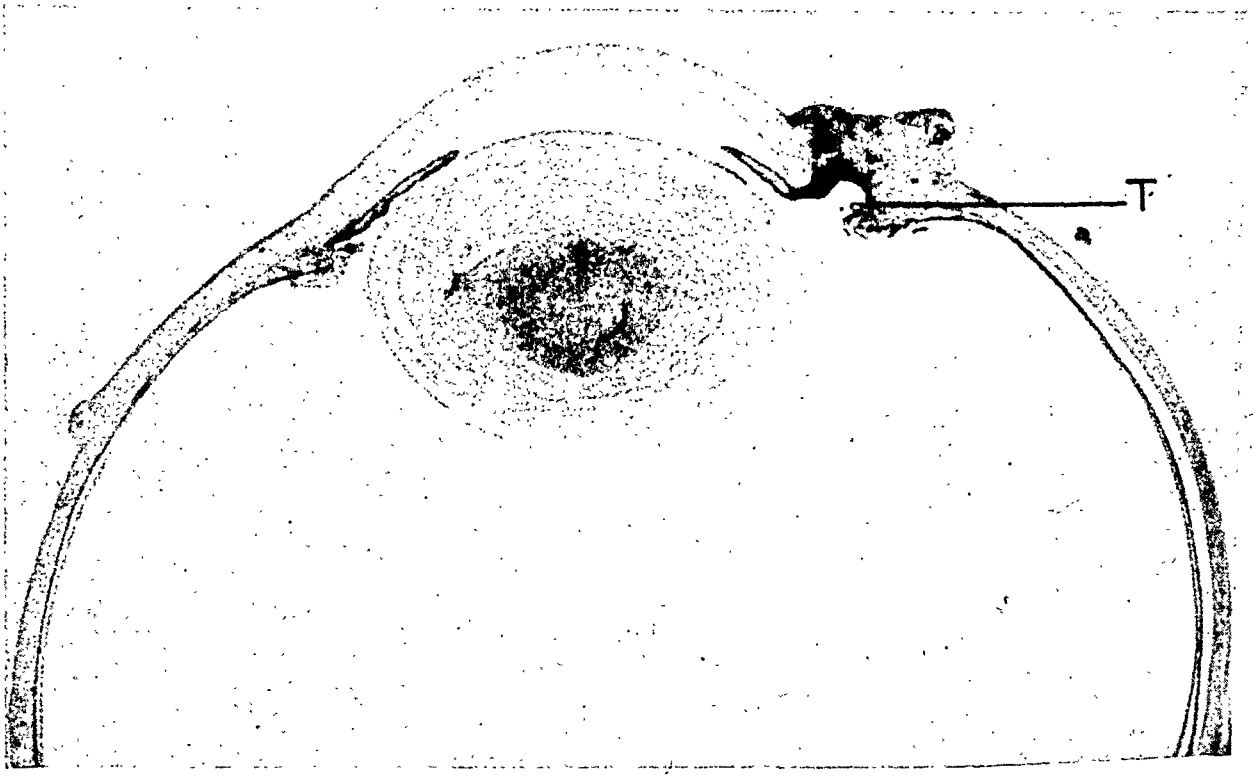

Fig. 6 (Payne). Unsuccessful trephining operation showing (T) operative wound.

The crystalline lens has moved in the direction of the filtration cicatrix. It is saved from complete dislocation by a firm adhesion of the pupillary area of the iris to its anterior capsule. The iris itself is almost diamond shaped in cross section and shows evidence of nuclear sclerosis. Some of the contraction of the lens cortex is due to hardening agents. Displacement of the lens is a fairly common finding after operations for glaucoma.

Most of the inflammatory changes in this specimen are in the vicinity of the operative wound. There is congestion of the blood

The eventual loss of this eye was due to the bandlike adhesion of the iris across the mouth of the operative wound, displacement of the lens, distention of the globe, and bullous keratitis.

Trephinations

Eyes (figs. 6 and 7) enucleated after unsuccessful trephinations may be illustrated by the description of a typical "failure."

The specimen shows that the anterior chamber is shallow, the crystalline lens is swollen, and the operative wound is closed by fibrous tissue. The cornea is irregular in

thickness. The epithelium is slightly undermined by new blood vessels and connective tissue at the limbus. The stroma is moderately infiltrated in the periphery. Descemet's membrane is curled in itself near the operative wound, and the endothelium is covered with a thin layer of fibrin. The operative wound is closed by dense connective tissue containing fragments of pigment, lymphocytes, and new blood vessels. The filtering cicatrix contains fresh hemorrhage. The iris is atrophic and is closely adherent to the cornea and lens on the unoperated side. An iridotomy has been performed as is shown by a part of the iris lying in the wound. The ciliary body and the choroid show atrophic changes with congestion of the blood vessels. The retina is undergoing degenerative changes with diffuse hemorrhage in its innermost layers. The crystalline lens shows cortical cataractous changes with nuclear sclerosis. The lens is in close relation to the filtration wound. The loss of the eye was due to fibrotic changes in the wound and close approximation of the lens.

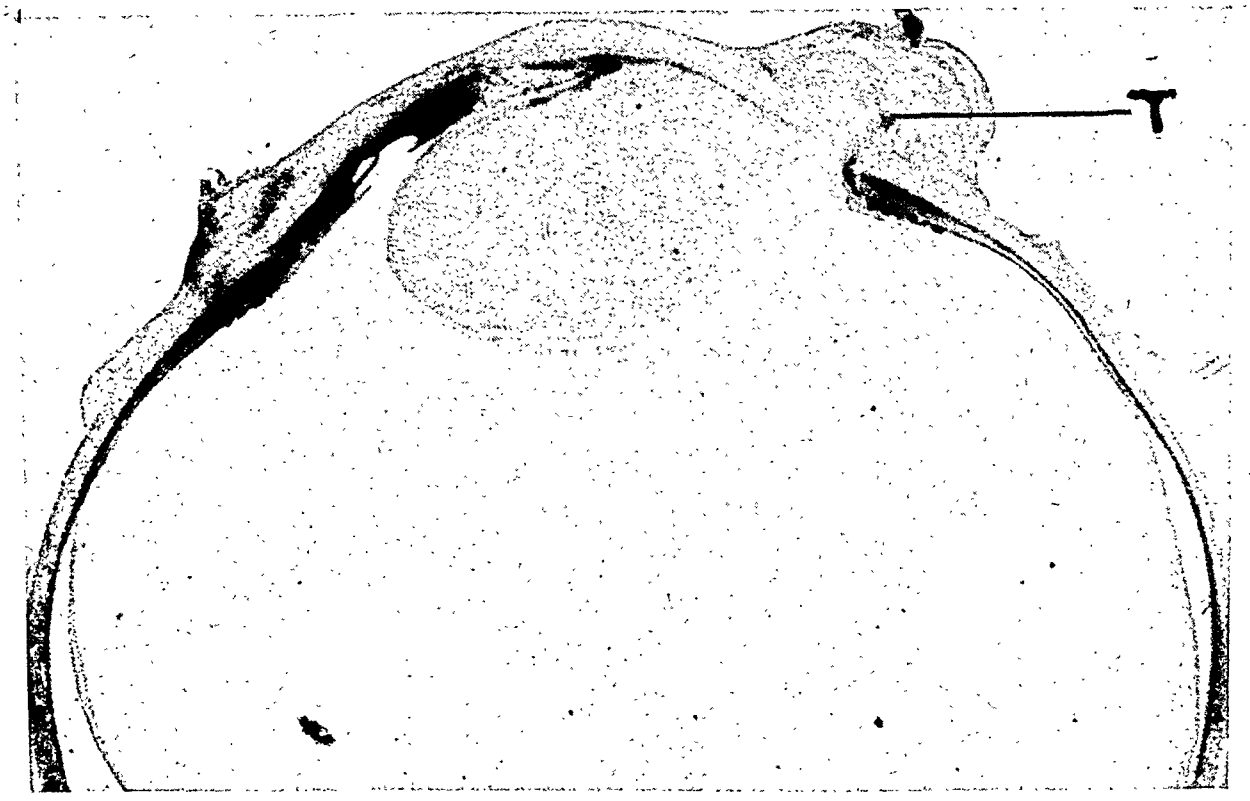

Fig. 7 (Payne). Operative failure after trephining operation, (T) showing herniation of crystalline lens.

Conclusions

1. Common pathologic changes are present in eyes removed after operative failures for chronic simple glaucoma.

2. Comparing the histology of normal eyes with that in chronic simple glaucoma may show the causes of operative failures.

3. Failure of the iridectomy operation may be due to persistence of synechias and not removing the iris at its roots.

4. Iris-inclusion operations may be closed by the iris itself.

5. Trephinations may become closed by fibrotic and inflammatory changes.

6. Specimens reviewed in the laboratory are operative failures.

7. Successful operations for glaucoma are not reviewed in the laboratory and far exceed the "failures."

A TECHNIQUE FOR MUSCLE RESECTION WITHOUT THE USE OF THE PRINCE FORCEPS*

ELTON YASUNA, M.D.
Worcester, Massachusetts

It has often been my feeling when performing or observing ocular muscle resections in which various types of forceps, such as the Prince, Reese, or Worth, were used that the surgeon was being inconvenienced considerably by the forceps, in spite of the fact that the muscle was being held securely. Frequently, the forceps are awkward and in the way, especially when working on the relatively small eye muscle of a child where space is at a premium. With corrective strabismus surgery being performed more and more frequently in young children, this annoyance with the use of muscle forceps assumes greater importance.

Over a period of time I began to question the concept that the Prince forceps† furnished the ophthalmic surgeon a secure and certain fixation on the muscle. The concept was challenged with caution, since the Prince type of forceps is almost universally accepted and used. Certain specific experiences and observations in muscle resection surgery, however, cause me to doubt that the forceps are always safe and certain in their action.

In some instances, the forceps slip a small amount after being locked, and the final amount of resection obtained is less than anticipated. When the forceps are used to pull the distal end of the muscle toward the site of insertion in order to place sutures and later to tie them securely, there is tension on the muscle and the forceps are apt to slip, especially if the teeth are worn or do not approximate accurately. It may be argued that this is a fault in the instrument rather than with the technique. Nevertheless, the procedure is essentially dependent on the instruments.

An argument in favor of the Prince type of forceps is the accuracy with which the amount of resection can be determined. If a 10-mm. resection is desired, then the instrument is placed the necessary distance from the insertion. Here, too, the concept of accuracy has to be questioned. Although in theory the instrument is placed at the required distance planned for the muscle resection, actually there results a certain amount of stretching and pulling on the muscle while inserting the forceps. This is especially true in large resections, even though the muscle and its adjacent tissues are thoroughly cleaned. Thus the final resection is less than planned even if measuring instruments have been used.

The forceps create further annoyance by engaging a large part of the surgical field which is necessarily limited by the relatively small structure of the extraocular muscle. The surgeon is frequently working around the instrument, especially during the placing and fastening of the sutures, at which time diligent care has to be exercised in order to avoid tying the forceps to the muscle.

Finally, another moment of awkwardness is usually encountered when the forceps are removed. The teeth of the forceps may be so strongly entrenched in the muscle fibers that the surgeon has to exert his full care and delicacy in extricating the instrument. The sutures are already tied, and excessive tension in this region may loosen or even damage the sutures.

Although the use of muscle-resection forceps has shortcomings and limitations, nevertheless these instruments will continue to be employed unless another procedure

* From the Department of Ophthalmology, Worcester City Hospital. Service of Dr. A. Eugene Messier.

† Since this particular type of forceps is widely used, the term "Prince forceps" will be used as generally referring to all types of resection forceps of similar principle.

can be devised which will eliminate or lessen the faults of the forceps. With this in mind the following procedure was initiated and developed. To date 29 muscle resections have been performed by this technique with increasing confidence in its value.

Surgical procedure

The conjunctival incision is made 6 mm. above the superior border of the muscle to be resected rather than over the muscle (fig. 1). In this way the small blood vessels about the muscle are avoided and all bleeding is eliminated. The original incision includes Tenon's capsule and extends down to the sclera. Following the exposure of the sclera and gentle dissection of the episcleral tissues with blunt-pointed conjunctival scissors, all cutting instruments are placed aside. The isolation and cleaning of the muscle is completed entirely with the use of strabismus hooks and ordinary eye forceps, and it is usual to accomplish this in a completely bloodless field.

A double-armed, 3-0 catgut suture is placed through the muscle insertion from beneath (fig. 2), each arm of the suture being about 2 mm. from the muscle margin. The assistant now gently raises the distal end of the muscle from the sclera and each arm of the suture is placed through the muscle at the desired distance from the insertion depending upon the amount of resection planned (fig. 3). The suture is not pulled up but a loop of each arm is left loose both above and below the muscle to avoid severing the sutures where the muscle is cut. All suturing is performed before the muscle is sectioned. The muscle is now cut about 2 mm. from the insertion (dotted line in fig. 3) while the assistant holds up the muscle with a hook. The sutures must be observed carefully to avoid injury to them. When the muscle is severed, the assistant grasps the cut distal end with a Graefe forceps and pulls the muscle toward the insertion until the new site of attachment is over the original insertion (fig. 4). The sutures are securely tied and the excess muscle trimmed. In this way the distal end of

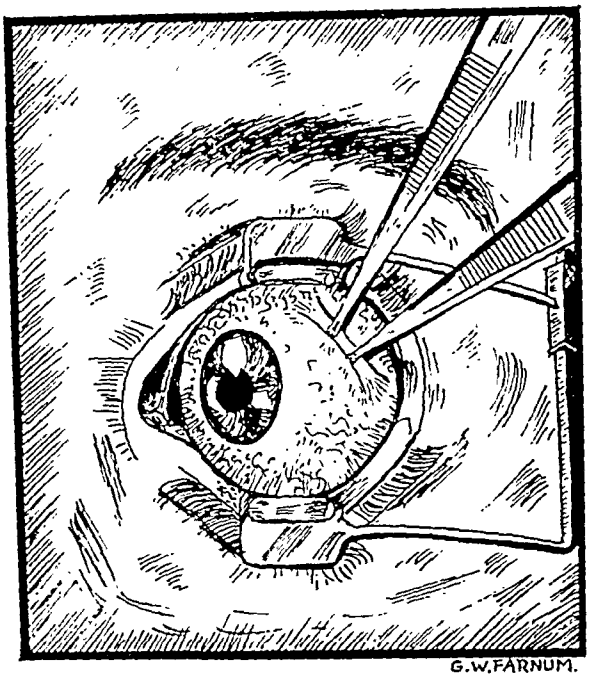

Fig. 1 (Yasuna). The conjunctival incision is made 6 mm. above the superior border of the muscle to be resected rather than over the muscle.

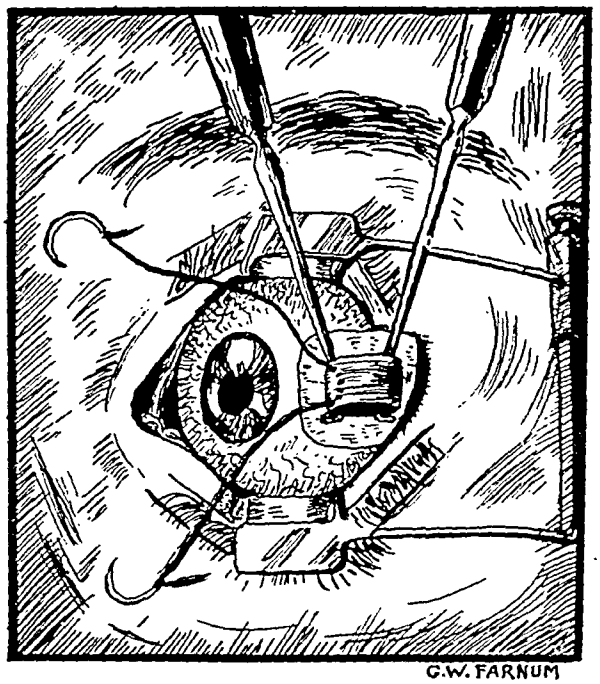

Fig. 2 (Yasuna). The suture is placed through the muscle insertion beneath, each arm of the suture being about 2 mm. from the muscle margin.

the muscle overlaps the insertion and places muscle over muscle which will result in a firmer union. The conjunctiva is closed with a continuous 6-0 black silk suture.

The above method is simple and the surgical field is never obscured with instruments. The amount of muscle to be resected is measured with the muscle in its normal anatomic position and no stretching is caused, as with the Prince forceps. When desired, larger resections have been possible with this method than with forceps. No vertical error is caused since the sutures are placed before the muscle is cut.

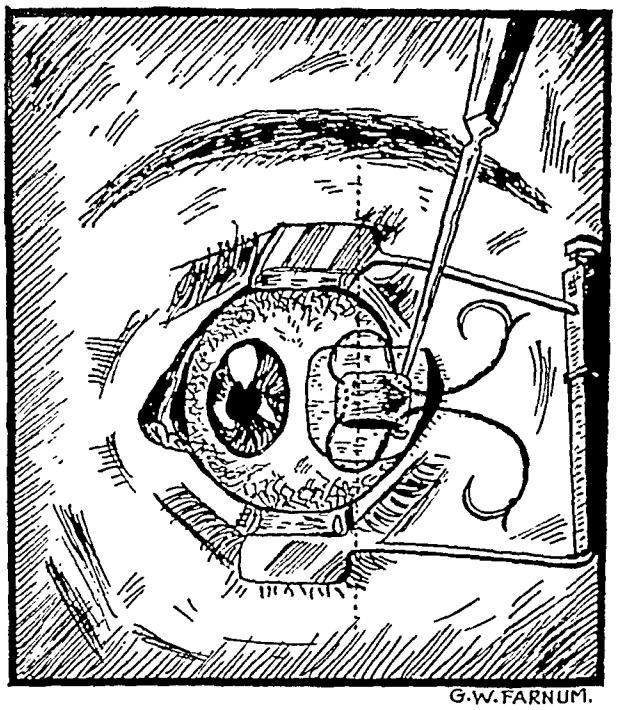

Fig. 3 (Yasuna). Each arm of the suture is placed through the muscle at the desired distance from the insertion, depending upon the amount of resection planned.

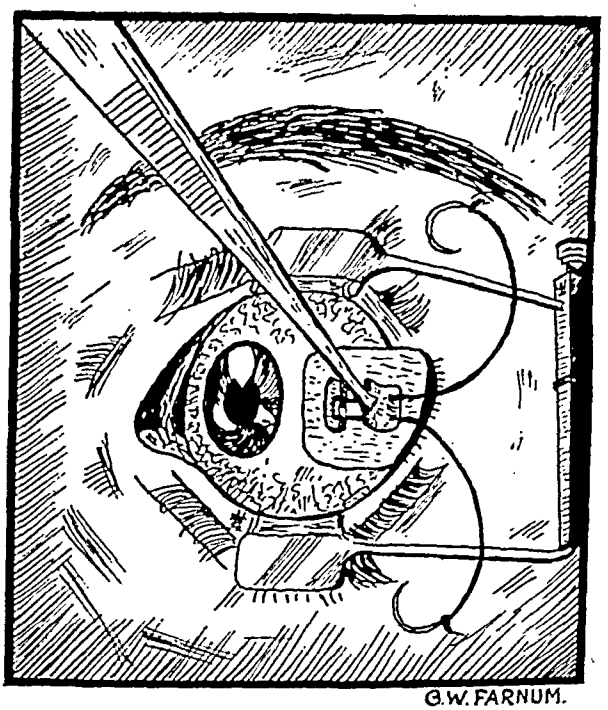

Fig. 4 (Yasuna). The severed muscle is pulled toward the insertion until the new site of attachment is over the original insertion.

The present standard textbooks on ophthalmic surgery[1, 2] do not describe a procedure for muscle resection without the use of forceps. On searching back among older ophthalmic surgical texts, however, a description is found in Török and Grout[3] of a resection method by Schweigger in which no forceps are used.

Conclusions

1. The use of resection forceps, such as the Prince, is not always secure, safe, and accurate. The instrument is awkward and obscures part of the surgical field.

2. A simple method of muscle resection without the use of forceps is described.

3. This method allows greater accuracy in determining the amount of resection, larger amounts of resection when necessary, and avoidance of vertical displacement.

A MODIFICATION OF ELLIOT'S OPERATION AND ITS APPLICATION TO HIGH TREPHINATION

A PRELIMINARY REPORT

WIKTOR ARKIN, M.D.
Warsaw, Poland

Although Elliot's trephining operation is in general use and is much easier than the Lagrange operation, many surgeons prefer cyclodialysis or simple iridectomy because they sometimes encounter difficulties both in the technique of the operation itself and in the postoperative results.

DIFFICULTIES IN TECHNIQUE

As for the technique of Elliot's operation, two points cause certain difficulties. (1) It is sometimes difficult to separate the conjunctival flap beyond the margin of the cornea without tearing. (2) Trephination of the sclera requires the use of a sharp instrument, much training, and great caution if the ciliary body is not to be injured.

It occurred to me that the introduction of a metal plate between the sclera and the ciliary body, before the sclera is buttonholed, would greatly facilitate the performance of the operation. It would give a firm support to the trephine when the sclera is punctured; it would protect the deeper parts of the eye from trauma; it would permit the surgeon to use an exceedingly sharp trephine which makes for better end results. (According to Meller[1] when a dull or blunt trephine is used, the scleral wound generally overgrows.)

MODIFICATION OF OPERATION

With these difficulties in mind, I modified the operation in the following manner (fig. 1).

TECHNIQUE

The conjunctiva is incised with scissors 1 cm. above the superior limbus of the cornea and is then separated up to its margin. An incision of the sclera is made as for a superior cyclodialysis; that is, on the vertical meridian, 5 to 6 mm. from the limbus. The cyclodialysis spatula, or the iris repositor, is introduced between the sclera and the ciliary body which is not broadly separated from the sclera. The spatula is left in place to act as a support for the trephine.

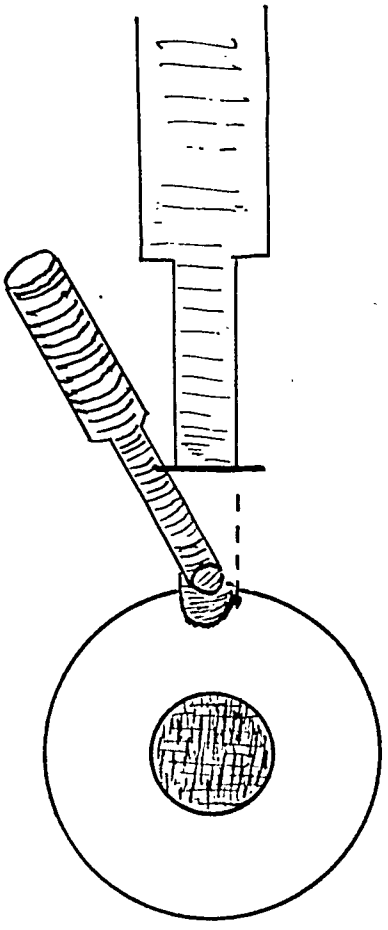

Fig. 1 (Arkin). A modification of Elliot's trephining operation.

Holding the spatula in the left hand, I use the *right hand* to perform the trephination in the corneoscleral margin at the meridian,

as is customary, while the sclera is lifted by the spatula. (The end of the spatula is visible across the cornea.) To avoid any slipping of the trephine, a wider spatula (3 mm. in width) may be used, or the spatula and trephine can be combined into one instrument (fig. 2).

Combining the operations of cyclodialysis and trephination, even with the broader

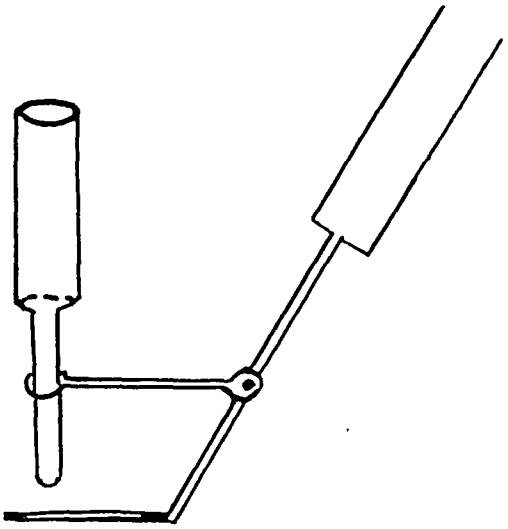

Fig. 2 (Arkin). The spatula and trephine can be combined into one instrument.

separation of the ciliary body, does not alter the final result. Cyclodialysis has for a long time been used with other operations for the relief of glaucoma in order to reinforce their action. No complications have resulted. Statistics show that, in cases of long standing, iridectomy is not effective in lowering the intraocular pressure but gives only temporary relief from an acute attack and that, in the end, a second operation (cyclodialysis) is indispensable.

Discussion

It would seem wise, therefore, to avoid two operations, when both procedures can be performed jointly. A majority of surgeons separate the ciliary body by means of a corneoscleral incision either before or after the iris is excised. Such a performance may be termed "cyclodialysis inferior" or "cyclodialysis superior," depending upon the technique used. I have come to the conclusion that it is much easier to execute the "cyclodialysis superior" first and then to perform a classical iridectomy immediately.

If cyclodialysis does not include a broad separation of the ciliary body, it does not cause an inflammatory reaction, and that is why it does not put an additional burden upon the eye if it is performed jointly with other operations for the relief of glaucoma. Indeed, cyclodialysis has one advantage in that it liberates the angle of filtration and thereby enables one to perform a correct trephination.

When the angle of filtration has trabecular and sclera-iris adhesions, the fact that the trephine on its way across the iris pricks through the iris tissue may be the reason that the aqueous does not leak away after the corneoscleral puncture is made.

When a trephination is performed as described, it is executed with greater safety because injury of the underlying tissues is impossible. The operator need not concentrate upon the sharpness of the trephine and, since there is support for the trephine, an even corneoscleral puncture can be made with a blunter instrument.

If a narrow spatula is used, the liquid flows out slowly, and the iris inserts itself on the sides. (It suffices then to withdraw the spatula and the iris prolapses only on removing the instrument.) It is important to remove the spatula slowly so that the liquid does not flow out too rapidly, causing dislocation of the lens or hemorrhage.

The chief disadvantage of this modification of Elliot's trephining operation is the possibility of a late infection being caused by the inclusion of corneal epithelium in the covering of the corneoscleral wound. Since the inferior part of the wound is only just covered with the corneal tissue which can easily be impaired, a secondary infection may follow. There is less danger of late infection after the Lagrange type of

operation because, when this procedure is used, the wound lies obliquely almost beyond the cornea.

Report of a case

While using a 2-mm. trephine to operate a case of glaucoma simplex, the instrument slid upward. Since it was too late to correct the instrument's position, I was compelled to finish the trephination with great care, striving not to injure the ciliary body.

In order to accomplish this, I maneuvered the upper part of the scleral disc close to the sclera and cut only the lower part with the trephine. When the instrument was taken away, I lifted the lower part of the disc with the forceps and cut away the upper part very carefully with the Graefe knife. Only when the spatula was introduced through the puncture in the anterior chamber did the aqueous flow.

As the spatula was introduced, I felt some resistance that indicated the presence of trabecular or scleral iris adhesions. Black tissue (the ciliary body) was visible in the superior portion of the wound and below the base of the iris which could be recognized by its different color. The iris did not prolapse because the wound lay almost totally on the ciliary body.

For fear of injuring the ciliary body, I did not try to draw out the iris but finished the operation and covered the wound with the customary conjunctival flap.

On the second postoperative day, the eye was quiet, and there were no signs of inflammation. There was good filtration and the intraocular pressure was reduced. Postoperative progress was normal, intraocular pressure became lower, and filtration persisted.

Comment

An analysis of this case made me conclude that performing a trephination in this manner (it could be named *superior trephination*) has some advantages. (1) The wound is covered completely with conjunctiva which facilitates separation of the flap from the corneal epithelium. Since the conjunctival flap is thicker, it is seldom perforated which is a certain safeguard against secondary infection. (2) Conjunctiva, more easily permeated by aqueous than corneal epithelium, completely covers the wound—not just half of it, as in the original Elliot's trephining operation. (3) When this modified method is used, the iris does not prolapse and obstruct the wound. Since the wound is bounded by the ciliary body, an iridectomy can be avoided. This latter circumstance necessitates an explanation.

Discussion

In executing the Elliot trephining operation in the traditional manner, it is almost always necessary to perform an iridectomy because the iris either prolapses or obstructs the wound. Because of the pressure of aqueous from behind, it is almost impossible to replace the iris since it is too frail to hold back this pressure.

The question may well be asked if iridectomy is not essential to the relief of high intraocular pressure. It would seem that the existence of free filtration is sufficient to reduce the pressure. I have found that a high ocular tension resulting from iritis (iritis glaucomatosa) can be controlled more quickly by trephination without iridectomy.

Since this technique is confined to sclerectomy, not only the iris, but the entire eye, is protected from injury, and the possibility of obstructing the wound with remnants of excised iris is eliminated.

One disadvantage of this technique lies in the possibility of injuring the ciliary body. For this reason, the modification in technique herein described is best suited to high trephination. This protects the ciliary body from damage and, at the same time, produces separation of trabecular adhesions.

Any fear that the ciliary body will fill

the wound may be dismissed. Even when a 2-mm. trephine is used, the ciliary body is too thick to obstruct the wound. Such a complication usually occurs after iridectomy or sclerectomy in which the wound is wider.

On the other hand, the iris is so delicate that its fold can obstruct even such a small incision as a buttonhole of the sclera. The higher in the sclera the incision is made, the less is the possibility of the iris prolapsing. However, it is important not to make an incision too high in the sclera for then the ciliary body would obstruct the wound completely and there would be no free filtration of aqueous.

In order to guarantee free filtration, a certain portion of the wound should be unobstructed and should open either directly into the chamber or, at least, touch its border.

In a survey of the available literature I found a paper by Schultz[2] with a discussion by Schieck. Assuming that a wound covered only with conjunctiva protects the eye against infection, Schultz used high trephination. In his discussion, Schieck said that high trephination injured the ciliary body and maintained that great caution was necessary to avoid this complication.

My method by which a spatula is used as a safeguard against the possibility of injuring the ciliary body would seem to be an answer to this criticism.

Summary*

1. A new method of trephination is described. It consists of introducing a spatula between the sclera and ciliary body as for cyclodialysis. The protection of the metal plate makes trephination easier and safer.

2. Cyclodialysis without great separation of the ciliary body does not detract from the end results, but on the contrary has certain advantages.

3. The so-called "superior trephination" has advantages over the classical or "inferior trephination." It is only considered more dangerous because there is fear that the ciliary body may be injured. This seldom occurs.

4. The use of a spatula between the sclera and ciliary body as protection in high trephination eliminates the possibility of injuring the ciliary body.

Targowa Street, W. 15

A NOTE ON METHODOLOGICAL EVALUATION OF SELECTED VISUAL TESTS*

JOSEF BROZEK, ERNST SIMONSON, AND JOSEPH C. FRANKLIN
Minneapolis, Minnesota

INTRODUCTION

In evaluating any method from the point of view of its usefulness in laboratory investigations on man one should ask at least three questions: (1) Is it affected by practice? (2) Does it yield, on successive applications, consistent results? (3) Is it sensitive to the experimental variables the effect of which it is used to test?

Too frequently the first two questions are neglected or decided impressionistically. Yet there is little doubt that the quantitative and impersonal approach should not stop at the stage of obtaining raw measurements but should be carried into the stage of evaluation as well. In the present paper we shall discuss from this standpoint a number of visual functions measured in connection with investigations on the effect of illumination on performance and fatigue. The work task, experimental design of the series, and the statistical concepts and computational formulas were presented in detail elsewhere.[1, 2] The reader may refer especially to a paper on ophthalmological functions, published in the JOURNAL,[3] for a more detailed discussion of the fundamental issues and statistical methodology.

SUBJECTS

The subjects were six young men with normal vision and ocular structures who participated in nutritional studies carried out at the laboratory during the year preceding the visual investigations. They were coöperative and conscientious, and were well adapted to experimental work.

* From the Laboratory of Physiological Hygiene, University of Minnesota. This work was supported in part by a grant from the Verd-A-Ray Corporation, Toledo, Ohio.

METHODS

The following functions will be discussed in this paper: recognition time for threshold stimuli, brightness discrimination, flicker fusion frequency, and blinking rate. The first three functions were measured before and after two hours of standardized visual work which reproduced, in a miniature job situation, the operation of conveyor inspection.[1] The blinking rate was determined during the course of visual work. These functions were a part of a large battery of tests applied in our studies on the effect of illumination intensity[4] and the spectral quality of light.[5]

RECOGNITION TIME FOR STIMULI OF THRESHOLD SIZE

The test of visual acuity consisted in designating the location of dots in white squares, 1.5 by 2.5 inches. The stimuli of different size were presented in random order. The distance between the test patch and the subject was kept at 18 feet, and the illumination remained constant. The time from the moment the stimulus was presented to the instant of recognition was determined. The recognition time for the smallest dot which was correctly located was taken as the test score.

BRIGHTNESS DISCRIMINATION

One half of the visual field in the Pulfrich photometer manufactured by Zeiss was set at a brightness level which served as a standard throughout the experimental series. The brightness level in the other half of the visual field was set at zero (darkness) and the subjects' task was to increase the brightness until it matched the standard. The deviation, expressed in arbitrary units, above or

below the correct value, served as a score. Both a red and a green filter were used. The score for each testing is based on five repeated determinations made with each filter.

Flicker fusion frequency

The flicker was produced by interrupting a beam of light by means of a rotating, perforated disc. The opening in the opal glass on which the light fell was about 1 cm. in diameter, with the distance from the light stimulus from the eyes fixed at 40 cm. The number of flickers per second was increased at a standard rate from a coarse flicker to the point of an apparent fusion. Three successive measurements were made at each testing and averaged.

Blinking rate

The blinking rate was determined by counting the number of blinks for five minutes. The count was taken at the start, at the midpoint, and toward the end of a 2-hour work period. Both the initial reading and the average value were considered, expressed as the number of blinks per minute.

Effects of practice

In experiments requiring testing repeated over a period of days (or months, as is the case in nutritional studies) it is desirable to reach a stable performance plateau before the start of the experimental work. The information on changes resulting simply for a repeated administration of a test and due to the complex of factors summed up in the term "practice" is essential for the planning of experimental work yet the data on this point are scarce. The initial test scores obtained under standard conditions before or at the start of the work test on the first 6 testing days, separated by 2 or 3 days during which the subjects worked as clerical or technical assistants in the laboratory, provide a useful material for a study on the effects of practice.

The men were well acquainted with the experimental procedures and were tested twice before the start of the experimental work proper. On inspection there was little change in the scores obtained on these two occasions. On the basis of theoretical considerations, as well as previous experience with some of the tests used in this series, no marked practice changes were expected. The presence of practice trends was tested by comparing the mean of the different functions for the first 3 testing sessions with the mean of the 4th, 5th, and 6th testing sessions. The data (table 1) indicate that the actual mean changes were small and reached the 5-percent level of statistical significance only in the case of flicker fusion frequency. This was somewhat surprising, since in our previous work no statistically significant effects of practice were observed when a group of 8 men was tested on 15 consecutive days.[6] Simonson and others found little change in the fusion level in 11 subjects who were tested repeatedly at least once a week up to 13 weeks.[7]

Probably the main factor which produced the apparent lowering of the fusion level in the present series was a better coördination of the perception of fusion by the subject and giving the signal to the experimenter, thus shortening the lag between occurrence of the fusion and reading of the dial. The second factor of potential importance in long-term experiments is the possible change in the criterion of "fusion." These factors are minimized if separate, repeated trials are made with definite rates of flicker. As indicated above, in this series the readings were made during the ascending, automatically increasing rate of flicker. However, the alternative procedure is more time consuming.

The actual "practice" change in the average flicker fusion-frequency score was small. In terms of the "fitness," the change was in the biologic direction of "deterioration": the higher the fusion score, the greater the capacity of the retinocortical system to perceive successive flashes as discrete stimuli and, therefore, by definition, the "better"

TABLE 1

THE DIFFERENCES BETWEEN THE MEAN SCORES AND THE F-TESTS OF THEIR STATISTICAL SIGNIFICANCE FOR THE FIRST AND SECOND SET OF THREE SUCCESSIVE TESTING SESSIONS

Function	Units	Mean Differences	Biological Direction of Change†	F-Values
Recognition time	sec.	−1.2	+	0.94
Brightness discrim., red	arbitrary	+0.1	(−)	0.41
Brightness discrim., green	arbitrary	−0.4	+	2.09
Flicker fusion frequency	flickers per second	−0.6	−	6.39*
Blinking rate, initial	blinks per minute	−1.6	+	1.78
Blinking rate, average	blinks per minute	−1.2	+	0.10

* For 1 and (18−1) = 17 degrees of freedom, the value of the F ratio at the 5% level of significance is 4.45, at 1% level it is 8.40.

† The plus sign indicates an "improvement," the minus sign a "deterioration."

the score. In the majority of the other functions, the changes were in the direction of "improvement" but remained well within the limits of chance variation.

CONSISTENCY OF REPEATED MEASUREMENTS

The data analyzed from the point of view of the consistency of the measurements were obtained in the 13th to 18th session of the series. The rows in Table 2 represent data obtained for each individual in the course of six testing sessions, separated by 2 to 3 days; the arithmetical averages of the rows indicate *individual means.* The columns represent testing sessions; averages of the columns may be referred to as *"daily means."*

$\bar{Y}_D$	4.5	5.3	6.8	5.0	5.0	5.6	

In a 2-way table we may compute three types of variation, characterized statistically in terms of variances:

1. Variation within the rows; this may be designated as "variance within individuals," V_{wI}.

2. Variation within the columns, expressed as "variance within days," V_{wD}.

3. The discrepancy between the scores predicted on the basis of the mean values for a given individual and a given day, and the actual measurements; this type of variability is expressed as the "random variance," V_R.

When there are no significant trends in the scores obtained in consecutive testing trials and when the ratio V_{wI}/V_R approaches one, the consistency of a test may be characterized in terms of the *intraindividual* variation (V_{wI}). This indicates the amount of inconsistency in the scores obtained on different days under standard conditions. In evaluating the magnitude of this "experimental error" we shall compare it with the *interindividual* variation (variance within days, V_{wD}). Ideally, we should know the population value of this characteristic; when we are working with small samples of highly homogeneous subjects, the V_{wD} is likely to be a gross underestimate of the population value. The comparison of V_R and V_{wI} with V_{wD} can be obtained in the form of a simple percentage

$$\left(\%\ V_R = \frac{100V_R}{V_{wD}}, \quad \%\ V_{wI} = \frac{100V_{wI}}{V_{wD}}\right)$$

or in a form of a coefficient of day-to-day consistency

$$\left(r_C = 1 - \frac{V_R}{V_{wD}}, \quad r'_C = 1 - \frac{V_{wI}}{V_{wD}}\right).$$

TABLE 3

STATISTICAL DATA CHARACTERIZING THE CONSISTENCY OF REPEATED MEASUREMENTS OF SELECTED VISUAL FUNCTIONS

Function	Mean Score	Variances			
		V_R	V_{wI}	V_{wD}	V_{wI}/V_R
Recognition time	5.8 sec.	9.6	8.7	16.4	0.91
Brightness discrim., red	2.6 units	0.18	0.19	0.78	1.06
Brightness discrim., green	2.7 units	0.09	0.10	0.20	1.11
Flicker fusion frequency	46.0 flickers	0.9	1.0	1.8	1.11
Blinking rate, initial	5.4 blinks	4.2	4.1	8.2	0.98
Blinking rate, average	5.8 blinks	1.5	1.6	9.2	1.07

Function	$\frac{100V_R}{V_{wD}}$	$1-\frac{V_R}{V_{wD}}$	$\frac{100V_{wI}}{V_{wD}}$	$1-\frac{V_{wI}}{V_{wD}}$
Recognition time	59%	0.41	53%	0.47
Brightness discrim., red	23%	0.77	24%	0.76
Brightness discrim., green	42%	0.58	50%	0.50
Flicker fusion frequency	50%	0.50	56%	0.44
Blinking rate, initial	51%	0.49	50%	0.50
Blinking rate, average	16%	0.84	17%	0.83

As indicated in Table 3, the average intraindividual (V_{wI}) and the random (V_R) variance are of about the same magnitude, their ratio being for all the visual functions tested very close to 1.00; consequently, both can serve as an indicator of the "chance variation" in scores obtained on repeated testing. When we express the "error variances" (V_R and V_{wI}) as percentage of the average interindividual variance (variance "within days," V_{wD}), the figures run from 16 percent for the blinking rate average to 59 percent for the recognition time, and the coefficients of consistency range from 0.84 to 0.41. In view of the high homogeneity of the sample, we may be certain that the average interindividual variance (V_{wD}) used as the criterion for the evaluation of the "ex-

perimental error" is too small and, consequently, the tests appear to have low consistency. Elsewhere[2] tentative limits for the evaluation of consistency coefficients have been set as follows: for very high consistency $0.91 \leqq r_c \leqq 1.00$, for high consistency $0.81 \leqq r_c \leqq 0.90$, and for low consistency $r_c \leqq 0.70$.

We have an empirical check on the effects of the homogeneity of the sample for the flicker fusion frequency, which was tested by the same instrument in a larger group of subjects; both groups were drawn from the same population. For the larger sample ($N = 36$) the interindividual variance was 19.40. Using this as an estimate of the population value, the percentage error ($100\ V_{wI}/V_{wD}$) is reduced from 56 percent to 5.2 percent, and the coefficient of consistency increases from 0.44 to 0.948 which is a very respectable figure. This value is close to the product-moment correlation of 0.981 obtained by correlating two sets of flicker fusion determinations made a week apart on the 36 men in the age range from 20 to 30 years.

For the other functions no such correction can be made because values for larger samples are not available but one may be certain that the consistency of the tests which at present appear low and in some cases very low would improve markedly if adequate estimates of the interindividual variability were available.

Sensitivity to stress

No attempt will be made to investigate this question systematically. The type of stress will be limited to visual work and the data will serve only as an illustrative example. The visual work used as the experimental "stress" involved recognition of moving letters, exposed for a fraction of a second, and has been described in detail.[1] The set of experiments considered in this context involved 2 hours of work at the illuminative level of 5 foot-candles. This represented a fairly severe strain and should be a reasonable criterion for testing the possible use of these functions for laboratory studies of visual fatigue.

TABLE 4

CHANGES IN THE VISUAL FUNCTIONS TESTED BEFORE AND AFTER TWO HOURS OF VISUAL WORK INVOLVING RECOGNITION OF LETTERS (VISUAL ANGLE OF TEN MINUTES) AT FIVE FOOT-CANDLES

Function	Mean Differences	F-Values	Biologic Direction of the Change†
Recognition time	+3.7 sec.	16.55*	−
Brightness discrim., red	+0.2 units	2.69	−
Brightness discrim., green	−0.05 units	0.15	+
Flicker fusion frequency	−0.9 flickers per sec.	18.33*	−
Blinking rate (initial-terminal)	+0.8 blinks per min.	1.01	−

* For 1 and $(36-1)=35$ degrees of freedom, $F_{0.05}=7.42$, $F_{0.01}=4.12$.
† The plus sign indicates an "improvement," and the minus sign a "deterioration."

The differences between the mean values of 36 individual determinations made before and after the 2-hour spell of intensive work or, in the case of the blinking rate, at the start and end of the visual work, are given in Table 4.

The change was in 4 out of 5 functions in the direction of deterioration but only the recognition time and the fusion frequency of flicker were affected significantly. In terms of biologic significance, as distinguished from statistical significance, the change in the flicker fusion frequency was small. The increase in the recognition time attained a value which would be relevant from the practical point of view.

The different behavior of the functions measured may in part reflect a true

differential sensitivity, in part it may be due to the fact that the determinations of brightness discrimination were made last in the series of tests with a delay of about 15 minutes as compared with the determinations of the recognition time and flicker fusion frequency which were measured immediately at the end of the work.

The change in the rate of blinking at intervals measured during work is not sensitive to the visual stress and can not serve as an "index of fatigue." This is in conformity with the experience of Tinker and other investigators (see ref. 8, esp. p. 440 ff.).

Summary and Conclusions

1. An attempt was made to evaluate a number of visual characteristics from the point of their usefulness in laboratory investigations of "fitness" and "fatigue."

2. The functions studied included recognition time for threshold stimuli, brightness discrimination, flicker fusion frequency, and blinking rate.

3. As a result of practice in taking the tests, there was a small but statistically significant drop in the fusion frequency of flicker. The decrease in the rate of blinking and in the amount of error made in matching a standard level of brightness (green filter) was not significant.

4. The consistency of the scores repeated on six different occasions under standard conditions appears to be low, due to a very high homogeneity of the sample. When, in the case of the fusion frequency of flicker, more valid estimates of the interindividual variation for the population were substituted for the estimates obtained on the given sample of subjects, the consistency criteria assumed satisfactory values.

5. When the functions were measured before and after 2 hours of strenuous visual work under 5 foot-candles, the difference between initial and terminal scores was in direction of biologic deterioration in all of the functions studied, except the brightness discrimination (green filter). The change was statistically significant only in the case of the recognition time and the flicker fusion frequency.

SOME EXPERIMENTS WITH GREEN SPECTACLES PRESCRIBED TO GLAUCOMATOUS PATIENTS*

R. B. ZARETSKAYA, M.D.
Moscow, U.S.S.R.

In our preceding work† it was shown that the illumination of the one eye with green light resulted in the lowering of the intraocular pressure in the other eye, this effect being especially pronounced in glaucomatous eyes. It seemed natural, therefore, to test the use of green spectacles, as a means tending to reduce intraocular pressure. The present paper contains a description of the attempts made by us in this direction.

Experiments involving the use of green spectacles by glaucomatous patients were carried out on 19 subjects with various forms of the disease.

The period of observation was 12 to 15 days for in-patients (11 cases), and 30, 50, and more days for out-patients (8 cases).

METHOD

The pressure was determined with the aid of the Schiøtz tonometer three times a day: at 7 a.m. when the patients were still in bed; at 1 p.m., and between 7 and 8 p.m., at the moments of a maximum or minimum intraocular pressure..

The patients were withheld from any medication during a whole day, or even two days, if the status of their eyes made it permissible. By the end of the second day, in most cases, the patient received green spectacles which he was asked to wear throughout the period of examination.

The spectacles were manufactured from green glass of a hue corresponding 511 mμ and with daylight transparency equal to about 21 percent.

In certain cases the use of green spectacles was combined with a greatly reduced dose of pilocarpine. The combination of green glasses with the instillation of several drops of adrenalin (1:1,000) was also made to test Kravkov's statement that the instillation of adrenalin at this concentration may increase the eye's sensitivity to the green light.

The effect of the use of green spectacles under the given conditions was evaluated by us from the run of the diurnal curve of intraocular pressure.

RESULTS

From an analysis of the curves obtained from testing patients, it may be seen that, notwithstanding the total suspension of pilocarpine medication, the intraocular pressure showed a pronounced tendency to decrease in patients wearing green spectacles; the range of fluctuations of intraocular pressure during the day was likewise found to decrease. (Degenerative alterations of these eyes were not advanced, nor was the level of tension excessively high.)

An appreciable effect was obtained when the use of green spectacles was combined with the administration of a very small dose of pilocarpine (0.5-percent solution twice a day).

In 20 of 25 diurnal curves, we were able to observe a clearly expressed decrease in intraocular pressure, as well as a reduction of the range in fluctuation, as compared to the records taken at the period when the administration of pilocarpine was entirely suspended. The decrease in tension was a fairly appreciable one—6.0 mm. Hg in 8 cases; 6.0 to 10 mm. Hg in 9 cases; 10 mm. Hg and more in 3 cases.

The decrease in intraocular pressure was much more striking, however, in certain

cases in which the use of green spectacles was combined with small doses of adrenalin.

The 24-hour curves reproduced in Figures 1 to 4 were plotted for some of the patients investigated by us and may well illustrate all that has been said.

Report of cases

Case 1 (fig. 1). The patient, a woman, 75 years of age, suffered from chronic glaucoma of the right eye and nearly absolute glaucoma of the left eye.

The eyes were quiet, corneas transparent, and the pupils were the size of a pinhead. The crystalline lens was sclerotic. Visual acuity of the right eye was 0.9; that of the left eye, light projection irregular. The visual field of the right eye showed a concentric contraction for the white, and a sharp contraction for the other colors. The fundus of the right eye showed a deep glaucomatous excavation of the papilla of the optic nerve; this was somewhat less profound in the left eye.

The tension as measured according to Sobansky in the arterial center of the retinas of the two eyes was 45 mm. Hg.

The patient has now been wearing her green spectacles for more than a year without receiving any supplementary medication.

No undesirable phenomena on the part of the patient's eyes have been recorded within this period during which she was under our continuous observation.

Case 2 (fig. 2). The patient, a man, aged 61 years, had chronic glaucoma of both eyes. He complained of a mist swimming before the eyes, iridescent halos when looking at the lamp, reduced visual acuity, but no pain. He had been treated since 1937 with instillation of 1-percent pilocarpine solution, without feeling any better. At the first examination, the patient was much annoyed by the continuous dimness in both eyes.

The pupils were extremely narrow (miosis medicam). Visual acuity was: R.E., 0.4 to 0.5, with a 0.5D. sph., 1.0; L.E., 0.4, with a 0.75D. sph., 1.0.

Green spectacles were prescribed and, as may be seen from Figure 2, the general level of the diurnal curve of tension for both eyes became lower. The patient enjoys his spectacles and feels more comfortable.

However, since the intraocular pressure in the left eye was occasionally found to fluctuate above the normal level, an attempt was made to combine the use of green spectacles with instillation of adrenalin solution (1:1,000). As seen from Figure 2, both the level of tension and its fluctuation range soon became quite normal.

Case 3 (fig. 3). Patient K, a man, 62 years old, had chronic inflammatory glaucoma of the right eye. The left eye was normal. He had been ill since 1938 when he suddenly became aware of reduced visual acuity, of iridescent halos, and mist before his right eye.

Visual acuity was O.U., 0.02, without correction; O.U., 1.0, with correction.

The fundus of the right eye showed a glaucomatous excavation of the papilla of the optic nerve, although not sharply pronounced. The papilla was hyperemic, the veins extended.

The visual field was somewhat concentrically restricted for the white, and somewhat more for colored lights. The left eye was within the normal.

On November 29th the patient was asked to wear green spectacles. Diurnal curves were analyzed for five days. During this period, the intraocular pressure persistently showed a wide range of fluctuation, although at a somewhat lower level. The patient felt well, and he was less annoyed by the feeling of mist swimming before his eyes. He liked to wear his spectacles which make him feel more at rest; he was becoming much less irritable.

On December 6th, a 1-percent pilocarpine solution was prescribed in addition to the

use of green glasses. This was to be instilled twice a day into his right eye.

Under these conditions intraocular pressure showed a marked decrease, although on separate days of the period of examination its level attained 44 mm. Hg.

The best effect was attained, however, by substituting a 1:1,000 solution of adrenalin, twice a day, for the pilocarpine. The patient was observed for 11 days. Without entirely normalizing the tension, the combination of green spectacles with adrenalin prevented the maximum tension from exceeding 34 mm. during these days.

It should be pointed out in this place that, during the course of our experiment, we often observed that the instillation of pilocarpine at shorter intervals caused the intraocular pressure to persist at a higher level than when less frequent doses, or no pilocarpine at all, were given.

Case 4. (fig. 4). At this juncture it is of interest to cite the case of Ku., aged 65 years, who suffered from chronic glaucoma of the two eyes. The diurnal curve of this patient, after he had refused to wear green spectacles combined with small doses of pilocarpine, and after pilocarpine and eserine every hour had been prescribed as a preoperational treatment, shows that there was a sharp increase in tension and that the level, in general, was much higher than during the preceding days. The range of fluctuation of tension, which had been 6.0 mm. or less, rose to 10 to 16 mm. during these days.

Comment

In addition to these successful results, cases were also encountered where the patients derived no benefit whatever from the use of green spectacles. Some even showed a slight increase in intraocular pressure, although this increase was observed in individual cases only, in patients whose intraocular pressure had for the most part been stabilized at a high level.

The questions arise: What is the clinical value of our investigations? And what is their practical application?

The encouraging results of our experiments make us believe that the use of green spectacles may, in certain forms of glaucoma, prove a helpful therapeutic procedure, especially if prescribed along with small doses of adrenalin or pilocarpine.

Discussion

The mechanism of the action of indirect stimuli upon the intraocular pressure is rather obscure and so is, although to a lesser degree, the mechanism responsible for the appearance of hypertension in the case of glaucoma.

Unquestionable, however, is the fact that green light, while acting upon the color receptor of our vision, produces a definite rearrangement in the vegetative nervous system, thus affecting also the neurovascular apparatus of the eye.

It may be assumed that the amounts of acetylcholine and sympathin in the eye are different, according to whether the eye is exposed to green or to red light: this may possibly be the cause of the opposite reaction of the intraocular pressure for the red or the green stimulus revealed by us.*

Conclusions

1. Preliminary tests have shown that the use of green spectacles prescribed along with a total withdrawal of pilocarpine medication produces in glaucomatous patients a well-pronounced tendency toward a decrease in their intraocular pressure. The beneficial effect observed was at its maximum in patients showing a medium level of intraocular pressure accompanied with no sharply expressed disturbances in the function of the sight.

2. The intraocular pressure in glaucomatous patients has been found to be most reduced when the use of green spectacles

---

*Am. J. Ophth. 31:721-727 (June) 1948.

was reinforced by the administration of small doses of adrenalin.

3. The mechanism of action of the green-light stimulus upon intraocular pressure still remains obscure. It is very probable however, that by acting upon the color receptor of the human eye, the green light brings about a definite rearrangement in the autonomous nervous system and thus affects the neurovascular apparatus of the eye.

Sadovaya-Chernogryazskaya Street. (14/19).

RUBEOSIS IRIDIS DIABETICA

JACK V. LISMAN, M.D.
New York

The association of new capillary formation on the iris with glaucoma in diabetic patients was first noticed by Salus[1] in 1928. He proposed the term rubeosis irides diabetica and called the associated glaucoma the true diabetic glaucoma in contradistinction to the usual primary glaucoma in the ordinary diabetic patient. Since his report of 3 cases, 37 more cases have appeared in the literature and have been reviewed by Fralick.[2] Two of the 5 cases reported by Fralick occurred in the absence of diabetes. The rarity of this condition is indicated in its absence in a series of 2002 diabetics in whom rubeosis was searched for, studied by Waite and others.[3]

The original description of Salus and his conclusions have been somewhat modified by the report of subsequent cases. As originally described, the surface of the iris is transformed by the appearance of new, light-red, capillary nets superimposed on an otherwise normal appearing iris tissue. These new vessels are in the region of the lesser circle of the iris, placed closely together and interlinked, and give this portion of the iris a reddish hue.

Other larger vessels run radially from the lesser circle toward the ciliary part where they disappear in the angle of the anterior chamber. The vessels never extend into the pupillary area itself.

The rubeosis is not related to the severity nor to the duration of the diabetes. Kurz[4] presents one case in a man, aged 29 years, with diabetes of only three years' duration. The rapidity with which glaucoma follows the rubeosis is quite variable and may appear concomitantly or may be delayed as long as five years, as in one case of Salus. One third of the cases have an associated essential hypertension. Hemorrhagic and proliferating retinopathy is frequently associated.

Wegner[5] reports one case of rubeosis associated with diabetic retinopathy that was successfully operated on for cataract by intracapsular extraction. In view of the inevitable glaucoma in all other cases and the interval of five years between the appearance of rubeosis and the glaucoma in the case of Salus, the cataract extraction was probably followed by glaucoma after a long interval.

Glaucoma is a sequel to the capillary formation and invariably appears if the cases are followed long enough. The glaucoma is associated with hemorrhage in the anterior chamber and does not respond to miotics; surgical intervention is always followed by disastrous consequences.

Gonioscopic examination of the angle was described by Kurz[4] who found large radially running vessels breaking up into many branches connecting directly with Schlemm's canal. The angle at first was bridged by numerous synechias between which ran many fine vessels; the angle was almost completely obliterated as the pathologic process advanced. Schlemm's canal was filled with

blood on gonioscopic examination. The histologic examination by Kurz revealed that the new vessels were not associated with inflammation and were not part of a new membrane but lay in and upon iris tissue itself.

These eyes respond not at all to treatment and because of the pain may have to be enucleated. In the stage of absolute glaucoma, the neocapillary formation disappears from view as the iris stroma undergoes atrophy and no evidence of the antecedent rubeosis is present. Kurz presents this fact as evidence that the new vessel formation is not part of an inflammatory membrane but part of the iris tissue and shares its fate when it atrophies. The characteristics of the associated glaucoma is that it is of the hemorrhagic type. There is always a deep anterior chamber.

Sugar,[6] in his classification of glaucoma, places hemorrhagic glaucoma in a separate category. This form of glaucoma may be seen in patients with diabetic rubeosis and also in thrombosis of the central vein of the retina and, clinically, the two types are not distinguishable. Sugar believes that the rubeosis occurs only when there are repeated large intraocular hemorrhages and that the neocapillary formation is a toxic effect due to the disintegrating blood; if the toxic effect of the disintegrating blood is less marked, the rubeosis may antedate the glaucoma by a long time.

Etiologically, the two types of glaucoma are the same, both being associated with massive intraocular hemorrhage and with severe angiosclerotic changes. The presence of albuminous material and extensive vascular membranes in the angle of the anterior chamber in thrombosis of the central vein has been well shown by Samuels, in 1933.[7] He states that the glaucoma "could be caused by a change in the metabolism of the eye, produced by toxic substances derived from the disintegration of red blood cells and a degeneration of the stroma of the vitreous."

The rupture of the thin-walled vessels when the tension if the eyeball is suddenly reduced by surgical procedures, is the reason the eye fails to respond to antiglaucoma operations.

Hemorrhagic glaucoma differs from simple glaucoma in its acute malignant onset with vascular congestion, and from true acute congestive glaucoma in that the anterior chamber is of normal depth rather than shallow.

Report of a case

History. F. W., a 53-year-old white woman, was seen on the eye service of the Morrisania City Hospital in December, 1944, complaining of a red, painful right eye of one week's duration. Examination in 1941 had revealed a corrected visual acuity of 20/40 in each eye; diabetic retinopathy and incipient cataractous changes were present in both eyes at that time.

The patient was a diabetic of 30 years' standing and had been taking insulin for the preceding 12 years. The diabetes was always easily controlled on 15 to 18 units of Protamine Insulin. There had been one episode of pyelitis. There had been 10 pregnancies with 4 miscarriages.

General examination revealed an obese woman with some evidence of weight loss. The heart was moderately enlarged. The blood pressure was 210/100 mm. Hg. The urine contained 4+ sugar but no acetone; 20 W.B.C. per H/p/F. The diabetes was easily controlled.

Examination revealed a visual acuity of 5/200 in each eye, not correctable by lenses. The right eye was markedly tender to palpation and there was minimal edema of the upper lid. There was marked ciliary injection. The pupil measured 5 mm. in diameter, and was fixed to light and for near. The pupillary border was irregular; two fine posterior synechias were seen below. The pupillary portion of the iris was light red in color and contrasted markedly from the brown ciliary portion. The color of the iris was due to the presence of numerous new capillaries, so small and so closely packed

together that even with the aid of the corneal microscope they were barely distinguishable individually. These vessels ran to the pupillary border and disappeared from view; they occupied the surface of the inner third of the iris and from this capillary net larger vessels ran radially into the angle of the anterior chamber where they could not be followed.

The cornea was steamy and the angle could not be examined gonioscopically because of the corneal edema. An aqueous flare was present but there were no precipitates on Descemet's membrane.

The surface of the iris not covered by the capillary net showed the normal pattern differentiation and no filling in of the crypts by newly formed tissue. The vessels appeared to run on the surface of the iris. Incipient cataractous changes were present and the fundus could not be visualized. Tension measured over 90 mm. Hg (Schiøtz). Transillumination was normal.

The pupillary responses in the left eye were physiological and the iris itself showed no abnormalities. Incipient cataractous changes were present, and the fundus could not be visualized. Transillumination was normal.

Treatment. After repeated instillations of atropine into the conjunctival sac of the right eye, the pupil dilated easily with the exception of the area anchored by the posterior synechias below. Tension dropped to 45 mm. Hg (Schiøtz) and the patient felt relieved of her pain. The corneal edema cleared somewhat, and the neocapillary formation on the iris appeared less prominent. The patient refused surgery and during the following six weeks vision fell to light perception.

Ocular tension during this interval was never controlled; it was observed that under miotics the tension would rise and would fall with mydriatics. The patient was most comfortable when the pupil was dilated. The patient finally consented to operation and a paracentesis of the anterior chamber was performed; as the aqueous escaped, the vessels on the surface of the iris dilated rapidly and ruptured. The anterior chamber was completely filled with blood.

Following operation, the ocular tension always remained over 90 mm. with considerable pain which was relieved somewhat by atropine. A hyphemia, measuring about 3 to 5 mm. in height, was continuously present. The rubeosis did not change in appearance. This eye was enucleated four months after operation.

Course. In February, 1945, three months after the onset of rubeosis of the right eye, the left eye became red and inflamed and presented the picture of rubeosis iridis similar to that previously observed. The vision had fallen to hand movements and the tension was over 90 mm. Hg. The tension was reduced to 45 mm. by the use of miotics. On attempting to inject novocain and adrenalin retrobulbarly, a retrobulbar hemorrhage was encountered, the eyeball became proptosed, and the tension rose again to over 90 mm.

The patient consented to operation, and a posterior scleral trephination was performed. At operation, the ocular tension was decreased slowly by expression of vitreous, with clearing of the corneal edema and relief of pain. There was no rupture of the capillaries on the iris. Tension was reduced to 20 mm.

The day after operation, the tension rose to 45 mm. Hg, and a large gelatinous exudate was present in the anterior chamber. The pupil was dilated rapidly with atropine, the patient was given sulfadiazine orally and within 24 hours, the gelatinous exudate disappeared. A small hyphemia had appeared and the rubeosis was not prominent.

During the next two weeks, tension was always moderately elevated but could always be massaged down to normal. The time then came when the elevated tension could not be massaged down and a Lagrange sclerectomy was performed with very little associated bleeding in the anterior chamber. The

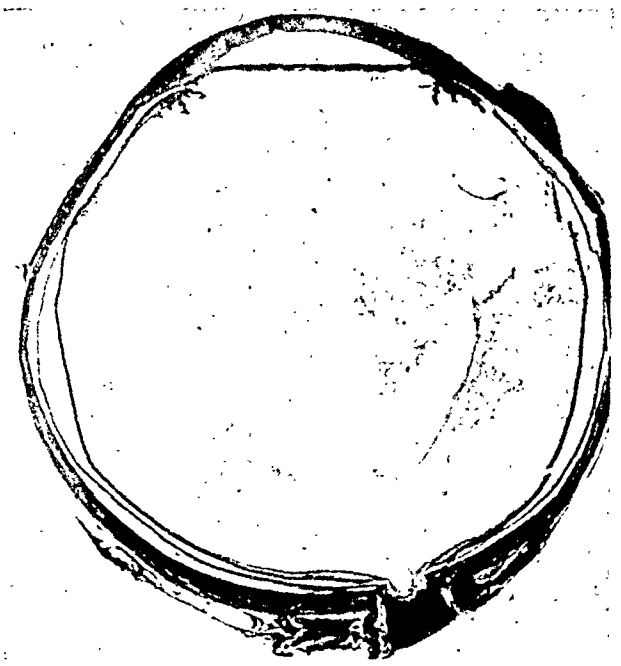

Fig. 1 (Lisman). Section demonstrating broad anterior peripheral synechia and deep glaucomatous cupping.

tension remained normal for two weeks postoperatively and then there were repeated hemorrhages into the anterior chamber and marked elevation of tension and loss of normal light projection.

Over a period of 10 months, the iris gradually became atrophic and the rubeosis almost obliterated. At one stage, the vessels crossed over the pupillary border onto the surface of the cataractous lens; even these vessels in time disappeared.

Histologic examination. (Dr. S. Gartner)

"There is an extensive infiltration of small round cells and hyperemia at the limbus. The anterior chamber contains a fibrinous exudate, some of which is adherent to the corneal endothelium. The angle of the anterior chamber is blocked by broad anterior peripheral synechias.

The iris is extensively attached to the periphery of the cornea (fig. 1). The anterior surface of the iris, especially in the part not adherent to the cornea has an additional layer of newly formed connective tissue which is vascularized with many small and medium-sized vessels and characterized by very thin walls. The older iris

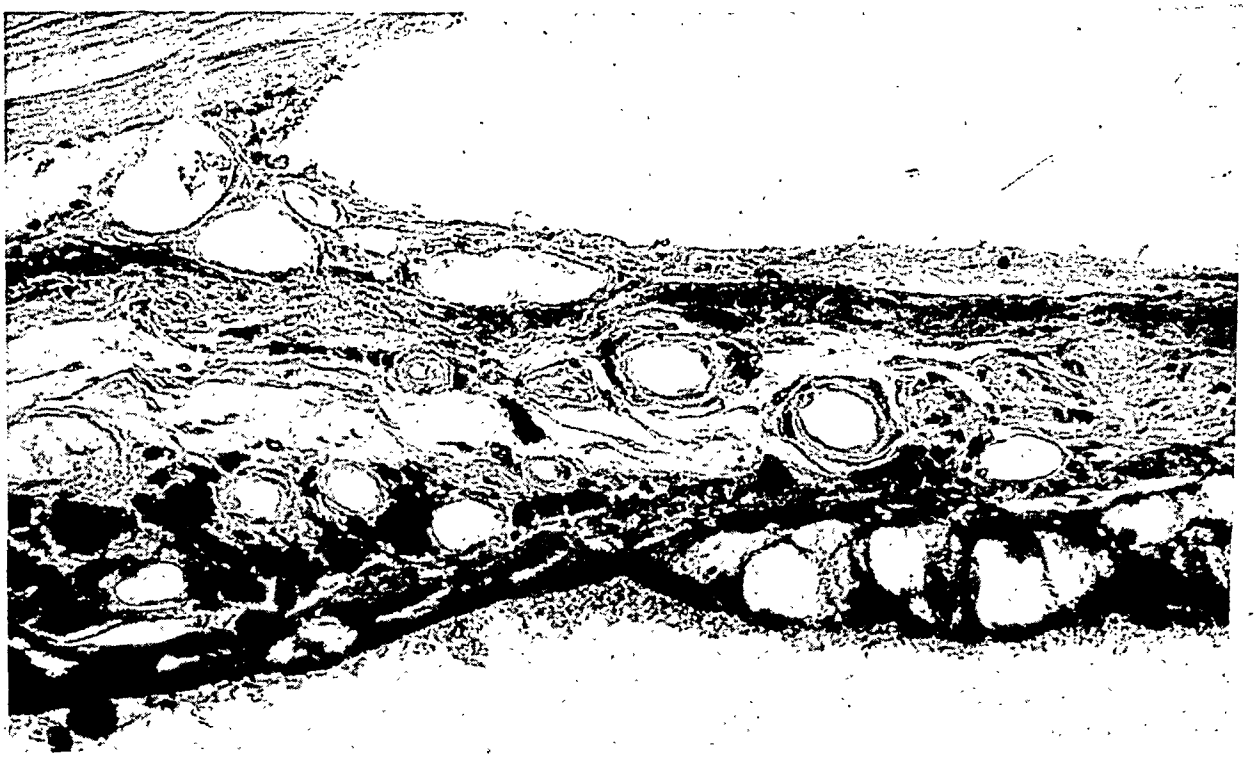

Fig. 2 (Lisman). Section showing layer of connective tissue and blood vessels on the iris surface and extending into the angle. The thin-walled vessels in this layer contrast markedly with the older iris vessels with characteristic thick adventitial coats.

vessels have the characteristic thick adventitial coat (figs. 2 and 3).

The pigment epithelial layer has been transformed into a thicker and irregular

Fig. 3 (Lisman). Layer on the iris surface.

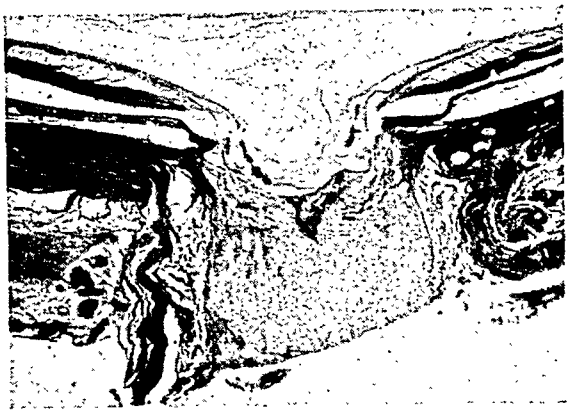

Fig. 5 (Lisman). Section showing atrophic cupping of the optic disc and newly formed connective tissue obstructing the central retinal artery.

layer honeycombed with cystic spaces. Some of the pigment epithelium has migrated into the iris stroma, which is thinned and atrophic (fig. 4). The ciliary body is normal.

The retina shows scant changes in the periphery and considerable at the posterior pole, where there is a paucity of ganglion cells, cystic spaces in the internal plexiform and internal nuclear layers. These cystic spaces may be the signs left by lipoid exudates which dissolved in the preparation of the section.

The external plexiform layer contains

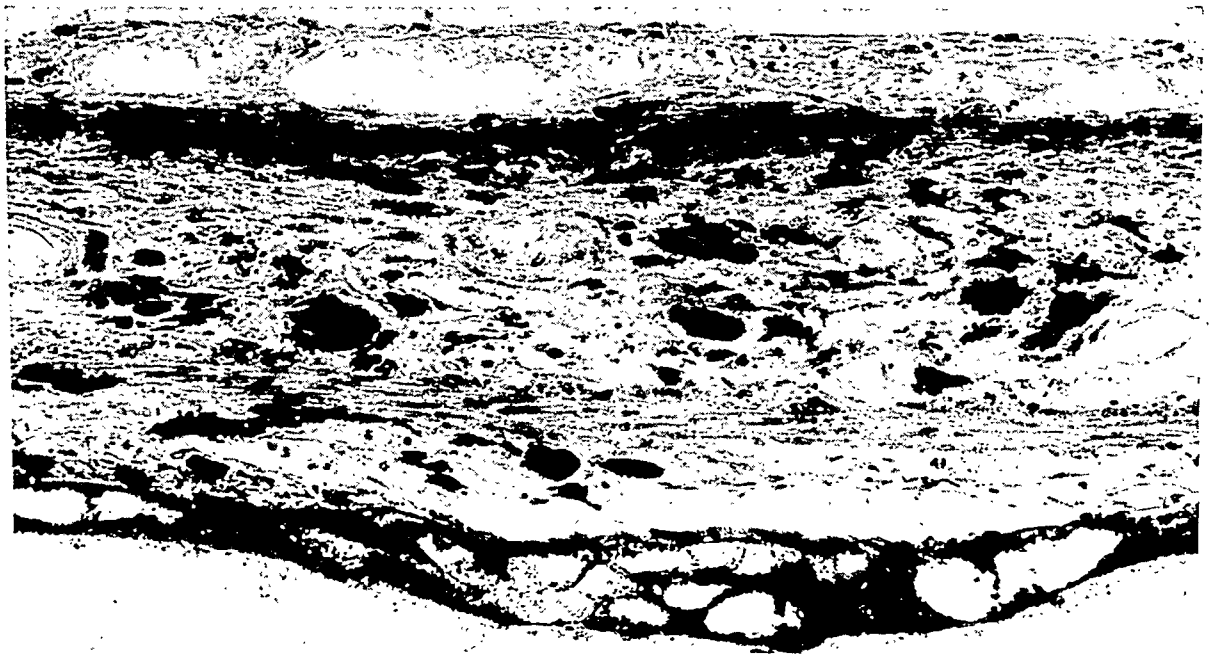

Fig. 4 (Lisman). Section demonstrating the cystic transformation of the pigment epithelium characteristic of diabetes.

some lipoid exudates. The optic nerve is atrophic. There is deep glaucomatous cupping of the disc (fig. 1). The central retinal artery at the nervehead has newly formed connective tissue in its lumen which almost obstructs it (fig. 5).

Diagnosis. Rubeosis iridis, peripheral anterior synechias, pigment epithelium cysts, optic atrophy, diabetic retinopathy, central retinal artery endarteritis, and secondary glaucoma.

Conclusion

The glaucoma associated with rubeosis iridis is an inverse glaucoma, since the ocular tension is more easily controlled by myd-

riatics. This is probably due to a mechanical squeezing out of blood from the vascular bed on the iris as the vessels are compressed in a dilated pupil. A scleral trephination can reduce tension slowly without danger of rupture of the capillaries on the iris; however, the tension is not controlled for long.

Summary

A case of rubeosis iridis in a diabetic is reported. Medical and surgical treatment was of no avail and blindness resulted. One eye was enucleated and histologic examination was possible.

Historical Miniature

Diabetic cataract, as an etiologic entity, was first recognized by T. W. G. Benedikt in 1842. He was educated at Leipzig and Vienna. In 1812, at the age of 27 years, he was made professor of surgery and ophthalmology at the University of Breslau, and remained there until 1856. He died at Breslau in 1862.

NOTES, CASES, INSTRUMENTS

REFRACTION CLINIC*

DISCUSSION BY
ALBERT E. SLOANE, M.D.†
Boston, Massachusetts

A 17-year-old student was unhappy with her present glasses which had been prescribed one year previously. She had no headaches, but stated that when she read, the print would run together. These symptoms of near difficulty were made worse by the wearing of the glasses, but were also present when she wore none. She found the glasses helpful at the movies, since they made her see a bit more clearly. Her visual acuity without glasses was 20/50 in the right eye, and 20/70 in the left eye. Retinoscopy (corrected) without drops was: +4.5D. sph. ⊂ −1.5D. cyl. ax. 180°; +5.0D. sph. ⊂ −2.5D. cyl. ax. 180°; revealed presence of a relatively high hyperopic error associated with astigmatism. Wearing: O.D., −1.0D sph. ⊂ −1.25D. cyl. ax. 180°; O.S., −1.25D. sph. ⊂ −2.0D cyl. ax. 180°. Subjective fog test revealed the following prescription:

O.D., 20/50 with a +3.25D. sph. ⊂ −1.25D. cyl. ax. 180° = 20/50
O.S., 20/70 with a +4.0D. sph. ⊂ −2.5D. cyl. ax. 180° = 20/50
→ 20/30, O.U.

Muscle balance was tested and found to be within normal limits. A 2-percent solution of homatropine was instilled over a period of an hour, along with two drops of paredrine and, another hour after that, refraction was again measured. At that time, she accepted, with drops, the retinoscopy (corrected) findings: +5.0D. sph. ⊂ −1.5D. cyl. ax. 180° = 20/40; +5.75D. sph. ⊂ −2.0D. cyl. ax. 180° = 20/50.

DISCUSSION

Discussion will bring out a number of questions.

1. "How is it possible that such an obviously gross error in refraction could be made?"

2. "How is it that the patient was able to tolerate the glasses at all?"

If we analyze her symptoms, she appeared to enjoy her glasses for distance, since she wore them at the movies, and they annoyed her only at near.

One possibility is that in writing the prescription, the ophthalmologist wrote "minus" instead of "plus" for the sphere, in which case, one would assume that the refraction was measured acceptably and undercorrection was purposely prescribed so that the person might get used to her glasses with a minimum of difficulty. This person is young, has an ample amount of accommodation, and is most helped by the astigmatic correction, and could well enjoy the glasses if such a sphere had been written as a "plus." The moral of this observation would be, "Always check the prescription when it is made up." In other words, "Check up on the optician as well as yourself."

A second possibility is that the optician made an error in the signs, and the same moral would apply.

3. It is possible that the examiner did not do a retinoscopy, and, therefore, any spherical lens he placed before the eye, did not improve vision appreciably. We are all aware of the fact that when minus lenses are placed before a young person who has a great deal of accommodation, the patient will observe that the print looks blacker and more distinct, but smaller and not necessarily more readable. So, it may well be that the person prescribed the minus sphere because

* From the House Officers' Teaching Clinic, Massachusetts Eye and Ear Infirmary.
† Director of Department of Refraction.

the patient stated that she saw blacker and more distinctly with them, even though she could read no more.

4. The patient may have had a pseudomyopia produced through a spasm of accommodation. The patient may not have been fogged properly, or may not have responded to a fog effectively, but if retinoscopy were done, this would easily have been discovered.

The second question that arose was "How was it that the patient could tolerate these glasses as long as she did?"

If you will examine the prescription carefully, you will notice that the astigmatism was corrected fairly accurately both as to amount of cylinder and particularly the axis. It is more than likely that the correction of the astigmatism which changed her basic refractive error from that of a compound hyperopic astigmatism to a simple hyperopia without astigmatism, was enough to eliminate some of her visual difficulty. Thus, the remaining amount of spherical error could be compensated for by her accommodation, and the elimination of the astigmatism was enough to make the patient feel better.

At this time, it would be well just to mention some of the ways in which spasm of accommodation can be recognized.

1. When the retinoscopy reveals a much higher hyperopic error than the subjective test; or when the opposite occurs—when a greater error is found by subjective testing than will be elicited by retinoscopy.

2. In the first case, the accommodation is stimulated to a spastic state by trying to read letters or trying to see. Whereas, in the second case, the spasm of accommodation is precipitated by the light flashing into the eye.

3. When near vision produces most of the symptoms, spasm may exist.

4. When during your subjective test, visual acuity fluctuates with a given lens, spasm is present. The best procedure in such cases is to heed the visual acuity report when the vision is at its clearest. For example, you might place before the eyes a strong convex sphere, and the person is able to read 20/40, but then says, "Now everything is all blurred out," or "now it blurs" to 20/70. The 20/40 reading would be the more accurate. For this reason, it is advisable to have the patient close her eyes each time you change a lens, so that you do not excite accommodation from this procedure. Another way of recognizing spasm is when retinoscopy is carried out both with fixation at distance, and fixation at near (using accommodation), and there is a great discrepancy between the two sets of findings. This procedure in itself is not entirely without discrepancy.

Solution

The surest way to have solved this case was by the use of cyclopegia, because then the procedure would have been fool proof. One cannot usually prescribe the full correction as found under cyclopegia without producing complaints in most people of this age who have a refractive error of this magnitude, and have not worn proper glasses before.

I believe one should correct all of the astigmatism that one could be sure of in this case, and then as much of the spherical portion of the hyperopia as the patient will comfortably accept. In most cases, I would say about one third to one half of the spherical portion. In this way, enough improvement in her vision would occur so that she could enjoy her glasses for distance, as well as at near, and still allow her to use some of her accommodation which apparently she has *no objections to doing.*

I would tell the patient that I am purposely not giving the full strength glass; that it is better to prescribe in graded steps. I would recheck her again in six months, at which time I would give her a fuller correction if accepted, and if her symptoms warranted.

The first prescription that I would prob-

ably give her would be: O.D., +3.25D. sph. ⊂ −1.25D. cyl. ax. 180°; O.S., +4.0D. sph. ⊂ −2.0D. cyl. ax. 180°.

QUESTIONS

House Officer: When you say you would correct as much of the error as she would accept, do you mean to bring her down to 20/20 or 20/15?

Dr. Sloane: Get the best possible visual acuity, whatever it be, 20/30 or 20/70.

House Officer: When the patient returns after six months, as requested, and has no symptoms and is satisfied with her glasses, what do you prescribe?

Dr. Sloane: I personally would make no change in the glass because the more fully one corrects the error, the more dependent will the patient become on her glasses. Since her muscle balance is not adversely affected by the lack of correction of the refraction, the patient can well go along. The patient has a good deal to gain through not becoming entirely dependent upon glasses, particularly a girl, aged 17 years.

House Officer: What are some of the defects in the application of findings from dynamic retinoscopy?

Dr. Sloane: The entire system of retinoscopy with accommodation at play is based upon the fact that convergence and accommodation work on a one-to-one ratio: That is, a diopter of accommodation will stimulate one meter angle of convergence and vice versa. This is not a hard and fast situation.

The exercise of convergence will also act as a check on the excessive use of accommodation. For example, looking at one-third meter, the person will use 3-meter angles of convergence. Therefore, he will only be able to use, according to this theory, 3 diopters of accommodation—the convergence holding the accommodation in check. Thus, if you retinoscope at a near distance, the amount of convergence employed will only allow the necessary amount of accommodation for that same distance to be employed. Thus, the movement that you would find with your retinoscope at that distance would be due to the refractive error itself. An allowance for lag of accommodation must then be made. Too many variables are present.

ACUTE GLAUCOMA IN AN ADOLESCENT

A. J. BOASE,* M.D.
Kampala, Uganda, East Africa

Dr. H. Saul Sugar (1947), describing a case of acute glaucoma in a young man, aged 27 years, states "This is probably the youngest case of true acute glaucoma on record, having started with prodomata at the age of 17 years." In view of this statement it seems worth while to place on record the following case.

REPORT OF A CASE

The patient is an Indian girl, aged 17 years, who is exceptionally intelligent, speaks perfect English, and until her recent incapacity attended to the bookkeeping in her father's business. Her past medical history is insignificant apart from an operation for "tonsils and adenoids" three years ago. She was brought to me on May 29, 1947, and gave this account.

History. Her trouble started five weeks previously with a severe headache which lasted for five days and was accompanied by progressive loss of sight. The eyes were not red at the outset but became so after a few days (mother's evidence). Her doctor gave drops for the eyes but she does not know what they were. She claimed emphatically that prior to this episode her eyes had always been perfect.

Physical examination showed a well-developed girl in sound general health but obviously blind. She insisted that she could see

* Ophthalmic specialist (British) Colonial Medical Service, Uganda.

light, although when asked to point at the window, through which bright tropical sunlight was entering, her projection was most inaccurate. Vision was recorded as barely light perception. There was no pain. Apart from some turgescence of the anterior ciliary vessels, suggestive of a caput medusae, the eyes were white. The pupils were widely dilated and inactive. Moderate corneal edema obscured the fundi. The tension in each eye was stone hard to digital palpation. I had unfortunately left my tonometer at another hospital and so missed the opportunity of recording the actual tension. Eserine (1 percent) was immediately instilled and repeated at half-hour intervals.

The patient was seen again two hours later, by which time I had recovered my tonometer. The pupils had contracted considerably but were not small. The edema was receding and a blurred view of the fundi could be seen. The anterior chambers were very shallow. The eyes felt appreciably softer to the fingers, and the tonometric reading was: O.D., 37 mm. Hg (Schiøtz); O.S., 40 mm. An operation was decided upon.

Surgical procedure. Under pentothal-sodium anesthesia, each eye was trephined and a peripheral basal iridectomy performed. The fistulizing operation was chosen because it seemed not improbable that peripheral anterior synechias might be firmly established.

Course. The postoperative course was uneventful with very little reaction, the eyes soon becoming white and the anterior chambers being reformed by the fifth day. The tension, however, was not satisfactorily lowered in spite of apparently good filtering blebs, although it could be reduced by massage. Atropine was used daily till the chambers reformed when eserine ointment (Cusi) was substituted.

Postoperative examination. During this period, the pupils were widely dilated and a clear view of the fundi could be obtained. The discs were seen to be deeply cupped. Vision was now hand movements. The response to eserine was surprisingly rapid, the pupils becoming moderately small by the following day. On the ninth day it was evident that the tension in the right eye was increasing, the tonometric reading was 37 mm. Hg (Schiøtz). A cyclodialysis was performed on this eye, again under pentothal anesthesia. It was observed that the effect of adrenalin drops (before the pentothal injection) was to cause wide dilatation of the pupil despite the thorough antecedent eserinization.

Course. The patient left on the 14th day. She had been having pilocarpine (1 percent) for the previous three days. The pupils were now small, satisfactory peripheral colobomas could be seen, and the Schiøtz reading was: O.D., 28 mm. Hg; O.S., 25 mm. Vision was still barely hand movements.

It should be added that a routine Kahn test was negative, and that in deference to her mother's wishes the patient had a course of sulfadiazine while in hospital.

Discussion

Apart from the age of the patient, the case presents features of unusual interest. The simultaneous onset of acute glaucoma in both eyes of a young girl otherwise in excellent health is alone remarkable. The development of deep cupping of the discs in the short period of six weeks is no less unusual, unless one postulates an antecedent physiologic cup of abnormal degree. Also illustrated is the validity of Sugar's contention that congestion is not necessarily an early concomitant of acute glaucoma. According to the evidence in the case herein presented, the eyes were not red for the first few days during which vision was lost and the tension must have been very high.

Etiologically, the bilateral onset suggests a common systemic cause. But what this might be remains a matter for speculation. A sudden allergic imbalance of the vegetative nervous system, expressed as an angioneurotic edema of the uveal tissue, is an explanation as difficult to accept as to reject

(Vanysek, 1946). The patient is at an age when hormonal control might be unstable, but there is nothing in her physical or psychic make-up to suggest that she is other than a perfectly normal girl. Moreover, if this were a significant factor, surely one would not find acute glaucoma in young adults the rarity it undoubtedly is.

The history of tonsillectomy prompted consideration of proliferative jugular endophlebitis as an etiologic factor (Meyer 1946). But it seemed to be beyond the limit of probability that both jugular veins could follow identical pathologic courses leading to simultaneous crises in both eyes.

Epidemic dropsy was considered, only to be ruled out.

Comment

For how long can an eye tolerate a very high tension without being irreparably damaged? Duke-Elder (1940) advises that, if medical methods fail to convert an acute attack into a chronic congestive phase within 24 to 48 hours, operation should not be delayed. Gradle (1936) would allow 48 to 72 hours for a trial of nonsurgical treatment. The late T. Harrison Butler (1943) cites a case of his own of violently acute glaucoma. "Both eyes had been treated, I think, for a fortnight with atropine; both were stone-hard with widely dilated pupils, and perception of light was abolished—a truly desperate case. I trephined both eyes and the result was incredible. The eyes became soft and lost all inflammation, and eventually both recovered, with a final acuity of 6/12."

Despite the small ray of hope afforded by this experience it was felt from the outset that the present case was beyond recovery, and that five weeks of gross hypertension was more than any eye could stand. The outcome has borne out this gloomy prognosis.

CARCINOMA OF THE INNER CANTHUS AND FOREHEAD

Max Hirschfelder, M.D., and Jack Frost, M.D.
Centralia, Illinois

Slowly advancing epitheliomas of the lid margin or of the canthi are frequently observed in elderly people. They usually are basal-cell carcinomas which demand either excision with plastic repair or treatment by X ray or radium. The following case of a tumor was one of the less common types and, although it seemed to originate in the region of the inner canthus, extended to a much wider area and behaved differently from clinical and pathologic standpoints.

Case report

History. An 85-year-old man, who otherwise was in surprisingly good health, had noted a swelling below the inner right eyebrow for a year previous to medical consultation. During the past few months this swelling had enlarged and extended to the forehead. Subsequently the right upper lid began to swell and to occlude the right eye.

Examination revealed a hard tumor, of the size of a large plum, which was firmly attached to its base. The skin was firmly

Fig. 1 (Hirschfelder and Frost). (Left) Appearance of the right eye on April 8, 1947, before radium therapy was instituted. (Center) Two months after radium treatment. (Right) Final result on October 15, 1947, six months after treatment with radium and one week after excision of edematous lid.

attached in the region of the inner canthus, where it was drawn in like a little navel. Over the rest of the tumor region it seemed to be movable. The skin over the forehead was smooth. The right upper lid looked like a tumor mass, but on examination was found to be composed of soft, edematous tissue, a sort of elephantiasis created by blockage of the lymph channels through the tumor. The right eyeball seemed displaced downward and slightly proptosed. Movements were limited in all directions. The bulbar conjunctiva showed venous hyperemia and edema. Media were clear and the fundus seemed normal. The regional glands were not enlarged.

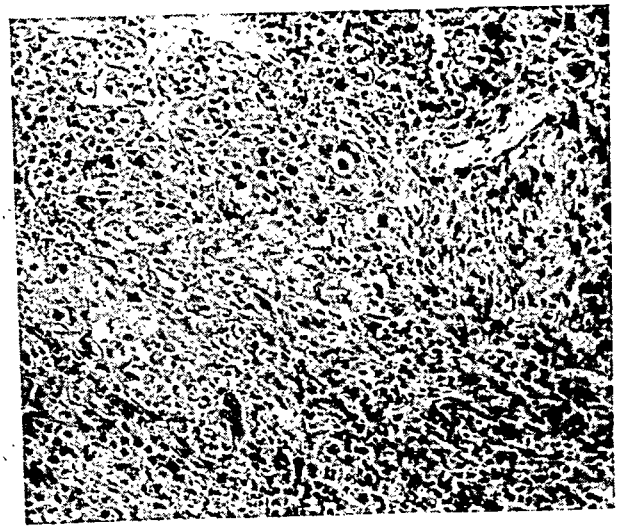

Fig. 2 (Hirschfelder and Frost). A microscopic section of the tumor.

Diagnosis. The X ray did not reveal a definite origin of the mass. There was a certain cloudiness in the right frontal sinus. A biopsy was taken and diagnosed as a squamous-cell carcinoma (H. C. Allen).

Treatment. While there was a definite possibility that this tumor originated from a paranasal (probably frontal) sinus and while the proptosis could have been caused by more than just an orbital edema, it was thought best to avoid extensive surgery in a man, aged 85 years. Radium therapy seemed to provide the best chance for success and, on counsel of Dr. H. Swanberg, Quincy, Illinois, 12 needles containing 15 mg. radium altogether were plunged into the tumor mass under local anesthesia. The needles contained radium ranging from 1.3 mg. to 2.6 mg. They were left in the tumor for a period of one week.

Result. The tumor softened perceptibly during this first week (April, 1947) and disappeared completely during the next two months. On a reëxamination six months after the radium treatment, it was found that the site of the tumor was flat and smooth and no recurrence was noted.

The lid itself was still markedly edematous and a portion, 10-mm. broad and 20-mm. long, was excised together with the underlying tissue. No sign of tumor was found by the pathologist in this tissue.

The eyeball showed a slight downward

displacement, but the engorgement of the conjunctiva had completely disappeared. Movements of the eye were considerably better, even though its position could not be called normal. It was assumed that there was an orbital edema similar to the one of the lid, although remnants of an orbital tumor could not be definitely excluded. The vision was the same in both eyes (20/70, uncorrected) and no radium damage was apparent. No double vision was noted by the patient and he was extremely satisfied with being able to see out of the right eye.

No recurrence of the growth was observed as late as May, 1948.

Comment

The case is presented because of its unusual features. We realize that it is uncertain that our radium treatment effected a permanent cure, and only continued observation and, if needed, another series of radium implants will promise a continued satisfactory result. It can well be argued that a more radical procedure would be better and more certain. There is, however, no doubt that the method used in this case was the easiest on the patient and the least disfiguring. For a man past the age of 80 years, it seemed to us the method of choice.

408 West Second Street.

A DEPENDABLE TYING FORCEPS FOR FINE SUTURES*

Warren D. Horner, M.D.
San Francisco, California

We now have finer eye sutures than we have forceps for tying them. This lack of a suitable forceps led me to experiment with various types of epilating forceps, since they are designed for grasping minute strands.

By micrometer measurement, I found the diameter of eye lashes to vary between 0.0015 and 0.003 inches, with an average of 0.0025 inches (0.0063 mm.). The diameter of 7-0 silk cataract sutures varied less, averaging 0.0026 inches. A cilium, therefore, is just a bit smaller than a cataract suture, a fact which makes a forceps properly designed for grasping the one efficient in grasping the other.

Some cilia forceps are too short to handle well, but the Beupre model is very adaptable and handy for suture tying. This forceps is an old favorite and has been listed in instrument catalogues for the past 20 years. It is of spring-grip construction, and has tapering and closely fitting smooth jaws set at an angle of 30 degrees. The instrument has a total length of about 4½ inches (11.4 cm.) and handles well. The jaws hinge smoothly and present no projections apt to catch the suture in tying an ordinary single or double hemostat knot. A 7-0 suture can be grasped anywhere along the jaws from the tip to the base, a distance of a full centimeter. The jaws open to a width of 4 mm., which makes it easy to pick up a thread.

A canvass of the instrument companies showed that the Beupre forceps was out of production for the present, but it is probable that there is a considerable number of old models about our offices.

The Paton needleholder is a delicate model closely resembling the Beaupre forceps, except that its jaws are slightly wider and heavier, and are straight instead of angular, which is an added advantage. By a little honing, the serrated jaws can be sufficiently smoothed down to grasp a 7-0 suture securely. This model is available† and after the modification just mentioned makes an ideal tying forceps. Most other needleholders either lack the precise bite necessary for tying fine silk or do not open widely enough to facilitate picking up a thread.

490 Post Street (2).

MECHANICAL FACTORS IN OCULAR PATHOLOGY

Reciprocal relations of injury and disease

Percy Fridenberg, M.D.
Rockville Center, New York

The practical significance of the factors mentioned in this paper appears most striking when related to definite clinical entities in which they play a role—actual, "traditional," or/and recognized, claimed and contested—as not infrequently happens, in criminal and civil courts or before compensation boards. Among these clinical entities, we may mention retinal detachment, glaucoma, interstitial keratitis, and sympathetic ophthalmia.

Before these topics can be intelligently presented, however, it is necessary and worth while to consider, in their general characteristics and manifestations, the role and the nature of the mechanical factors active in the basic processes of ocular physiology, such as circulation of blood and other intraocular fluids, tissue development, metabolism, and intraocular pressure. It is also of equal importance to consider such pathologic changes as atrophy, various forms of cellular degeneration (colloid, amyloid, fatty, and so forth), and the equally varied forms of inflammation—hemorrhagic or specific.

Mechanical factors

There are two categories of mechanical factors: (1) The external, and (2) the local ocular.

External factors

Gravity, barometric pressure, radiant energy, heat, and cold are constantly acting forces in that very close environment, the telluric atmosphere, and have determining and contolling influences on the life manifestations of the individual and the race.

In accordance with their cosmic nature and massive scope, these forces affect the entire body including the eye, although this organ by its position and structure is vulnerable to much less intense and persistent violence.

Local mechanical forces

There is, however, another group of mechanically acting forces that contrasts most strikingly with the environmental agencies. These local mechanical factors act on a smaller scale of intensity and dimensional spread, although the resulting pathologic processes often produce disturbances of function which would seem to be out of proportion to the causal factors.

Resulting pathologic processes

Among these processes we note expanding lesions associated with neoplastic formations, malignant or benign, of a more or less solid nature (callus, dense connective tissue) or semifluid nature (fatty, lipoid, dystrophic), fluid effusions of blood, lymph, and pathologically altered intraocular fluids (vitreous, aqueous).

The modus operandi may consist in pressure atrophy of delicate structures of functional importance, lowered viability and vitality by way of connective-tissue infiltration or scar contraction, actual solution of continuity (a tear or break), and alterations of volume and spatial relations to other structures—conditions almost equally sinister in their implications for so delicately adjusted an organ as the eyeball. Incidentally, these local pathologic changes may result in what clinically constitute actual traumatic lesions.

Indirect complications

Gravity acting upon a sound and healthy eye causes no definite pathologic change and only transient discomfort when an unusual body posture results in a gravitational rush of blood to the head. This observation also

applies to the centrifugal force and communicated motion of intraocular contents. Pathologic changes in intraocular fluids and semifluids may, however, intensify the effect of these processes. The dramatic example is the danger associated with such motions, even within the normal range of extent and intensity, in the presence of fluid vitreous. Under such a circumstance, their agency in causing retinal tear or detachment or in nullifying the effect of an operative procedure for reattachment is well known.

Similar implications apply to the possibility of pathologic changes which are larval, inactive, but potentially hazardous in the reaction of the eye, which harbors them, to some slight trauma or to some other forms of eye disease. For example, a potentially virulent spirochaetae may be quiescent in the cornea or optic nerve but may flare into action if that tissue is subjected to some insult, however trivial.

Circulatory disturbances

It is not at all improbable and may well be assumed that, aside from actual tissue lesions, circulatory disturbances and functional anomalies may form intraocular "fifth columns" and act as clinical conspirators with traumatic violence below the usual levels of causal significance.

In glaucoma, the pupillographic studies of Lowenstein, Schoenberg, and others have shown quite clearly that increased fatigability of the reflex miosis, a latent hazard of pupillary exhaustion, is a definite clinical sign of incipient or prodromal increase of intraocular pressure.

Studies of early signs of disease

Such studies of very early signs of actual eye disease and/or of a definite predisposition thereto must be taken into account in the interpretation of the reciprocal relations between ocular pathologic processes and trauma.

Evaluation of chronology will depend for accuracy on our definite knowledge of a starting point for the eye affection in question. With this knowledge we can reach a definite conclusion as to the rate of progress of the disease. A correct decision as to this is of obvious importance in the matter of lenticular opacities, but there are other conditions in which it is of practical importance to reach a correct decision as to the starting point of the disease.

Previously sound eye

This brings one to a discussion of the "previously sound eye," a concept that logically must be taken into consideration in any attempt to decide whether or not a given injury is antecedent to the existing pathologic condition of the eye.

The assumption that an eye was "sound" at the time of injury is generally made on the absence of evidence, clinical or otherwise, of previous eye disease and on a similar lack of record to that effect. Signs of disease, like those of injury, are often evanescent, or so slight as to be overlooked, ignored through carelessness or failure to use all the finer methods of examination for their detection.

This negates the validity of any decision except one based on previous, periodic eye examinations. Thus, the halos of increased intraocular pressure, the presence of foreign bodies, peripheral lens opacities, slight but pathognomonic lesions at the ora serrata, incipient atrophy, even tears may not be discovered until after an injury to the eye has been sustained and a careful study of ocular conditions brings these changes to light. It is then that definite knowledge replaces assumption.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

October 6, 1947

DR. DANIEL KRAVITZ, *president*

SYMPATHETIC OPHTHALMIA OR PHACO-ANAPHYLAXIS?

DR. DANIEL KRAVITZ said that the possibility of sympathetic ophthalmia has caused the removal of many eyes, probably in some cases unnecessarily. On the other hand, procrastination has resulted in a nightmare to many an ophthalmologist.

The case reported by Dr. Kravitz was of a man, aged 70 years, who was examined on November 4, 1946, with a history of sudden loss of vision in both eyes, severe headaches, and vomiting for over 24 hours. For many years he had been treated at the out-patient department of the Kings County Hospital for chronic glaucoma of the left eye. His vision, taken on examination by another ophthalmologist in September, 1946, was 20/200 in the right eye, improved to 20/100 with a −0.75D. sph. Both eyes presented all the classical signs of acute glaucoma and both eyes were stony hard. He was placed on a mixture of eserine, pilocarpine, and cocaine with no appreciable effects, and the following day he was entered at the Brooklyn Hospital where a basal iridectomy was done on the right eye and a modified Lagrange operation on the left eye. Convalescence was uneventful and he was discharged on November 11th. On November 13th, the tension was: O.D., 22 mm. Hg and O.S. 20 mm. (Schiøtz) and, it was noted that there were diffuse lens changes in both eyes. He was able to find his way around with difficulty. Because of his poor general condition, he was unable to return until December 12, 1946. Tension in both eyes had remained the same and he saw just enough to get around. At his next visit, January 9, 1947, tension in the right eye had increased to 2 plus, the eye was considerably inflamed, and there were many deposits on the posterior corneal surface.

His next visit was on January 29, 1947, at which time his eye was stony hard and very painful. He presented the picture of a severe plastic iridocyclitis. In the 3-week interval between the last two visits, he had seen several ophthalmologists, most of whom advised enucleation. The left eye was white and free of any signs of inflammation. Removal of the right eye was urged, and the following day it was enucleated at the Brooklyn Eye and Ear Hospital. He was discharged two days later.

On February 5, 1947, seven days after removal of the right eye, the left eye was white, there were no signs of inflammation and he was able to grope his way around. Tension was 20 mm. Hg (Schiøtz).

He was unable to return until February 18, 1947, at which time the tension in the remaining eye was 2 plus. It was red and painful and there were many large deposits on the posterior cornea. He was placed on salicylates, penicillin, hot compresses, and atropine. The patient did not return for further treatment but subsequently entered the New York Hospital, on the service of Dr. MacLean. The further course of the patient is unknown.

SYMPATHETIC OPHTHALMIA VS. PHACO-ANAPHYLAXIS

DR. J. ARNOLD DE VEER discussed the histopathologic interpretation of sections of the enucleated right eye of the case presented by

Dr. Kravitz. While the clinical course suggested sympathetic ophthalmia, the picture found in the enucleated eye was that of endophthalmitis phaco-anaphylactica. The following alternative interpretations of the case were suggested and discussed:

1. That a bilateral phaco-allergic reaction may have occurred, such a phenomenon representing a type of sympathetic ophthalmia.

2. That the phaco-allergic postoperative inflammation had been the precursor of sensitization to uveal pigment and that sympathetic ophthalmia had supervened, although not yet identifiable histologically at the time of enucleation of the exciting eye.

Because the patient had passed from their supervision prior to the sectioning of the enucleated eye, no immunologic studies were made by the reporters of this case.

Clinical aspects of sympathetic ophthalmia

Dr. Harold H. Joy said that the foremost predisposing cause of sympathetic ophthalmia is a perforating wound involving the ciliary body or the root of the iris, particularly if there is incarceration of uveal tissue or lens material. As a rule, the exciting eye undergoes a prolonged low-grade uveitis with occasional exacerbations and a tendency to phthisis. However, the clinical picture is not characteristic, and sympathetic ophthalmia may follow a violent acute traumatic uveitis or it may occur in the presence of glaucoma or even panophthalmitis.

The incubation period is extremely variable, but usually 1 to 3 months after injury a mild serous iridocyclitis appears in the fellow eye. Less frequently the inflammation originates posteriorly in the choroid. In either case, the process develops into a chronic plastic uveitis characterized by massive cellular reaction, and subject to exacerbations and recurrences. In spite of comparatively mild inflammation, exudation is profuse, and there is early and persistent development of posterior synechias, and gradual secondary involvement of all the ocular tissues. Cataract and glaucoma are frequent complications and, if the latter is not checked, phthisis bulbi ensues.

The only means of making a positive diagnosis is by histologic examination of uveal tissue. However, a presumptive diagnosis may be made if the case fulfills the following conditions: (1) The presence of uveal inflammation in the injured eye caused by exogenous infection. (2) A reasonable interval between the injury and the onset of uveitis in the fellow eye. (3) The presence in the fellow eye of the rather characteristic plastic uveitis. (4) Proof that this inflammation is not due to some other cause.

Sympathetic ophthalmia is much easier prevented than cured, and this can usually be accomplished by removal of the exciting eye before the process has extended to its fellow. Hence, the shorter the interval between injury and enucleation the greater the prophylactic value. Removal of the exciting eye within two weeks after injury always prevents sympathetic involvement, but further delay nullifies, or at least markedly lessens the favorable effect. Evisceration is not as effective a preventive procedure due probably to the occasional retention of uveal tissues. Prophylactic enucleation is contraindicated if there is reasonable hope of retaining or regaining useful vision. If sympathetic uveitis does not follow within two weeks after enucleation of the exciting eye, the chance of it occurring is slight, and it almost never appears after one month.

It is essential that treatment begin early and be thorough. It is quite generally agreed that enucleation of the exciting eye has little or no favorable effect after sympathetic uveitis is once established. However, until this has been proved, prompt enucleation of a blind exciting eye is indicated, at least in early cases. Practically all that can be done in treating the sympathizing eye is to attempt the establishment of maximum mydriasis. Secondary glaucoma can frequently be controlled by repeated corneal paracenteses. Any

surgical measure involving the uvea should be postponed if possible for at least one year after subsidence of inflammation, and should be preceded by desensitization.

No form of systemic treatment has been proved entirely adequate. The use of massive doses of salicylates and nonspecific foreign-protein therapy appear to be the most effective, particularly if supplemented by desensitization therapy through uveal pigment. The sulfonamides and penicillin have, on the whole, been disappointing and it is too early to assess the value of streptomycin.

The prognosis is always uncertain, due chiefly to variation in degree of severity, the reasons for which are unknown. The most important prognostic factor of which we have control is the early institution of proper and thorough treatment. In such patients a favorable prognosis may be expected in two-thirds of the cases. Unfortunately a great many patients are not seen until the disease is well advanced, and these are apt to result badly in spite of all treatment.

Discussion

General discussion of these three papers followed.

Dr. Andrew J. Rados said that the only possible treatment is the prophylactic enucleation of the exciting eye. An interesting study was made by Dimmer, who stated that during the first World War no case of sympathetic ophthalmia occurred in the armies of the central powers; the English and French army reports were also of similar nature. Dimmer compared these results with the high incidence of sympathetic ophthalmia in the relatively short Franco-Prussian War of 1870-71, and came to the conclusion that the disappearance of sympathetic involvement was due to the timely enucleation of the offending eyes.

The anaphylactic theory of the sympathetic ophthalmia was based on the theory of Elschnig-Bail, that the uveal pigment has an organ-specific quality and leads to hypersensitiveness of the uvea of the fellow eye. My own research of uveal-pigment specificity with complement fixation tests contradicted the organ-specific results of Elschnig, disproving the anaphylactic origin due to uveal pigment. Later on von Szily, one of the best known research workers in the domain of anaphylaxis, came to a similar conclusion; namely, that sympathetic ophthalmia cannot be explained theoretically as anaphylaxis due to pigment antigen. The negative outcome of his experiments led him to search for other possibilities, like neurotropic viral infection.

Sympathetic ophthalmia after enucleation usually occurs only in the first 14 days, and is extremely rare after this period, which would not be the case if it were due to pigment anaphylaxis. Once the organism is sensitized the so-called anaphylactic reaction would hardly be so promptly prevented by removal of the offending eye. The second very important objection is the fact that sympathetic ophthalmia never appears in the form of an acute uveitis in the second eye but frequently is seen in the form of neuroretinitis. If one would accept pigment anaphylaxis as the explanation of sympathetic ophthalmia, then the cases of sympathetic neuroretinitis are unexplainable, because the pigment anaphylaxis could establish itself only in such pigment-bearing tissues as the uvea.

Verhoeff and Lemoine conceived the idea of phaco-anaphylaxis in order to explain the postoperative inflammatory reaction of the eyes with extracapsular extraction. The followers of their theory never tried to explain the involvement of the other eye on the basis of phaco-anaphylaxis. If one accepts the idea of phaco-anaphylaxis of the first eye, then the intracapsular removal of the lens of the other eye would eliminate the possibility of the lens anaphylaxis because the lens antigen could act only on the lens of the other eye, but not on the uveal tissues. The clinical observation that the discission of juvenile cataract of one eye (where the

entire lens masses remain for spontaneous absorption) is rarely the cause of a postoperative uveitis of the operated eye and never results in a uveitis of the fellow eye contradict the possibility of phaco-anaphylaxis as the basis of sympathetic ophthalmia of the second eye. Finally it should be mentioned that the histologic picture of sympathetic inflammation differs greatly from that of anaphylactic inflammation.

Dr. Isadore Givner said that he agreed with Dr. Rados that sympathetic ophthalmia and endophthalmitis phaco-anaphylactica are two distinct entities. He cited a case, which he felt did not bear out Dr. Rados's contention that, in endophthalmitis phaco-anaphylactica, it is necessary to have the lens of the second eye opened before changes can occur in the second eye.

The patient, a woman aged 74 years, had bilateral cataracts, a history of asthma, and her blood pressure was about 200/100. On May 7, 1946, a combined extracapsular extraction was performed in the right eye. The operation was uneventful and, except for the fact that a small quantity of lens cortex was left in the anterior chamber after irrigation, the eye looked and did well.

On June 3rd, a few keratic precipitates were noted in this eye. These were large and connected with fibrin strands, the type of keratic precipitates that are seen as an allergic response to lens material and not infection. The eye remained white and except for a secondary membrane was in excellent condition at the end of July.

On August 1st, the left eye developed a secondary glaucoma with keratic precipitates and a tension of 90 mm. Hg (Schiøtz). Positive transfer showed a 4-plus reaction to lens antigen. An iridencleisis with sclerectomy was performed, which controlled the tension. After a discission of the secondary membrane, vision of 20/20 was obtained in the right eye; the left eye went on to phthisis bulbi.

Dr. Posner concluded that this case suggested that enucleation of the first eye is not indicated in endophthalmitis phaco-anaphylactica and, therefore, the clinical differentiation from sympathetic ophthalmia is important.

Occlusion of the central retinal artery

Dr. Abraham L. Kornzweig presented a case with sudden loss of vision of the right eye in a woman aged 72 years. Examination of the fundus revealed a partial occlusion of the central retinal artery, and edema of the macula. The vision of the left eye was 20/30. The patient was observed for two years, during which time there was no improvement in the vision. The arteries of the retina of both eyes showed marked hypertensive changes, such as tortuosity, increased light reflex, and compression of the veins.

This patient died, and both eyes were obtained. The right eye was sectioned serially in order to determine the condition of the arteries which had become occluded. The important serial sections of the eye were shown. The artery was traced from a distance of about one-half inch from the optic disc through the lamina cribrosa and on to the dics. The central retinal artery was narrowed but patent. Several sections that were stained with the Weigert-Elastica stain showed evidence of fibrous bands in the lumen of the artery. The artery was distinctly narrowed, almost to the point of obliteration, as it passed through the lamina cribrosa. On the disc, one vessel showed marked narrowing and what looked like recanalization. The retina showed atrophy of the internal layers up to the internal nuclear layer, which was thinned down to one row of Müller's nuclei. The macula was also seen and it was considerably atrophic.

Because of the absence of complete occlusion of the central retinal artery by embolus, thrombus, or endarteritis, a spasm of the artery was considered as contributing to the closure of the vessel.

DR. ORWYN H. ELLIS, *chairman*

CLINICAL RADIUM AND ROENTGEN THERAPY

DR. IAN MACDONALD (by invitation) presented the action of the different rays and their effect on living tissue. The alpha rays are extremely caustic and produce flash burns. In beta radiation the electrons are travelling at high speed, and filters are used to produce emanations of 95 to 98 percent. Gamma rays are produced by electromagnetic radiation, are extremely penetrating, and require 25 centimeters of lead to filter completely.

The essentials for determining the radiologic effect are quality, intensity, and quantity. In inflammatory states, before the pyogenic stage, irradiation may produce resolution without suppuration. Chronic inflammatory states, such as tuberculosis of the lids, will respond quickly to irradiation. For eyelid conditions, beta radiation is usually advised. Basal-cell carcinoma responds to low voltage X rays, with the eye shielded. The deep penetrations of retinoblastoma usually respond well to therapy. Since nerve tissue is practically unaffected by X ray, extremely high doses can be given.

Radium salts in monel metal capsules are the most practical for short beta radiation treatment. In the treatment of inflammatory conditions, it is important that the cells are not destroyed, that the changes are reversible so that the cells can return to normal. In the treatment of neoplasms the destructive change is desired, so that the cell changes are irreversible.

CHEMISTRY AND BIOCHEMISTRY OF THE VITREOUS

DR. RICHARD WINSLER (Department of Chemistry, University of Southern California, by invitation) presented a detailed technical discussion. The vitreous is a collagen gel, or a series of alveolar sheets. The fibers seen on pathologic preparations are artefacts in fixation products, and the evidence for membrane existence is poorly substantiated. The osmotic pressure is in equilibrium with the aqueous and serum, and cannot be responsible for swelling in pathologic conditions. Swelling of the vitreous can be varied by changes in the pH, but not in the physiologic range. The fractionation of proteins and the composition were reviewed, and it was pointed out that the vitreous has mucoprotein and residual protein not present in aqueous and serum. Glucosamine plus glucuronic acid produces hyularonic acid, the latter is probably primarily responsible for the viscosity of the vitreous. The relative metabolism of the vitreous is very low, and there is doubt as to whether there is any oxygen consumption at all. Dr. Winsler closed this interesting evening with the challenge that the mysteries of the vitreous were still mostly unexplored. At least part of the etiology of glaucoma might be uncovered.

Daniel B. Esterly,
Secretary.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

October 23, 1947

DR. BURTON CHANCE, *chairman*

RETINOBLASTOMA CURED BY RADON

DR. JOSEPH WALDMAN AND DR. CHARLES E. G. SHANNON presented a proved case of retinoblastoma (microscopic and gross study of the enucleated eye) that had been treated and observed for 12 years. Retinoblastoma in the remaining eye had been treated and cured for a period of nine years (1938).

Enucleation of the left eye was performed in 1935 when the patient was aged 10 months. The optic nerve was microscopically free of tumor cells.

Roentgenotherapy to the right eye was given. It will be noted that the total of 3,404R units given was far below the dose advised by the fractionated method of Martin and Reese. In November, 1938, 2½ millicuries of radon were applied in dental compound and sewed to the overlying sclera. Following this, 1 application of 2½ millicuries, 3 applications of 5 millicures, and 1 application if 7½ millicuries of radon were used in a previously described holder (Waldman, J.: Arch. Ophth., 24: (Jan.) 1940) from March, 1939, to May, 1942. The patient was 10 months old when treatment was instituted, and is 13½ years old at this time.

Typical irradiation cataract and fundus changes, probably incident to radon therapy, were described. Visual acuity was 6/60. The patient attends a sight-saving school.

The lens changes and perhaps the macular changes, too, may become more marked. In retrospect, the areas thought to be new growths in April, 1942, may quite possibly have been a late reaction to the radon applied previously. This condition has been noted and described by Martin and Reese in their large series treated by fractionated roentgenotherapy.

Conclusions. We can do no better than to endorse the procedure of Martin and Reese in the treatment of retinoblastoma:

1. *Unilateral* ocular involvement—prompt enucleation. Bimonthly ophthalmoscopic examination of remaining eye for one year; trimonthly in 2nd year; every 4 months in 3rd year; every 4 months in 4th year; every 6 months in 5th year.

2. *Bilateral* involvement—prompt enucleation of the more diseased eye and irradiation therapy with idea of saving life and conserving vision in remaining eye, if the growth is not too far advanced.

For ocular and intracranial involvement of relatively easily accessible areas, craniotomy and excision of growths with enucleation are recommended.

The local use of radon by the method described (Arch. of Ophth., 24: (Jan.) 1940) is recommended as another form of treatment of this malignant disease, particularly where the exact and careful technique of fractionated roentgenotherapy described by Martin and Reese is not available.

Discussion. Dr. Charles E. G. Shannon: I would like first to congratulate Dr. Waldman on his excellent paper. I can speak freely as I am in no way responsible for its production. It is entirely Dr. Waldman's.

Unquestionably with an advanced gliomatous growth in one eye, and a beginning growth in the other, enucleation of the more severely involved eye should be carried out at once and irradiation by radium or fractionated roentgen rays in the other eye should be instituted. We are all familiar with the extraordinary success with which Martin and Reese have carried out the fractionated or divided principle of roentgen radiation. However we felt it to be more practical to irradiate the remaining eye in the patient with radon seeds. Our first attempt to implant the seeds on the sclera opposite the site of the growth according to the technique of Stallard was a bit harrowing and, therefore, a different technique seemed necessary. It was at this point that Dr. Waldman solved the problem by the development of what he has termed a "pliable silver-band applicator." It was a most ingenious device, and it proved its value by reason of the comparative ease with which the implantation could now be carried out. Six applications over a period of four years (1938-1942) finally witnessed the complete elimination of the growth.

Dr. William Zentmayer: There are two features in this case that interest me very much. The first is the appearance of circinate degeneration of the retina, inasmuch as it has been observed in other cases. In the *Transactions of the Ophthalmological Society of the United Kingdom,* volume 64, there is a case reported by S. Philips, strikingly similar to Dr. Waldman's, treated with radium. In this case, the circinate lesions appeared just as they did in Dr. Waldman's

so there is evidently some relation between the radium application and the appearance of degenerative changes. Perhaps something similar to what occurs in the lens.

I feel that in the area where the radium was applied, the changes seen are not only destruction of the choroid, but that there is superimposed connective tissue, the result of the action of the radium. This also has been noted in other cases, and particularly in the case I mentioned above. So marked was this, that it was taken by the surgeon to be a recurrence of the growth, and he reapplied radium. He later came to the conclusion that he was mistaken, and what he took to be a recurrence of the growth was the formation of fibrous tissue.

I might say that six years ago I had the opportunity to do an interstitial implantation of a radon seed in a case of retinoblastoma. A child was sent up from Florida who had had the left eye removed for glioma. This diagnosis was confirmed by Dr. Verhoeff. In the eye that remained, the growth was very extensive. It extended from the lower margin of the disc almost to the equator in the inferior quadrant of fundus, the vessels were exceedingly large and tortuous. Through the coöperation of Dr. Pendergrass, I secured some radon needles, and inserted them into the tumor itself. Unfortunately, the child developed whooping cough, and had to be taken from the hospital and was taken home to Florida so there was no observation beyond a period of about a month, but unquestionably, there was already shrinking of the mass. I was told that the child improved so that she could see to go about. Death resulted from spinal metastasis.

Dr. I. S. Tassman: I should like to ask as a matter of information when are you justified in considering a case of this kind cured clinically?

Dr. Edmund B. Spaeth: Just one difference of opinion with Dr. Waldman which is not tremendously important. He spoke of the irradiation cataract changes as due to the radon. I doubt it very much. The extent of dissemination of beta emanations is so short that the position of the radon seeds could not affect the lens. I believe his patient's irradiation cataract is undoubtedly due to the earlier X-ray therapy which was used. I am rather unwilling to have the radon blamed for the radiation cataracts when they probably did not occur from that.

Dr. Zentmayer: It appeared in the case reported in the *Transactions of the Ophthalmological Society of the United Kingdom,* volume 64, 1944.

Dr. Edmund B. Spaeth: Without roentgen therapy?

Dr. William Zentmayer: Yes.

Dr. Edmund B. Spaeth: It is rather interesting.

Dr. Joseph Waldman: Thank you very much, Dr. Shannon, for your comment.

In answer to Dr. Spaeth's remark about the course of X ray (3104R) causing the cataract, rather than the radon, I believe it is a possibility. On the other hand, repeated exposure to radon has been reported as causing the same disturbance. I think that H. L. Hine, F. Moore, H. B. Stallard, and J. G. Milner in the *Transactions of the Ophthalmological Society of the United Kingdom* have reported such cases. (To Dr. William Zentmayer) Is that the reference you have in mind, sir?

Dr. Zentmayer: I think the author is Philips.

Dr. Joseph Waldman: Yes, sir, that is in the same journal—S. Philips.

In answer to Dr. Tassman, I do not know actually when you are justified, but it has been the custom, I believe, pathologically so to speak, to consider a five-year cure. Now, whether you can say cure without adding five years I do not know, so if you want to be exact, I suppose we can say this is a nine-year cure.

Ptosis operation: Friedenwald technique

Dr. Edmund B. Spaeth presented a film

showing operative procedure for the correction of ptosis, according to the Friedenwald technique.

Attention was called briefly to the history of the use of nonabsorbable sutures in ophthalmology. The indications for the utilization of the occipital frontalis in correcting ptosis by this technique were stressed. The technique lends itself best to correcting high degrees of ptosis in young children, as an interim operation, and for the correction of ptosis with flaccid lids in the presence of a completely paralyzed levator.

Discussion. Dr. Francis Heed Adler: The majority of these children with congenital ptosis have marked epicanthus. I have always felt that any operation designed to correct the ptosis was doomed to failure unless the epicanthus was first taken care of, and this generally should not be done before the child is 5 or 6 years of age. This operation looks very simple and effective, and I am wondering whether Dr. Spaeth finds that it corrects the deformity adequately without doing anything for the epicanthus.

Dr. Edmund B. Spaeth: Dr. Adler asked the question about epicanthus and its relationship to ptosis in very young children. It is a most pertinent question. I feel that epicanthus should not be surgically corrected until the child's face has reached an adult size. Most of these youngsters have a very shallow bridge of the nose or none at all. The configuration of the nose of the father or the mother will aid one in forming an opinion of what might occur in these children, as the bridge of the nose develops and elevates. Of course, children do not always develop similar to their parents. Epicanthus frequently continues and needs corrections in spite of the development of a normal bridge. Some rather unpleasant instances have come to my attention of epicanthus, and its correction in the very young years of life by plastic surgeons who were not ophthalmologists. When the time is proper for correction of epicanthus, it is not always a problem of surgery at the inner canthus alone. Frequently the external canthus also needs adjustment because of dissimilar lengths of the lid margins.

Any type of levator surgery which can be done will modify but little the degree of epicanthus present. Some logical ptosis operations will actually augment the epicanthus at that time; namely, such a procedure as the Hunt-Tansley. On the other hand, the Machek and Gifford operations do modify favorably epicanthus if present at the time the ptosis is being corrected by these techniques. They probably are the only two ptosis operations which do help to correct epicanthus. Unfortunately they have limitations as to their use. Under such circumstances, it again appears that the proper time to correct epicanthus is not when the patients are still in early childhood, but in the later years of child life, or in early adult life. Then that which is still residual, in spite of more mature development, must be corrected. It would seem at the 14th or 15th year of life is perhaps the best time for that surgery.

Severe papilledema in diffuse infections of the nervous system

Dr. Joseph C. Yaskin, Dr. Robert A. Groff, and Dr. Henry A. Shenkin, Philadelphia,* (by invitation) presented this subject.

In most instances a frank bilateral papilledema presents few diagnostic problems since the history of the case, the evidences of focal brain disease, or the presence of acute infection makes the etiologic diagnosis fairly evident. Most cases of papilledema are eventually traceable to space-taking lesions, such as tumor, abscess, subdural hematoma, and less frequently to arachnoiditis, and frank infectious processes of the temporal bone and paranasal sinuses (otitic hydrocephalus, nonsuppurative encephalitis).

* From the Departments of Neurology and Neurosurgery, Graduate School of Medicine, University of Pennsylvania.

We have encountered a number of patients with bilateral papilledema in whom the etiologic diagnosis was difficult but important since some of those patients required operative intervention to save eyesight. It is the purpose of this presentation to report 12 patients in all of whom bilateral papilledema was present, but could not be accounted for on the basis of any of the causes mentioned above.

The 12 cases (average age, 24 years) showed bilateral papilledema and other less marked evidences of increased intracranial pressure. Although no definite etiologic factors could be established, it was felt that the process was probably infectious in nature, but did not fall into the category of arachnoiditis, pseudotumor, otitic hydrocephalus, or localized, nonsuppurative encephalitis of known etiology.

The papilledema varied from 2 to 10 diopters, it was accompanied by hemorrhages and exudates and lacked the characteristics of papillitis. The visual acuity was only slightly impaired, excepting in those patients who had marked papilledema.

The study of the spinal fluid was not helpful in establishing a diagnosis. Ventriculography was performed in 10 cases and ruled out an intracranial mass lesion.

The average duration of papilledema was 3½ months with a range between 1½ and 6 months. Focal brain signs were absent in the majority of patients, and were only confusing in the six patients who presented them.

In addition to symptomatic treatment, some patients were benefited by ventricular drainage; two required a subtemporal decompression, and two were subjected to a suboccipital exploration. Of the 12 patients, 2 died, 5 made a complete recovery, and the remaining developed some degree of secondary optic atrophy and diminution of visual acuity.

The problem of bilateral papilledema of undetermined etiology is not new, and has been discussed previously by a number of investigators. In the course of time, especially with the advent of air studies, more frequent exploratory procedures, and painstaking autopsy material study, new etiologic factors have been ascertained leading to the concepts of arachnoiditis, otitic hydrocephalus, pseudotumor, and nonsuppurative encephalitis. We believe that our series of cases are not included in the above categories, although there must be some overlapping of concepts relating to the etiology and pathogenesis.

In attempting to arrive at an etiologic diagnosis in our cases, it is evident that the increased intracranial pressure was not due to any obstructive lesion. Nor was it likely to be due to any marked edema of the brain since all our patients were alert throughout their clinical course.

It would seem reasonable to assume, therefore, that the increased pressure was due to some factor which either increased the output of spinal fluid or interfered with its absorption. We suggest the presence of some infectious process, reasoning largely by analogy to similar conditions produced by infections of the temporal bone and paranasal sinuses. We cannot exclude toxic or allied factors, especially since the spinal fluids were singularly free from elements of an inflammatory nature. Thus, the absence of pleocytosis would justify the conclusion that the principal mechanism in our cases is one of fluid exchange such as one sees in other parts of the body in allergic or similar reactions.

It is suggested that future ultraspectrophotographic studies of the spinal fluid such as are now being carried on by Dr. Adolph Spiegal in Philadelphia may give us more information on the etiology and pathogenesis of these cases. Such information may help to explain why small lesions on the surface of the cerebrum may give rise to marked increase in intracranial pressure; whereas, large lesions in the vicinity of the ventricles, as, for example, the gliomas of the brain stem, give rise to no papilledema

until late in the course of the disease.

Irrespective of etiology and pathogenesis, these patients present practical problems in diagnosis and treatment. Every case of papilledema with or without other evidences of increased intracranial pressure should be suspected from the start as harboring an intracranial space-taking lesion until proved otherwise. In all patients in whom there is no clear etiologic factor, such as infection of the temporal bone and paranasal sinus, syphilis, system infections or intoxication (lead), or hypertensive encephalopathy, and, unless the patient progresses rapidly toward recovery, there should be an air study. In our experience ventriculography is the procedure of choice since it is safer, causes less discomfort to the patient, and, in most instances, provides the necessary information to exclude a space-taking lesion.

Even more important is the consideration of the management of these patients. In the absence of any known etiologic factor the treatment is largely symptomatic. Several of our patients were probably benefited by repeated ventricular drainages. Five of the 10 surviving patients developed a secondary optic atrophy of varying degrees. We feel reasonably certain that two of our patients owe whatever vision remains to a subtemporal decompression. Considering the seriousness of diminished visual acuity and the relative simplicity of subtemporal decompression, it is our feeling that a decompression should be done more frequently in an attempt to prevent visual impairment. The question of more extensive exploratory procedure must be left to the judgment of the mature clinician and his evaluation of the individual case.

Conclusions. 1. There are patients who have papilledema and other evidences of intracranial pressure probably due to alterations of the cerebrospinal fluid circulation and/or chemical composition of the fluid, the nature of which is unknown. It is suggested that in these cases routine spinal-fluid studies should be augmented by ultraspectrophotographic studies.

2. Unless the progress in these obscure cases is satisfactory from the standpoint of ocular findings, ventriculography should be employed, in that an intracranial mass lesion cannot be definitely excluded without its aid.

3. Operative intervention in the interest of preserving vision should be seriously considered in those cases whose progress is unsatisfactory, despite the inability to demonstrate an intracranial mass lesion.

Discussion. Dr. Francis Heed Adler: The one thing these cases all have in common is a papilledema of unknown origin. I did not hear Dr. Shenkin mention polycythemia vera. I presume that this was ruled out in all of these cases. We have had three patients at the University Hospital which Dr. Shenkin probably knows about in which this was the final diagnosis. All three had choked discs.

Dr. Robert H. Trueman: Mr. Chairman, I would like to add a few words of comment on one of the cases presented by Dr. Shenkin, in that Dr. Spaeth and I had the opportunity to reëxamine her only a few days ago. She was the young girl that had the very high degree of papilledema.

The first time that Dr. Spaeth and I saw the case, in consultation, she had between 4 and 5 diopters of papilledema in each eye with vision of 6/15, bilaterally. We saw the case daily with Dr. Yaskin and Dr. Groff and watched a rapid increase in the papilledema, and a decrease in the visual acuity in each eye. Under conservative therapy, the patient's general condition deteriorated, and the papilledema increased to 10 diopters in the right eye and 8 diopters in the left eye with a decrease in vision to light perception, bilaterally. It was at that time that it was felt that operative intervention was absolutely imperative. Isn't that correct, Dr. Yaskin?

Dr. Joseph C. Yaskin: Yes.

Dr. Robert H. Trueman: It was at that

time that Dr. Groff did the subtemporal decompression. Immediately thereafter the papilledema began to recede, and the visual acuity to improve. At the time of her discharge from the hospital, her papilledema had receded between 2 to 3 diopters in each eye.

At the time of her reëxamination several days ago, we found an optic atrophy secondary to the papilledema, but the remarkable thing we felt, was the fact that in the eye that had had the 10 diopters of papilledema, her vision was now 6/22, while in the eye that had had the 8 diopters of papilledema, her vision was now 6/7.5. Her visual fields showed a moderate concentric contraction for form and color.

I feel that this case should emphasize Dr. Shenkin's closing remark that, in this type of case with rapidly deteriorating vision even without evidence of a space-taking lesion, decompression is essential for the continuation or preservation of whatever visual acuity is present or, as this case has pointed out, for an improvement in that visual acuity following the surgery.

Dr. Joseph C. Yaskin: Mr. President, I should like to emphasize some of the points of our paper since Dr. Shenkin did not have sufficient time to do so. In each of these cases, the outstanding problem was the saving of the eyesight. Most of these patients, when first seen, were suspected of having a brain tumor, but no evidence of any space-taking lesion could be found. Unfortunately, no very distinct evidence of infection could be determined even after prolonged studies.

Because of the ever present fear of blindness, we resorted to measures that we ordinarily avoid. Thus, we did not hesitate to do lumbar punctures in the presence of papilledema. We also did air studies on less than usual provocation.

In some cases, even though preliminary air studies failed to disclose a space-taking lesion, we decided on exploration, because of the desperate condition of the patient. It required a great deal of careful analysis and judgment to decide when to do air studies, and to operate, and in all these matters the ophthalmological findings played a major role.

I am quite sure that two of our patients owe their eyesight to decompressive procedures, and that, without these procedures, they would have been totally blind. One girl had not only subtemporal decompression for the papilledema but, because of the progressively increasing loss of sight, and despite the negative ventriculogram, a posterior craniectomy was resorted to.

Lastly, we have learned from the study of this group of patients that, in the presence of increased papilledema, air studies and decompression should be resorted to even though the process is not due to any definite cranial entity such as tumor, subdural hematoma or arachnoiditis.

Dr. Henry A. Shenkin: In reply to Dr. Adler's question, I cannot say that we eliminated polycythemia in each and every one of these cases, however, I was personally familiar with each patient, and I can tell you these people did not look polycythemic, and, furthermore, the course of the disease, I think, rules out the question of polycythemia.

The only other comment which I would like to make is that, unfortunately, some of these patients come to the hospital in series, and some of the younger residents are impressed with the fact that there may be 2, 3, or 4 cases of papilledema that turn out not to be due to brain tumor, and then for a year after that, they are a little disrespectful of papilledema as an evidence of a brain tumor. In general, I think it should be emphasized that true papilledema is due to brain tumor. Other causes are rare. Papilledema should be regarded as being due to brain tumor until proved otherwise.

George F. J. Kelly,
Clerk.

Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 664 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE JUNE MEETINGS

The 17th scientific meeting of the Association for Research in Ophthalmology was held in Chicago on June 21st and 22nd. It was noteworthy for several reasons: the size and excellence of its program and the bestowal of the first Proctor Medal.

Since its origin until the present, the association has held its meeting on one day only and limited the number of papers that were presented to 10 or, at the most, 12. It is an evidence of the marked growth and development of experimental ophthalmic research in the United States that 24 excellent papers were on the program.

Some of these presentations, notably those of Frenkel; Leopold *et al.;* Harris and Gehrsitz; Kinsey and Barany; and Newell and his associates, were particularly outstanding. Elsewhere in this number of the JOURNAL will be found the complete program.

Approximately 160 members and guests were in attendance. Most of these members were present at the association's banquet the evening of June 21st and witnessed the

presentation of the first Proctor Medal for ophthalmic research to one of its most distinguished members, Jonas S. Friedenwald of Baltimore. The award was made by Francis Heed Adler of Philadelphia, and was modestly received by Friedenwald who paid generous tribute to his co-workers of 25 years in outstanding research at Johns Hopkins Hospital.

In his acceptance address, Dr. Friedenwald spoke of the evolution of medical progress from the Natural-History stage through the era of Clinical Research. He pointed out that important discoveries from clinical studies are becoming fewer as the field is gleaned, while the era of experimental investigation into the basic problems of medicine is still unharvested and is, so far, inexhaustible.

He mentioned the pleasure and excitement to be found in experimental work. No one will agree with him, however, that the work is easy unless he is a master of modern techniques in chemistry, physics, and mathematics, as is Friedenwald.

The Proctor Address, given by Dr. Friedenwald the following morning, summarized his studies of the past 25 years on the "Formation of the Aqueous." It was a fascinating exposé of the painstaking work and laborious steps in the attempt to answer this fundamental problem of ophthalmic physiology.

On June 23rd, the scientific session of the Section on Ophthalmology of the American Medical Association began. John A. MacMillan of Montreal, Canada, was the guest of honor of the section. The subject of his address was "Diseases of the Lacrimal Apparatus." It is pleasing to note that Dr. MacMillan was elected an associate member of the A.M.A. by the House of Delegates.

The chairman of the section, Everett L. Goar, in his address, discussed "Ophthalmic Education and Results in the United States."

Thirteen other scientific papers were read and well discussed. The program was excellent. Among the outstanding contributions were those of Reese on "Retrolental Fibroplasia and Persistent Hyperplastic Primary Vitreous: Two Entities"; Ingalls on "The Epidemiology of Encephalo-ophthalmic Dysplasia"; "The Use of D.F.P. in Glaucoma," by McDonald and Leopold; "The Blindspot Syndrome," by Swan; and "The Use of Streptomycin and Streptomycin Plus Promizole in Experimental Ocular Tuberculosis," by Alan C. Woods.

The Research Medal of the section was presented to Alan C. Woods of Baltimore by Francis Heed Adler in the name of the executive committee of the section. The important and significant contributions of Dr. Woods in the fields of ocular immunity, allergy, sympathetic ophthalmia, tuberculosis, and uveitis were cited.

Unlike the Proctor Medal, the Research Medal of the section is granted for both clinical and experimental research. The choice of the recipient for this year's medal was a popular one.

A gold medal of the A.M.A. for scientific exhibits was given to Bertha A. Klien, department of ophthalmology, Northwestern University, for her splendid exhibit on "Diseases of the Fundus Oculi"; a bronze medal was awarded to William Stone, Jr., Massachusetts Eye and Ear Infirmary, for his exhibit on "A New Type of Movable Implant"; and John G. Bellows and Chester J. Farmer, of Northwestern University Medical School, received a certificate of merit for their exhibit on "Treatment of Ocular Infections: Use of Chemotherapeutic Agents."

After many years of devoted service, Arthur Bedell resigned as delegate of the section to the House of Delegates. A rising vote of thanks for his service to the section was evidence of the esteem, affection, and gratitude felt by the members of the section for Dr. Bedell. William L. Benedict of Rochester, Minnesota, was elected the delegate to replace Dr. Bedell.

M. Hayward Post, Jr., of St. Louis, was elected chairman, and Brittain F. Payne of New York, vice chairman, of the section for 1949.

The section recorded its support of the resolution adopted by the House of Delegates in 1947, condemning the acceptance of rebates and calling for punitive measures against members and fellows of the American Medical Association who are guilty of the practice.

The secretary, Trygve Gundersen, was appointed to represent the section on a joint committee with other ophthalmic organizations to investigate the use of penicillin as a prophylactic agent against ophthalmia neonatorum. A committee of the section to act jointly with representatives of the other ophthalmic organizations to celebrate in 1950 the centenary of the discovery of the ophthalmoscope by Helmholtz was proposed.

In spite of the rather small attendance, about 300 members having registered, the meeting was interesting and successful. The 1949 session will be held in Atlantic City, June 6th to 10th.

Derrick Vail.

OBITUARY

WALLACE PYLE
1875-1948

Dr. Wallace Pyle died June 10, 1948, at his residence in Orange, New Jersey, after several weeks' illness.

He was born in Jersey City, New Jersey, a son of the late Dr. Edwin Pyle. He attended the University of Michigan for two years, and then entered the Medical School of the University of Pennsylvania, from which he received his degree in medicine in 1897. He interned in Christ Hospital, Jersey City, and later became ophthalmologist on the staff of that hospital and several other Hudson County hospitals, including the Jersey City Medical Center.

He was a fellow of the New York Academy of Medicine, the American College of Surgeons, the American Academy of Ophthalmology and Otolaryngology, and the American Medical Association. He was also a member of several local medical societies.

Dr. Pyle was always affable, courteous, and generous. These traits, together with his professional ability, endeared him to his patients and his fellow practitioners. His ethical standards were of the highest. His chief diversion was travel. He made numerous trips to Europe, the far East, Alaska, the western part of the United States, and South America.

His wife, Ida Jarvis Pyle, a son, two daughters, and seven grandchildren survive him; also, a brother, Dr. Edwin Pyle, a physician in Waterbury, Connecticut.

Elbert S. Sherman.

CORRESPONDENCE

SPASTIC MYOPIA AS A COMPLICATION OF GLYCOSURIA

Editor,
American Journal of Ophthalmology:

Various writers have referred to refractive changes in diabetics. I should like to submit the following case which seems to be one of transient myopia accompanying transient glycosuria.

A retired Anglo-Indian lieutenant, aged 61 years, came to the Eye Clinic at Kotagiri, the Nilgiris, South India, complaining of rapidly changing vision. His old glasses (+0.5D. sph. for distance; +2D. sph. for reading) were no longer comfortable and he found that he could read better with no glasses. However, his distant vision without glasses was only 6/9, O.U.

Manifest acceptance on December 12, 1942, was: O.D., −0.75D. sph. ⌒ −0.75D. cyl. ax. 90° = 6/5; O.S., −1.0D. sph. ⌒ −0.25D. cyl. ax. 90° = 6/5. Reading acceptance was: O.D., +1.0D. sph. ⌒

+0.75D. cyl. ax. 180°; O.S., +1.25D. sph. ⊂ +0.25D. cyl. ax. 180.°

As the patient had been taking a strychnine tonic, he was advised to stop this and return for refraction and retinoscopy in 12 days. On December 24th, the repeated tests gave the same acceptance as before.

Glasses with the new prescription were comfortable for a time but after the patient, who meanwhile had learned of a diabetic condition (2-percent sugar), took insulin (5 injections only) and followed a diabetic diet, he could no longer tolerate the new glasses but returned to wearing the ones with the old prescription. By February, 1943, he was no longer able to use the new glasses.

A glucose tolerance test on March 6, 1943, showed: Fasting blood sugar, 75 mg. per 100 cc. After administration of 50 gm. glucose, it rose to 106 mg. at the end of 30 minutes; at the end of 1½ hours, it returned to fasting level, and reached 62 mg. at the end of two hours. Urinary sugar was absent throughout the test, the curve appeared to be normal, and there was no evidence of diabetes.

For some weeks before he discovered 2-percent sugar in his urine, the patient had noticed polyuria and polydipsia. By maintaining a low-carbohydrate diet after the five injections of insulin, he has remained sugar free. Never, since he became sugar free, has he been able to tolerate the new minus lenses prescribed during the time when he was suffering from glycosuria.

Parsons in his *Diseases of the Eye* (p. 591-592) says that in addition to diabetic cataract, retinitis, intraocular hemorrhages, and retrobulbar neuritis which may occur with diabetes, there are "remarkable changes in the refraction of the eye, both in the direction of hypermetropia and myopia," and he attributes this to "alterations in the refractive index of the cortex of the lens."

On page 319 he refers to the lenticular changes in diabetic cataract, and says "there is little doubt that osmotic changes are a prominent factor in the pathogenesis and account for the accumulation of droplets beneath the capsule of the lens."

In 1929, K. K. K. Lundegaard in Copenhagen wrote, "In diabetes mellitus a sudden hypermetropia arises due to alteration in the lens." The onset he described as a "sudden mist" obscuring the vision. But in our patient, there was no such symptom, and the lens remained clear throughout.

Instead of trying to explain the transient myopia with glycosuria in terms of osmosis beneath the lens capsule only, I would like to suggest the possible effect of diabetes on the ciliary muscle as well.

I recall two cases admitted to a large American hospital at different times, and by different resident physicians, both of which had been rushed to the surgical ward as "emergency appendix." In each case, fortunately, the coma and the boardlike rigidity of the abdominal muscles were discovered to be due to diabetic coma before surgical intervention supervened. Insulin produced rapid cessation of all symptoms. Both patients were children from the same home who had formed the habit of frequenting their father's candy shop and feasting on sweets instead of eating the meals their mother prepared for them.

If big abdominal muscles can become spastic with diabetic crises, is it not possible that the transient myopia also is a spastic myopia.

David O. Harrington of San Francisco, (J.A.M.A., *133:* (Mar. 8) 1947) makes no reference to diabetes but in his discussion of "Psychosomatic Disorders" describes a temporary visual disturbance which he considers to be due to a spastic myopia. "This condition," he says, "sometimes called 'ciliary spasm,' is thought to be due to spastic contraction of the ciliary body with resultant increase in antero-posterior diameter of the lens." He considers this to be always associated with emotional disturbance. The ex-

amination revealed "spastic myopia."

Although Harrington makes no mention of the myopia of diabetes, or of transient glycosuria, is it not possible that the pathogenesis of transient myopia with transient hyperglycemia and glycosuria may be a "measurable temporary *spastic myopia*" which appears when there is sugar in excess and disappears when the patient's blood sugar returns to normal?

BOOK REVIEWS

EL TRACHOMA. By Virgilio Victoria, M.D. Buenos Aires, El Ateneo, 1947. 315 pages, 76 illustrations.

The book is motivated by the desire to correlate the bibliographic data on trachoma with the author's clinical observations, and to stimulate public-health activity for the control of the disease in Argentina. Practicing in Tucumán, a trachoma-infested part of Argentina, Dr. Victoria has a large clinical, administrative, and research experience with the disease.

Of the six chapters into which the book is divided, three are devoted to a description of the clinical and laboratory features, one to therapy, one to the constitutional implications of the disease, and one to the public-health problem, principally as it affects Argentina. A bibliography follows each chapter.

The author rejects the view that invasion with pathogenic microörganisms is a complication of trachoma, and considers this invasion as an integral and constant part of the pathogenic process. He therefore discourages the use of the expression "complicated trachoma" as a misnomer.

In the first three chapters the trachomatous lesions in the conjunctiva, cornea, lids, and the lacrimal apparatus are described in detail, and illustrated with colored drawings and excellent microphotographs of pathologic material examined at the Institute of Regional Medicine of the University of Tucumán.

In the chapter on therapy the various therapeutic procedures reported in the literature are reviewed, and there is a useful and detailed account of the treatment patterns set up by Busacca, and followed in the main by the author in the management of the various phases of the disease.

While the procedure described by Busacca as "kneading-massage" is still the sheet anchor in the treatment pattern, the addition of sulfa therapy is recognized as of great value in hastening cicatrization, shortening the duration of treatment, and eliminating the need for subconjunctival injections. The chapter on surgical management of entropion and trichiasis is clear, concise, and illustrated with excellent drawings by Boltasar Isasi.

No new viewpoints relative to etiology are presented; the author does not believe that lymphatic diathesis, nutritional deficiencies, malaria, syphilis, tuberculosis, and intestinal parasites play any role in the etiology of trachoma, and denies the existence of natural or acquired immunity.

He believes that the great danger of infection is in childhood, and considers trachoma infectious in all its stages. In support of this contention he cites the case of an infant, 35-days old, with follicular trachoma, whose contact was limited to his mother; she had a cicatrized conjunctiva and had had no clinical symptoms for over 10 years.

Population density, low altitude, constant winds and dust, periodic migrations of labor groups without sanitary provisions, are factors favoring the spread of the disease; temperature and humidity appear to be without influence; and hygienic living conditions and the availability of running water diminish its incidence.

From the point of view of public health it may be said that Dr. Victoria is progres-

sive and sound. He advocates control of trachoma under a national public health program because of the greater economic capacity of the national government to support the program, the possibility of uniform prophylactic, therapeutic and technical patterns, and the freedom from interference from local regulations.

Specifically, he advocates supervision in schools, industry, and armed services through traveling dispensaries, educational campaigns, visiting-nurse services, and quarantine of trachoma patients with secretion.

An interesting survey of the trachoma problem in Argentina, of the industrial implications of the disease, and a tabulated analysis of the permanent visual disability of 100 patients conclude the book.

On the whole, this is a very useful volume, particularly for those who are required to deal with trachoma on any considerable scale.

Ray K. Daily.

TRANSACTIONS OF THE SOCIÉTÉ BELGE D'OPHTHALMOLOGIE. April 27, 1947, pp. 1-182.

Seventeen papers and case histories are presented. L. Weekers reports on a modified technique in the surgery of extensive divergent squint. The resected tendon of the internal rectus is attached to the conjunctiva and drawn toward the external rectus.

A. Potvin and J. Helin studied the sedimentation rate in ocular allergic diseases and found that it is of minor importance in diagnosis but of considerable interest in the prognosis of allergic manifestations.

R. Weekers' paper on the symptomatic treatment of ocular hypertension includes a study on D.F.P. and is a survey of his clinical observations. The drug, stimulating the parasympathetic, produces a miosis, a distention of the uveal vessels, and a spasm of accommodation and so changes the aqueous humor and the intraocular pressure. Its action is similar to that of eserine but lasts longer. A single instillation in favorable cases may hold the tension in normal limits for 8 to 10 days.

L. Coppez showed a film demonstrating corneal tattooing with platinum chloride. Van Canneyt and Kluyskens presented three case histories of secondary band-shaped keratitis and the possible etiology of this corneal degeneration.

A. De Jaeger and J. Bernolet suggest canthotomy as a preliminary to retrobulbar injection and akinesia in cataract operations. De Walsche reported on a tumor of the ciliary body whose first clinical symptom was hemeralopia.

In 10 patients with chronic glaucoma, 2 with retinitis pigmentosa, 2 with senile macular degeneration, and 2 with embolism of the central artery, J. Zanen and R. Wibolt could not verify the claim that retrobulbar injection of benzyl imidozoline influences the circulation of the choriocapillaris and retina.

Improvements of the ocular prothesis by using synthetic resin were recommended by R. Weekers and F. Roussel. A. Fritz compared the results of the retinal microphotometry with those of angioscotometry. R. Weekers and Thibert reported on congenital microcorie and M. Appelman on an ethmoidal-lacrimal fistula. Bilateral paracentral scotomas in a patient with an occipital lesion were studied by M. Humblet who also reviewed the anatomy and physiology of the central visual areas.

Alice R. Deutsch.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Bocci, Georgio. **A rare bacteriologic finding: a bipolar germ recovered from palpebral vaccinia ulcers.** Boll. d'ocul. 26: 561-569, Sept., 1947.

A farmer's wife, 34 years old, acquired from her vaccinated son vaccinia pustules on her right lower lid which were complicated later by an ulceration of her right bulbar conjunctiva. A germ was found in smears and isolated by culture in blood agar, characterized by negative Gram staining, deeper staining of the ends of the rods measuring from 0.5 to 1.5μ, lack of capsules, lack of spores, motility, rapid growth in pepton agar, pellicle formation on broth and, if not identical with, resembling the rare germ Malleomyces pseudomallei or Pfeifferella Whitmorei. The lesions healed under staphylococcus anatoxin treatment in ten weeks.

Grant, W. M. **Ocular injury due to sulfur dioxide. II. Experimental study and comparison with ocular effects of freezing.** Arch. Ophth. 38:762-774, Dec., 1947.

Serious ocular injuries have occurred in the refrigeration industry from accidental contact with a jet of liquid sulfur dioxide. Experiments were conducted on the eyes of living rabbits to determine the cause of the severe damage. Freezing of the anterior portion of the eye for several seconds (by a nontoxic refrigerant) produced mild and transient disturbances. Lesions similar to those caused by liquid sulfur dioxide could be produced by several seconds' exposure to the pure gas at room temperature. It is concluded that the production of severe ocular injury by liquid sulfur dioxide is not due to freezing or to the formation of sulfuric acid, as has formerly been postulated, but is the result of its ready penetration of the corneal epithelium in high concentrations and its action, principally as sulfurous acid, in

denaturing corneal proteins, including enzymes. John C. Long.

Rosso, S. **Crystalline antigens and anti-crystalline antibodies in the aqueous humor.** Ann. d'ocul. 181:213-219, April, 1948.

The concentration of antibodies in the blood serum is tremendously greater than in the aqueous. Amorphous antibodies which have apparently not been studied as thoroughly as some other types are possibly a rather important factor in the genesis of cataract and some uveal diseases, such as endophthalmitis phaco-anaphylactica. Only alpha-globulins apparently have an antigenic action on the lens. The degree of antigen sensitivity has not been reported in studies of animals therapeutically treated for cataract. Intracapsular lens extraction is preferred in animal experimentation because lens masses affect the antigen and antibody composition of the aqueous. The preferred antigen and the grading of animal sensitiveness are discussed at some length. The aqueous of normal rabbits showed no complement change in seven of eight rabbits. Replaced aqueous, however, is clearly positive. In aphakic eyes the aqueous was also positive for 60 days after the beginning of the treatment. The blood serum of animals treated with crystalline proteins changed the complement in the presence of the same antigens employed in parenteral injections. In the normal eye the primary aqueous is not affected. In the secondary aqueous and in aphakic eyes the reaction is more active.

Solis-Cohen, Myer. **The real removal of focal infection as the cause of ocular disorders.** Am. Practitioners 2:576-579, May, 1948.

Focus of infection is bacterial, not structural, and is removed when the patient manufactures enough antibodies to destroy the organisms and neutralize the toxins. There is a frequent association of oral sepsis with ocular lesions. Tonsillectomy and sinusotomy do not remove the offending organisms. Most primary foci are in the upper respiratory tract. A properly cultured vaccine of proper dosage will contain endotoxins that will stimulate the production of bacterocidens.

Woods, A. C., and Burky, E. L. **Studies in experimental ocular tuberculosis. The effect of promin and promizole in experimental ocular tuberculosis in the immune-allergic rabbit.** Tr. Am. Ophth. Soc. 45: 170-183, 1947.

Both promin and promizole exert a deterrent action in the immune-allergic rabbit. The action of the two drugs is about equal. Histologic evidence of tuberculosis persists in the majority of the eyes of treated animals, but the lesions are much fewer and less severe than in con-

trol eyes. On transfer experiments with the extract of the uveal tract from the eyes of seven treated animals only one positive result was obtained. All controls gave positive transfer.

These results may be due either to a degradation or attenuation of the virulence of the organs allowing the resistance of the host to become more effective or to a direct bacteriocidal action on the bacilli.

VEGETATIVE PHYSIOLOGY, BIOCHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Bárány, Ernst. **The rate of equilibration of intraocular pressure.** Acta ophth. 25:175-187, 1947.

The purpose of this investigation was to ascertain how rapidly the intraocular pressure regains its equilibrium. In a study of the influence of blood pressure on the intraocular pressure it was found that the effect of a change of blood volume in the eye is of short duration; after it is over the real change in equilibrium level due to the factors influencing the formation and circulation of aqueous becomes manifest. Bárány points out that the studies of Wessely and Duke-Elder did not take into consideration the first transitory changes. The briefly reviewed data of experimental investigation on the period of equilibration leads to the fairly unanimous conclusion that the period of equilibration should lie between 5 and 15 minutes. Bárány's own investigations consisted of a series of experiments on rabbits' eyes. Thirty minutes after placing a van Leersum loop on the carotid the tension was measured. Slight pressure of a finger on the eye on the side of the closed carotid was applied through the lid for 6 to 7 minutes. After the pressure was removed tonometry was performed on each eye alternately, with one reading per minute until constant values had been obtained, which was no longer than 15 minutes. The result was a series of slowly falling pressures in the control eye, and pressures that rose quickly at first and then slowly in the massaged eye. The mathematical deductions for the time constant are given in detail. For rabbits the time constant is 6 to 8 minutes, if the carotid is closed, and somewhat less if it opens. This corresponds to an equilibration time of 12 to 24 minutes. Only after the lapse of this period, as a minimum, can one be certain that the intraocular pressure reflects the change in equilibrium level.

Ray K. Daily.

Bárány, Ernst. **The influence of local arterial pressure on aqueous humor and intraocular pressure.** Acta ophth. 25:189-193, 1947.

This is a report of an attempt to demonstrate the passive changes in the caliber of the uveal vessels produced by changes in blood pressure. Previous experiments of compression of the carotid with a van Leersum loop have shown that the local blood pressure is reduced to about one-third of its normal level immediately after closure of the carotid. On ophthalmoscopic examination a slight diminution in the caliber of the retinal and long ciliary arteries is seen, with no change in the veins. On the release of the carotid pressure there is a distinct increase of the arterial caliber, but none in the veins. The vessels observed in this study were the capillaries of the ciliary processes, which in the albino rabbit pass down the back of the iris and can be seen with the corneal microscope as a shadow through the iris. There was no change in the uveal capillaries. Reduction of the arterial blood pressure by occlusion of the carotid caused a distinct and prompt decrease in the caliber of the uveal arteries but no discernible change in the caliber of the choroidal veins, nor in the ciliary processes at the back of the iris. Bárány believes that passive vas-

cular changes play no role in protecting the intraocular pressure from the influence of blood pressure changes. Since the capillary blood pressure is low there can be no possibility of passive aqueous formation. Ray K. Daily.

Christini, C., and Cuisa, W. **Methylization of the lens: normal and cataractous.** Ann d'ocul. 180:742-745, Dec., 1947.

In the metabolic reduction of the living protein molecule, methylization plays an apparently important part as one of the oxidoreductors. It also participates in the combustion of carbon with resulting CH_3 groups, and in lens metabolism. Cholin, methionine, and cysteine are involved as well as nicotinic acid and its amides, normally and especially in the diabetic. The methylization product of nicotinic acid (trigonelin) and that of nicotinic amide (trigonelin amide) were extracted from transparent beef lenses and cataractous human lenses. In cataractous lenses these products of methylization were absent, which is considered of importance.

Grignolo, Antonio. **Investigations concerning the possible interference between the bacteriostatic action of penicillin and the lytic action of the lacrimal lysozymes.** Boll. d'ocul. 26:699-709, Nov., 1947.

In vitro experiments performed on liquid and on solid culture media showed no interference of the agents named in the title; micrococcus lysodeicticus, hemolytic streptococcus, and staphylococcus aureus were the germs examined. Two figures show the Petri dishes after 24 hours of incubation (bibliography.)
K. W. Ascher.

Huber, A. **The pharmacology of the blood-aqueous barrier.** Ophthalmologica 114: 217-227 (Oct.-Nov.) 1947.

The rate of appearance of intravenously injected flourescein (2 cc. of a 10-percent aqueous solution of sodium-fluorescein) in the anterior chamber of human eyes has been extensively studied by Amsler and Huber (Ophthalmologica 111:155, 1945). Slitlamp examination permits fairly accurate in situ estimates of the fluorescein concentration in the aqueous. In normal human beings with normal eyes, the rate of appearance varies within fairly wide limits. There is, however, a high test-retest consistency in the same individual. The rate of the appearance of fluorescein in the anterior chamber may serve as a criterion of the permeability of the blood-aqueous barrier. In the paper under review Huber reports the effect upon the appearance of fluorescein in the anterior chamber of some of the commonly used ophthalmological drugs.

Atropine and homatropine are ineffective. Pilocarpine and eserine accelerate the appearance of fluorescein. Adrenaline injected subconjunctivally during the first 10 minutes delays and then slightly accelerates the entrance of fluorescein. In the discussion of this paper before the meeting of the Swiss Ophthalmological Society in 1946, F. P. Fischer states his preference for eosine injections as a permeability test. Eosine has the advantage of a very constant particle size upon injection into the blood stream whereas fluorescein occurs in several different particle sizes. Huber objects to the use of eosine because of its toxicity. The marked individual variations observed with fluorescein do not interfere with the latter's use in pharmacological studies since the individual's other (untreated) eye reliably serves as a control.
Peter C. Kronfeld.

Leoz de la Fuente, G. **Prostigmine in ophthalmology.** Arch. Soc. oftal. hispano-am. 8:130-133, Feb., 1948.

The author concludes that oral or parenteral administration of prostigmine has no effect on the pupil of the normal or

glaucomatous eye. Instillation of 3-percent prostigmine bromide does not affect the tension of the normal eye, but in an eye with hypertension, the instillation produces a fall in ocular tension, and miosis, which reaches its maximum in 30 minutes after which the miosis diminishes. The fall in tension persists for a longer time, varying with the conditions of each individual eye. The hypotensive action is similar to that of ½-percent eserine, and is better tolerated. The instillation is painless and does not produce the undesirable general and local effects occasionally produced by eserine, nor an annoying spasm of accommodation. Ray K. Daily.

Matteuci, P. **The innervation of the ciliary muscle in man.** Ophthalmologica 114:377-383, Dec., 1947.

According to the theory of Cogan (Arch. of Ophth. 18:739, 1937), contraction of the radial fibers of the ciliary muscle causes accommodation of the eye for far while contraction of the circular portion causes accommodation for near. According to the same theory the radial portion is innervated by sympathetic fibers or adrenergically and the circular portion by the parasympathetic or cholinergically. The specific purpose of the paper under review is to compare histologically the innervation of the three portions of the ciliary muscle in man. A number of human eyes with malignant melanomas, but normal anterior segments became available for this work. The silver impregnation method of Gros was used to demonstrate nerve fibers and their ramifications in the ciliary muscle. All three divisions of the ciliary muscle were found to contain myelinated parasympathetic as well as nonmyelinated sympathetic fibers. "The theory of Cogan needs revising."

Peter C. Kronfeld.

Panzardi, Domenico. **Effect of pentothal anesthesia on corneal reflex, intraocular pressure, and pressure in the central retinal artery; possibilities of this new anesthetic in ocular surgery.** Boll. d'ocul. 26: 570-580, Sept., 1947.

In 18 patients, anesthetized with sodium pentothal, the corneal reflexes disappeared rapidly and remained absent during the whole anesthetic period. Only three out of these 18 lost their corneal reflexes slightly later. Intraocular pressure values were diminished by 5 to 12 mm. Hg and assumed normal values at the end of the anesthesia; the increase is usually slow and the preanesthetic figures are found when the anesthesia is over. In all but one case, the light reflexes of the pupils remained active although weaker than before the anesthesia; in one case, it took two hours for the light reflex to reappear. The pupillary diameter is diminished during the anesthesia; in two patients a slight initial mydriasis was observed. The pressure in the retinal artery is increased for between 5 and 25 grams during the anesthesia; the measurements were taken only after ocular surgery, therefore it cannot be said whether in the initial period an opposite change might have been present. In 17 out of 18 patients, the eyes remained in primary position during the whole period of anesthesia. The author does not advocate the use of sodium pentothal in cases suitable for local anesthesia; if however severe pain is anticipated and general anesthesia seems preferable, sodium pentothal should be used in eye surgery for its quick and comfortable application. K. W. Ascher.

Ruedemann, A. D., and Schneider, R. W. **Alteration in plasma proteins in various types of cataract.** Tr. Am. Ophth. Soc. 45:319-327, 1947.

Twenty-seven patients with lens vacuoles and ten controls were studied in detail with reference to measurements of total and fractional plasma proteins by the electrophoretic method of Tiselius. In

24 patients an absolute increase in the beta globulin fraction was found. Three patients showed a relative increase in beta globulin fraction. None of the controls showed a comparable plasma protein pattern. David O. Harrington.

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Bertotto, E. V. **The stereophotogrammetric study of the anterior segment of the eye.** Am. J. Ophth. 31:573-579, May, 1948. (8 figures.)

Campbell, D. A. **A comparison of dark adaptation with the psychological state in miners.** Brit. J. Ophth. 32:225-226, April, 1948.

This paper presents a comparison of the results of two articles reported in this same journal. It was seen that the average threshold values of dark adaptation in persons with hysteria or anxiety neurosis and in malingerers are the same as in those with normal mentality, whereas they are higher in the manic depressive individual and in the dull and backward. In the control group of miners, the psychologically abnormal had a lower threshold than the normal, while in the certified cases of miners' nystagmus the rise in threshold in hysteria and anxiety neurosis was more marked in those without nystagmus. Thus there is no significant relationship between the psychological state and the threshold of dark adaptation. Orwyn H. Ellis.

Campbell, D. A., and Tonks, E. **A comparison of dark adaptation in miners with their nutritional state.** Brit. J. Ophth. 32: 205-208, April, 1948.

A careful inquiry was made into the nutritional state of about 100 miners. Owing to the system of rationing there was no seasonal variation in the dietary content of vitamin A, nor in the choice of diet available. The blood levels of plasma carotene, vitamin A, and alkaline phosphatase, and liver dysfunction, tested by the thymol turbidity method, were determined. The raised threshold for dark adaptation, which is a constant feature of all miners, was not due to a lack of vitamin A or D, nor to any obvious nutritional disturbance. Orwyn H. Ellis.

Crisp, W. H. **Errors in the practice of ocular refraction.** Rev. brasil. oftal. 6:125-131, March, 1948.

After some historical considerations, the following points are emphasized: Hyperopia is usually undercorrected and need not be so. At least five out of six hyperopic patients can learn to use their full correction, with full use of their visual acuity, provided frame-fitting is perfect. The full trial-case measurement of hyperopia is always a slight overcorrection, because of the fact that rays of light forming a point at 4, 5, or 6 meters are divergent when they reach the patient's eye. The accurate myopic measurement at the trial case is a slight undercorrection, for the same reason. Eyestrain is frequently produced by undercorrection of myopia, because the patient resorts to various maneuvers to sharpen his vision. Accurate correction of either hyperopia or myopia is frequently impossible without exact correction of astigmatism and vice versa. Subjective tests for astigmatism are necessary and possess more accuracy and finality than the objective tests. The patient should be given his full visual acuity and not a supposed normal of acuity such as 20/20. Both eyes should be refracted with equal care and accuracy. W. H. Crisp.

Eames, T. H. **Comparison of eye conditions among 1,000 reading failures, 500 ophthalmic patients, and 150 unselected children.** Am. J. Ophth. 31:713-717, June, 1948. (2 tables.)

Feldman, J. B. **Use of the telescopic amblyoscope in visual training for defective vision.** Arch. Ophth. 38:494-505, Oct., 1947.

A telescopic amblyoscope is described which can be used for prognosis and for the training of defective vision in patients with ametropia of various intensities. Forty-seven patients with intractable ametropia were given reading lessons with this instrument once a week for twelve weeks. Prognosis may be determined by having the patient look through the telescopic amblyoscope at a test chart 6 meters away. Vision thus obtained, plus or minus one line, is the final vision to be expected after 12 lessons. The role of suppression in cases of amblyopia is discussed. A table is presented showing the number of patients, the number of lessons given, and the initial and terminal vision of each patient, as well as one that shows the refractive error and weekly progress in each of four cases. John C. Long.

Fillippi Gabardi, E. **Concerning contact lenses.** Rassegna ital. d'ottal. 17:3-10, Jan.-Feb., 1948.

The history of contact lenses begins with Cartesio, who, in 1637, suggested placing in contact with the cornea a tube containing water and having a lens at the distal end. He established the fact that light was no longer refracted by the corneal surface but from the distal end of the tube. The aim was to obtain an enlargement of the image.

In 1827, Herschel attempted to correct the defect in the corneal curvature in keratoconus and irregular astigmatism by the use of a spherical lens with parallel faces. This was placed over the cornea, using the animal gelatine for the medium between lens and cornea. Antedating Herschel was Thomas Young's effort to correct astigmatism by Cartesio's method but he found that it gave insufficient enlargement of the image.

The more modern practice of using contact lenses made of glass dates from 1887 when Fick of Zürich, Kalt of Paris and Müller of Hamburg independently began this work. Constant efforts to improve the technique and material has brought us to the present state where 90 percent of patients can wear contact lenses from 8 to 18 hours daily.

E. M. Blake.

Halldén, Ulf. **Use of polarized light in scotometry with binocular fixation.** Brit. J. Ophth. 32:186-188, March, 1948.

To obviate the universal difficulties of scotometry with monocular fixation of an eye with poor central vision, Halldén used polarized light. The screen is viewed with both eyes through polarized filters with the planes of polarization as right angles to each other. The test object is a spot of light which also shines through a filter which can be rotated to become invisible to either eye while the whole screen and fixation point are clearly visible to both eyes. The test object can be varied in size and color. The author uses a screen of aluminized sheet iron, and small permanent magnets as indicators.

Morris Kaplan.

Herzau, W. **Examination and measurement of discrepancies of ocular correspondence.** Klin. Monatsbl., f. Augenh. 112:267-277, 1947.

Discrepancies of ocular correspondence may exist under natural conditions during asymmetric convergence, under certain artificial optical conditions as in corrected high anisometropia and, finally, under pathologic conditions involving asymmetry of the eyeballs. Determination of the horopter is not quite as exact as haploscopy with the eikenometer of Ames or the Trieder haploscope. Other methods include the metroscope of Tschermak which measures the appearance of equal distances and instruments which compare

double images. The author describes an instrument based on these two last mentioned principles. It consists of a central fixation point which is binocularly seen and of four movable illuminated arrows (two on each side, one above the other) which are seen monocularly by means of polarization. This instrument measures either the apparent equalization of distances or coincidence. (9 figures, references.) Max Hirschfelder.

Hwai-sze Fang, **Amplitude of ocular accommodation in Chinese.** Chinese M. J. 66:32-34, Jan., 1948.

The accommodative power of 1,242 male Chinese subjects between 16 and 35 years of age was tested. It was found that the Chinese possess an amplitude of accommodation higher than that of Japanese but inferior to that of Americans and Germans. Irwin E. Gaynon.

Jaeger, A. **Limits of visual acuity.** Klin. Monatsbl. f. Augenh. 112:244-251, 1947.

After referring to the fact that the visual acuity of the light adapted eye conforms to an angle of 60 arc seconds and that the diameter of the foveal cones corresponds to this finding the author discusses the limits of visual acuity of the dark adapted eye. At the threshold of visual acuity in the dark adapted eye he finds a fluctuation in the visual field and the test objects "come and go" to the observing eye. This fluctuation disturbs the full utilization of the stage of adaptation. It can be avoided if one does not use total darkness for such adaptation but light values which correspond in intensity to the subsequent test objects. More constant values for visual acuity in subdued light are found in this manner. Similarly, a slight diffuse illumination is brought about by the tapetum lucidum of many animals, and this apparently is the purpose of the tapetum lucidum in night vision. (References.) Max Hirschfelder.

Jonkers, G. H. **Objective adaptometry.** Ophthalmologica 114:397-408, Dec., 1947.

Objective adaptometry is based on the elicitation of opticokinetic nystagmus by a pattern of white and black vertical stripes which move horizontally across the examinee's field of vision. The author has developed the method further by determining the most suitable dimensions of the pattern and the most suitable speed of its movement. He records the nystagmus by means of a cathode-ray-oscillograph with the electrodes placed against the skin overlying the temporal orbital rims. In a few trained examinees he obtained remarkably good agreement between subjective and objective tracings of the course of dark adaptation. "How far this method can be applied to clinical research I hope to be able to investigate further. In all probability, it (the method) is unfit for use in cases of unrest of the eyes. . . . The name 'objective adaptometry' may suggest a little too much."

Peter C. Kronfeld.

Krimsky, Emanuel. **Corneal light reflex in diagnosis of retinal correspondence.** Arch. Ophth. 38:468-486, Oct., 1947.

The physiology of retinal correspondence is discussed. The use of the corneal light reflex as an aid to the measurement of squint and in the study of retinal correspondence is described. The position of corneal light reflexes should tell one whether retinal correspondence is normal or abnormal. Any method or apparatus which can produce clearcut corneal light reflexes that can be flexibly displaced is suitable for the study. The technique of testing with the rotary prism, the phorometric stereoscope, the anglometer, the synoptophore and the Maddox rod is discussed. The original article should be consulted for the detailed conclusions derived from the study of retinal correspondence. John C. Long.

Lenoir, M., and Rose, M. **Molded contact glasses.** Arch. d'ophth. 7:604-608, 1947.

The authors review the history of molded contact lenses and describe in detail their technique for making molds of the eye as a preliminary to the fabrication of plastic contact lenses. They have definitely abandoned the use of preparations such as Negocoll, which require heat for melting, and work entirely with a plastic known as Perspex which can be used cold. The technique as outlined is complex and the authors believe it should be treated as a true ocular operation, and conducted with the same care. When properly done the mold will reproduce accurately all visible parts of the globe.

Phillips Thygeson.

Lo Cascio, G., and De Leonibus, F. **Experimental facts concerning intracapsular accommodation.** Boll. d'ocul., 26: 609-629, Oct., 1947.

Emmetropic eyes of young people with more than normal visual acuity and accommodation of about 9 diopters were measured before and during accommodation, and the dioptric values of the crystalline lens, the position of the principal points, both in rest and in accommodation, were calculated. In one eye, the intracapsular accommodation was found to be 28.5 percent of the whole accommodative effort, in the second eye, it was 65 percent. (2 figures, 22 tables, references.)

K. W. Ascher.

Loutfallah, Michel. **The cross cylinder of Jackson.** Ann. d'ocul. 181:136-147, March, 1948.

The history, description, theory and technique of this well-known adjunct to refraction are discussed in detail. The method is used to determine the best combination of sphere and cylinder to verify the strength of the cylindrical component, to localize the cylinder axis and to verify the spherical component.

Chas. A. Bahn.

Macnie, J. P. **Clinical aniseikonia.** Tr. Am. Ophth. Soc. 45:229-240, 1947.

From a clinical and statistical study of cases fitted with iseikonic glasses the author concludes that no symptoms are characteristic of aniseikonia; that the presence of aniseikonia can not be anticipated on the basis of anisometropia or the magnitude of the refractive error; that it is not possible to anticipate whether the correction of aniseikonia will aid the individual and that iseikonic lenses should be used only for the relief of symptoms and then only after the failure of the usual ocular therapeutic measures to give relief.

David O. Harrington.

Miles, P. W. **A comparison of aniseikonic test instruments and prolonged induction of artificial aniseikonia.** Am. J. Ophth. 31:687-696, June, 1948. (5 figures, 9 references.)

Osborne, E. S. **Nature's disturbances and cures in ophthalmology.** J. M. A. Georgia 37:142-144, April, 1948.

Most of the asthenopia caused by illuminants are traced to those of short-wave lengths. Yellow-green wave lengths cause the least eye fatigue. Dark glasses, tinted lenses, dim lights and poor illumination stimulate rod vision but fails to stimulate and activate cone vision.

Irwin E. Gaynon.

Raphael Sebas, S. **Cross cylinder.** Rev. brasil. oftal. 6:173-177, March, 1948.

This brief article emphasizes especially the following points: a normal eye, or one rendered emmetropic by spectacle lens, will have its visual acuity disturbed if a Jackson cross cylinder is placed before it in any position. Self-observation of the effects of the cross cylinder is of great

utility to the oculist because it illustrates what passes through the mind of the patient when subjected to these tests.

W. H. Crisp.

Sharpley, F. W. **The dark adaptation of coal miners suffering from nystagmus.** Brit. J. Opth. 32:199-204, April, 1948.

Dark adaptation tests were made under strictly controlled conditions, not only on miners who were obviously suffering from nystagmus, but on miners who were not and also on completely normal men in other occupations. The final rod threshold value only was measured with a series of short flashes. The continuous increase in the threshold value with age in normal subjects was very evident. It was noted that the threshold value in all miners, with or without evidence of the disease, was substantially higher than in the normal group. Orwyn H. Ellis.

Tower, Paul. **Contact lenses for correction of myopia complicated by lesions of the retina and choroid.** Arch. Ophth. 38: 521-528, Oct., 1947.

Contact lenses were prescribed in 30 cases of myopia with degenerative conditions of the fundus of the eye. The data on 12 cases presenting more pronounced pathologic changes are presented, 4 of which are described in detail. In each case vision was greatly improved as to clarity and detail of objects perceived.

The reasons for the improvement of vision through the use of contact lenses are discussed. The increase in the size of the retinal image is approximately 20 percent in the case of a minus 10.00 lens. The average wearing time for the contact lenses was seven hours. John C. Long.

v. Tschermak-Seysenegg, A. **Binoculars with different image size (aniseiconic binoculars).** Klin. Monatsbl. f. Augenh. 112:277-279, 1947.

A quick change of magnification in a binocular is sometimes desirable to enable an observer of wild life or an airplane spotter to identify certain details. The construction and application of aniseiconic binoculars for comparing moving images in different magnification is described. An auxiliary lens attachment is suggested which changes the magnification in one of the tubes of the binocular sufficiently to create a noticeable size difference in haploscopic vision.

Max Hirschfelder.

Valière-Vialeix. **The stenopaic slit: its clinical applications and technique.** Ann. d'ocul. 180:721-741, Dec., 1947.

Generally speaking, vision is improved by the stenopaic slit in abnormalities due to defective light transmission, but not improved in defects of perceptive origin. Acquired diffuse lesions, such as corneal edema and vitreous opacities, are exceptions to this statement. Regular, refractive errors, irregular ones as in conical cornea, and lens opacities are included in the first group. Visual defects due to inflammatory or degenerative lesions of the uvea, retina or optic nerve form the second group. If the visual defect is essentially optical and focal, a supplementary smaller pupil which facilitates marginal sharpness of more diffuse retinal images will tend to improve vision. The more transparent media are used to the greatest optical advantage. Thus in a patient with a partial senile cortical cataract and the sequellae of uveitis, that part of the visual loss due to the former would probably be improved by the stenopaic slit, but the sight loss due to the uveitis would not be improved. The optical principles involved and the technique of its use are discussed at some length. Chas. A. Bahn.

5

DIAGNOSIS AND THERAPY

Amsler, M. **Qualitative examination of the function of the macula.** Ophthalmologica 114:248-261, Oct.-Nov., 1947.

For the quick qualitative examination of the central portion of the visual field the author recommends a black screen ruled with white ink in squares, which at the distance of 28 cm. subtend an angle of one degree. At this distance the whole screen represents a square measuring 20 degrees in width and height. The center is marked by a white spot. To facilitate central fixation in cases of absolute central scotoma the diagonals are also traced out in white. The subject who looks at the screen monocularly is asked the following six questions: (1) Do you see the white spot in the center of the square? (2) Keeping your eye on the white spot (or on the intersection of the diagonals) do you see the four corners of the big square? Do you see the four sides? Do you see the entire square? (3) Keeping your eye on the white spot, do you see a regular system of small squares? Or do you notice interruptions, spots or blotches disturbing the regular arrangement of squares? Is the latter veiled or blurred in spots? Where are these spots? (4) Keeping your eye on the central white spot, do you see the white lines of the square pattern in their proper relationship, that is parallel or at right angles to each other? (5) Aside from spots or deformities do you see any other irregularities, any movement, vibration or discoloration of any of the lines? (6) Where do you see those spots or deformities? How many little squares are there between the spot and the center of the field?

The method described here is essentially that of survey perimetry ("Uebersichts-perimetrie," of Salzer [Internat. Congress, Amsterdam, 1929 and Klin. Monatsbl. f. Aug. 85:34, 1930]). It is very generally used for quick orientation before the quantitative campimetry.

Peter C. Kronfeld.

Arruga, H. **Formalin sterilization in daily practice.** Arch. Soc. oftal. hispano-am. 8:134-136, Feb., 1948.

Arruga keeps his instrument sterile in metal or glass containers in which he places a tablet of formalin. Bacteriologic studies demonstrated the effectiveness of this method of sterilization. The illustrations show a tonometer, diathermy handles, lacrimal probes, sutures, and syringes in their containers. (9 illustrations.) Ray K. Daily.

Bell, A. E. **A modified erisophake.** Am. J. Ophth. 31:610, May, 1948. (1 figure.)

Bruens, E. **The visible influence of concentrated sulfonamid instillations on the tissues of infants in gonorrheal ophthalmia.** Klin. Monatsbl. f. Augenh. 112:251-255, 1947.

Solutions of 10 to 30 percent Albucid and 10 to 20 percent Cibazol were used in hourly and half hourly intervals. Aside from the therapeutic effect on the gonococci such concentrated solutions are at the same time irritating to the eye. Increased redness of the lid margin, edema of the lids, possible damage to the corneal epithelium and pain are cited as proof. A bluish-red discoloration of the conjunctiva is often found in the healing stage of the disease. This may be due to the removal of the pathogenic organisms or to a toxic vasoconstrictor effect of the sulfonamides. The author now uses 15 percent Albucid and 15 to 20 per cent Cibazol solutions. Max Hirschfelder.

Chamlin, Max. **Recording of visual fields.** Am. J. Ophth. 31:565-573, May, 1948. (7 figures, 11 references.)

Doggart, J. H. **Slit-lamp microscopy.** Brit. J. Ophth. 32:232-246, April, 1948.

The author discussed the history of the development of the slitlamp and corneal microscope. He notes the many advantages of its use, especially the diagnosis of different forms of lens change, and of metal impregnation of certain structures of the eye. The types of pigment changes

and depositions of the cornea and lens are described. The instrument has proved to be of inestimable value, although early ophthalmologists were sceptical as to its worth. Orwyn H. Ellis.

Dufour, R. **Modern methods of localization of intraocular foreign bodies.** Ophthalmologica 114:298-303, Oct.-Nov., 1947.

The author recommends the method of Goldmann and Bangerter which consists of roentgenographic localization of the foreign body with reference to a metal ring attached to the cornea by means of tiny hooks (Ophthalmologica 107:75, 1944). The advantages of this method are that the plane of reference, the ring, cannot slip and that incorrect position of the globe during the taking of the picture can be recognized by distortion of the ring in the X-ray picture. The author has worked out a diagram to make the best possible use of this simple roentgenographic method. Peter C. Kronfeld.

Esteban, Mario. **Fluoroscopy for diagnosis and localization of intraocular foreign bodies.** Arch. Soc. oftal. hispano-am. 7:1038-1090, Nov., 1947.

The author has used fluoroscopy instead of X-ray pictures for diagnosis and localization of intraocular foreign bodies with good results. He uses the Ritter unit used in dental work and describes his technique. He hopes that this procedure can be combined with the magnet for the extraction of foreign bodies imbedded in the posterior segment of the eye.

J. Wesley McKinney.

Huber, A. **The Tyndall phenomenon in the anterior chamber.** Ophthalmologica 114:228-241, Oct.-Nov., 1947.

The author describes a photometric attachment to the slit-lamp of Haag-Streit which permits accurate measurement of the intensity of the light beam in the anterior chamber, and thus permits accurate quantitative studies of inflammatory processes of the anterior segment of the eye. The incident light is divided into a main portion which enters the eye in the usual fashion and produces the Tyndall phenomenon in the anterior chamber. The other portion of incident light is deviated into an optical system that reduces and accurately measures its intensity and a clever optical device permits direct comparison with the Tyndall phenomenon produced by the main portion of the incident light. In the discussion Goldmann describes a similar apparatus. The colloidomeder of Roenne, an attachment to the slitlamp of Zeiss intended for the same purpose (see Kronfeld, Am. J. Ophth. 24, January, 1941), has apparently not stood the test.

Peter C. Kronfeld.

Hylkema, B. S. **An eye speculum with different blades for upper and lower lids.** Brit. J. Ophth. 32:184-186, March, 1948.

Since the two lids are entirely different both anatomically and functionally, it seemed to the author that the specula with two similar blades could be improved considerably. Simple retraction of the lower lid by the ordinary specula is all that is necessary; on the other hand, the upper lid must be pushed back into the orbit and elevated away from the eye against the upper rim of the orbit. In the new speculum, the lower retractor is a blade formed as a simple hook while the upper retractor possesses an arch which is parallel to the surface of the bulb. The two blades are interchangeable on the speculum for the right and left eyes. The use of the wire speculum is deplored.

Morris Kaplan.

Kelly, T. S. B. **A note on intra-vitreous penicillin.** Brit. J. Ophth. 32:153-160, March, 1948.

The cases here treated with intravitre-

ous penicillin were roughly divided into four groups: prophylactic, post-traumatic vitreous infection, postoperative vitreous infection and vitreous infection of unknown origin. Nine cases are described in this series, in six of which an eye was enucleated mostly as a prophylaxis against sympathetic ophthalmia and not as a result of progress of infection. However, since it could be assumed that all nine eyes would have ordinarily been removed, the treatment is considered unquestionably beneficial. Routinely a retrobulbar injection of novocaine and adrenalin is given; then, in the traumatic lesions, through the wound of entry one or two thousand units of pure penicillin in 0.1 or 0.2 cc. of distilled water is injected into the vitreous. Where there is no wound, the drug is injected with a tuberculin syringe about 8 mm. back of the limbus, and the needle is inserted no more than 5 mm. The author feels that chance of benefit makes the injection worthwhile in prophylaxis of all wounds and suggests that is is also useful in longstanding uveitis. He also uses it in doses of 100 to 200 units per cc. as a routine prophylaxis in vitreous transplants. Morris Kaplan.

Knapp, A. A. **The time for eye surgery.** New York Medicine 4:16-19, March 20, 1948.

Surgery may be performed any time from the first few weeks of life to the last. Complicating systemic diseases need not cause the eye surgeon to delay. Cataract surgery should be performed as early as is necessary to give the patient the vision required for his occupation. The two stage operation with preliminary iridectomy is the safer method. Glaucoma surgery should not be delayed after medical treatment has been found to be ineffective. The patient that has glaucoma should be prepared for surgery psychologically early in the course of his disease. The surgery of detached retina and strabismus and traumatic and plastic surgery of the eye are discussed.

H. C. Weinberg.

Knipfer, A. **Late results of Roentgentherapy in hemorrhagic glaucoma.** Boll. d'ocul. 26:644-654, Oct., 1947.

Eyes irradiated for treatment of hemorrhagic glaucoma during the years 1937-1945, were reviewed after an interval of two to ten years. Among 41 patients, 19 could not be studied long enough but they had a tolerable relief of pain when seen last; eleven patients had a good result, two were improved, and in nine, no effect could be ascertained. The action of the X rays is to be understood as a) relief of spasm in the thrombosed vessels, hyperemia and improved circulation, possibly even recanaliculisation; b) reabsorption of the effused blood; c) restriction of the transudation inside the eyeball; d) analgesic action. In successful cases no new hemorrhages occurred, and the retinal vessels showed a certain degree of healing. Failures are ascribed to inadequate technique, mostly overdosage, insufficient duration of treatment, and the nature of the underlying disease such as arteriosclerosis, hypertension, diabetes, or menopausal vascular crisis. Early treatment is necessary; not more than 80 r should be given per session, in highly irritated eyes even only 40 r; three to five applications should be given over a period of two to three weeks, particularly if some vision is left and in more resistant cases, after an interval of two to four weeks, another series of three or four applications is indicated. (More than 50 references.) K. W. Ascher.

Koke, M. P. **A review of common ocular problems in children.** California Med. 68:370-373, May, 1948.

The author presents a comprehensive review of the common ocular problems

in children. Of 2,432 ocular problems 51 percent were refractive errors, 11 percent were muscular abnormalities, and 35 percent were due to external disease. In the list of congenital abnormalities two cases of retrolental fibroplasia were seen and four of toxoplasmosis. The author recommends the dilatation of all infants' pupils during the first office visit.

O. H. Ellis.

Kornerup, Tore. **An investigation, in successively variable monochromatic light of vessels of the human eye in diseased conditions.** Acta ophth. Suppl. 28, 1947, pp. 1-117.

The author examines the vessels of the eye with the use of monochromatic light. The light source is a carbon arc. The light is thrown on a dispersing system, the monochromator, the essential part of which is a constant deviation prism designed by Pellin and Broca. The prism can be rotated to bring different parts of the spectrum before a slit which cuts off all light but a certain wave length which can be read on a scale.

On observing the retinal vessels with a wave length of about 575mμ the vessels are distinctly seen. However, if the prism is slowly rotated to bring the longer wave length of the spectrum before the slit, at a certain wave length the vessels disappear because they assume the same color as the surrounding tissues. This wave length is noted and is called the L value (L for long). If the prism is now rotated back so that rays of shorter wave length are projected upon the slit, there will appear a wave length at which the retinal arteries of medium or finer caliber just become visible, this is the K value (K for short). The arithmetical mean between L and K value is the LK value.

It was found that the veins have a higher LK value than the arteries, thus in a pericorneal injection the arteries can be distinguished from the veins. If the LK value of the pericorneal injection showed a steady decrease, the course of a disease, such as iritis, scleritis, or keratitis was favorable, if, however, the LK value increased, the disease progressed to deterioration. The variations in the LK values are probably associated with variations in the percentage saturation of oxygen in the examined area.

The author also determined the LK value of the normal arteries. The pathologic arteries had a lower LK value and thus the author was able to detect a pathologic change in the arteries earlier than it was possible to recognize with the ophthalmoscope. In diabetes the LK value revealed pathologic changes in the retinal arteries in 60 percent of eyes which on ophthalmoscopic examination appeared normal. The assumption of many authors that the arteries in diabetes are normal is thus contradicted. The retinal hemorrhages seen in some cases of diabetes are in the majority of cases of venous origin.

R. Grunfeld.

Mata López, Pedro. **Penicillin of retarded elimination in ophthalmology.** Arch. Soc. oftal. hispano-am. 7:1111-1120, Nov., 1947.

For the past year the author has been using penicillin in sesame oil and bees' wax. Doses of 50,000 and 100,000 units per cc. were administered daily by injection. By this means he avoids the inconvenience of giving repeated intramuscular injections or frequent local applications of this drug. The therapeutic effects in ocular infections were found to be the same as those of an aqueous solution of penicillin.

J. Wesley McKinney.

Morón Salas, José. **A new gonioscope.** Arch. Soc. oftal. hispano-am. 8:149-159, Feb., 1948.

Morón Salas designed a new gonioscopy lens, which when placed on the eye permits inspection of the entire angle, with-

out the necessity of rotating the lens, as with the Goldman and Allen lenses. The technic for using the lens is described in detail. (16 illustrations.) Ray K. Daily.

Pelayo y Martín del Hierro, M. **Citrin or vitamin P in ophthalmology.** Arch. Soc. oftal. hispano-am. 7:1129-1140, Nov., 1947.

Vitamin P has been found to be effective in the treatment of capillary fragility and permeability. The author has successfully treated postoperative hemorrhage following cataract extractions, dacryocystorhinostomy and plastic surgery of the lids. Citrin is administered by mouth, intramuscularly and intravenously in doses of 7½ grains or more per day with no toxic effects. J. Wesley McKinney.

Streiff, E. B. **Plastic operations.** Ophthalmologica 114:294-298, Oct.-Nov., 1947.

After some general remarks about plastic techniques used in the Eye Department of the University of Lausanne (Switzerland), the author describes two specific operations: (1) a tarsorrhaphy just temporal to the lacrimal puncta for the correction of lagophthalmos and ptosis of the lower lid after facial nerve palsy, and (2) the repair, by means of a sliding skin graft, of a hole in the nasal orbital wall after exenteration for orbital malignancy. Peter C. Kronfeld.

6

OCULAR MOTILITY

Campbell, D. A., Harrison, R., and Vertigen, J. **Binocular vision in miners.** Brit. J. Ophth. 32:226-232, April, 1948.

The binocular vision in full light adaptation and in full dark adaptation of miners with nystagmus was compared with that of a large group of miners of the same age. It was noted that in all men the subjective angle tends to become convergent when they are dark adapted. The majority of miners showed an abnormal fixation in that their eyes tended to look upwards. All miners were found to have a lower percentage of stereoscopic vision than other men, and those with nystagmus only occasionally were found to have stereoscopic vision.

The power of adduction did not vary with illumination. Miners who had good stereoscopic vision had a noticeably greater power of adduction than normal. As would be expected, miners of all types who had poor stereoscopic vision had little power of duction. Orwyn H. Ellis.

Hilgartner, H. L. **Paralysis of superior rectus and inferior oblique from diabetes mellitus.** Am. J. Ophth. 31:608-609, May, 1948. (3 figures.)

Kirby, D. B. **Surgery of strabismus.** Rev. brasil. oftal. 6:135-142, March, 1948.

The necessary surgery may properly be executed at an early age. The operation should be rather such as will require supplemental surgery than one whose excess will have to be corrected later. Various surgical details are reviewed with respect to the more usual as well as the rarer types of case. Use of a routine technique is not advisable, but the process should be adapted to the individual.

W. H. Crisp.

Marín Amat. **A new technic for muscle shortening in strabismus.** Arch. Soc. oftal. hispano-am. 8:143-148, Feb., 1948.

This technique eliminates the use of a muscle clamp, and secures the reattachment of the muscle to its original insertion by looping the muscle. The steps of the

operations are as follows: an elliptical piece of conjunctiva is excised over the muscle, the conjunctiva and Tenon's capsule are undermined, the muscle is stretched on two muscle hooks, pulling in opposite directions and a fixation suture is introduced through the tendon, which is cut in front of the suture. The three reattachment sutures of 00 silk pass through the distal lip of the conjunctiva and the capsule of Tenon, loop the muscle, pierce the episclera at the original insertion, and come out through the proximal lip of the conjunctiva. (6 illustrations.)

Ray K. Daily.

McGillivray, James. **Vertical deviations.** Canad. M. A. J. 56:361-365, April, 1948.

Vertical deviations are classified as those which occur in infancy and usually are paretic in origin and those which occur in children over one year of age. The patients in the first group usually have false projection, amblyopia or suppression. The others usually have a certain degree of fusion, and usually can obtain single binocular vision. The functional anatomy of the vertical muscles is reviewed.

Failure to obtain single binocular vision denotes an incurable vertical deviation but a good cosmetic result with useful vision may be obtained by the use of surgery and orthoptics. The operation of choice often is that performed on the inferior oblique. Early refraction, prompt occlusion, and preventive measures are advised to help prevent false projection or amblyopia from developing. (15 figures.)

Meacham, C. T. **A screen for prism cover test.** Am. J. Ophth. 31:610, May, 1948.

Motto, M. P. **Practical surgical points in strabismus.** Ohio St. M. J. 44:465-468, May, 1948.

Surgery should be performed before the sixth year. If the refractive error is small, operation may be performed earlier. Overacting internal rectus muscles require recession, underacting external rectus muscles require resection but never more than three millimeters. Refraction should be done several months after surgery.

Irwin E. Gaynon.

Rintelen, F. **Disturbance of conjugate gaze.** Ophthalmologica 114:325-331, Oct.-Nov., 1947.

The author describes an unusual disturbance of ocular motility in a bricklayer, 27 years of age, who, one year after a fall from a height of 15 feet, complained of blurred distance vision and diplopia. The immediate effects of the fall had been an extensive scalp wound without bone injury, unconsciousness for a few minutes and a mild retrograde amnesia. Ophthalmologic examination two years after the accident revealed (1) ciliary spasm (amount not stated), (2) spasm of convergence causing a constant non-paralytic esotropia of 20 prism diopters for distance, (3) fixation of both pupils in extreme lateral version, (4) horizontal jerk nystagmus in monocular excursions regardless of their direction, (5) a peculiar disturbance of lateral gaze and convergence, characterized by jerky, "reluctant" performance of the internal rectus muscles and normal, smooth performance of the external. Similar ocular motor disturbances have been observed in cases of postencephalitic Parkinsonism in which the basal ganglia and specifically the globus pallidus and the substantia nigra are involved. By analogy, the author assumes a traumatic lesion of the basal ganglia as the basis of the various motor symptoms exhibited by his patient.

Peter C. Kronfeld.

Sala, C., and Pozzan, A. **The latent asymmetry from galvanic stimulation re-**

vealed by the optokinetic nystagmus. Riv. oto-neuro-oftal. 22:263-271, July-Aug., 1947.

A number of normal individuals were studied to determine whether the optokinetic nystagmus could reveal a latent asymmetry of the vestibular nuclei in galvanic stimulation. After the number of the nystagmust jerks in the horizontal plane was established the latent asymmetry produced in the vestibular nuclei was recognized by noting that the nystagmus jerks were more frequent in one direction than the other. Scobee, R. G., and Green, E. L. Size of line in the Maddox-rod test. Am. J. Ophth. 31:697-699, June, 1948. (1 table.)

Weber, E. Esotropia with diplopia in myopes. Ophthalmologica 114:320-324, Oct.-Nov., 1947.

In 1922 Bielschowsky described a peculiar disturbance of coordination that occurred in myopes and was characterized subjectively by diplopia of gradual onset and present only in distant vision. The objective findings were comitant esophoria and intermittent esotropia at distance only, with normal excursions and without any perceptible paralytic component. The condition which many Americans would describe as divergence insufficiency differs from divergence paralysis in that the onset is gradual, in contradistinction to the sudden development of divergence paralysis.

Two cases of such divergence insufficiency in myopes are described in detail. The treatment consisted of prisms incorporated in the distance correction. The results of the treatment are not stated.

CONJUNCTIVA, CORNEA, SCLERA

Amsler, M. Keratographic observations of corneal transplants. Ann. d'ocul. 180: 746-748, Dec., 1947.

Two series of corneal photographs are presented in which the image of the Placido disc is reflected. In one series the reflection is irregular because the corneal transplant surface is optically perfect whereas in the other the reflecting surface is normal. Unexplained poor vision in some corneal transplants may thus be better understood.

Chas. A. Bahn.

Atkinson, W. S. Delayed mustard gas keratitis (dichlorodiethyl sulfide). A report of two cases. Tr. Am. Ophth. Soc. 45:81-92, 1947.

The signs and symptoms of delayed gas keratitis are reviewed and two cases with illustrative photographs are presented. Recognition of this condition is important in order to establish the service connection of the disability.

David O. Harrington.

Bischler, V. A case of congenital sclerocorneal cyst. Ophthalmologica 114:371-376, Oct.-Nov., 1947.

A congenital small intrascleral cyst in the 9-o'clock position near the limbus with large secondary extension into the stroma of the inferotemporal quadrant of the cornea was treated successfully by aspiration and removal of the anterior wall of the scleral portion. With the disappearance of the corneal extension pocket the cornea cleared and the vision improved to 20/20 with a smaller astigmatic correction than before the operation.

Peter C. Kronfeld.

Bourquin, J. B. Eosinophilia in the conjunctiva and in the blood. Ophthalmologica 114:203-216, Oct.-Nov., 1947.

Scrapings from the normal human con-

junctiva contain no eosinophile leukocytes even in the presence of high degrees of eosinophilia in the patient's blood. The conjunctival eosinophilia is a characteristic sign of allergic conjunctivitis of which the author gives a detailed clinical and histopathologic description. The subjective symptoms (itching and pricking sensations) are out of proportion to the objective findings (slight hyperemia, epithelial and lymphoid hypertrophy, swelling of the preauricular gland). In contra-distinction to vernal catarrh "simple" allergic conjunctivitis is characterized clinically by transparency of the conjunctiva, and histologically by the absence of fibrotic changes in the stroma. Eosinophilia in the conjunctiva, as well as in the blood, is characteristic of both conditions. Antihistaminic drugs are effective in both conditions. No mention is made of any effort to determine the specific offending allergen. Peter C. Kronfeld.

Bowes, C. F. **The use of anti-allergic drugs in the treatment of phlyctenular ophthalmia.** Brit. J. Ophth. 32:163-164, March, 1948.

In 15 children who had phlyctenular disease, a positive Mantoux reaction and positive X-ray evidence of tuberculous infection, benadryl and antistin were used. Benadryl was given as elixir and antistin as tablet. Divided doses, increasing with time, were given and none of the expected side actions of benadryl were noted but some drowsiness was present with the antistin. No appreciable beneficial effects could be found. Morris Kaplan.

Buerki, E. **A new method for the preservation of corneal tissue.** Ophthalmologica 114:288-293, Oct.-Nov., 1947.

Pieces of cadaver cornea are more easily available than whole corneas or eyeballs. The methods which are now in use for the preservation of whole eyeballs (storage in serum, whole blood or in a moist chamber, at 4 to 6 degrees centigrade) are not applicable to the excised cornea, which swells and becomes cloudy under these conditions. The author discovered that the excised cornea remains perfectly clear and retains its normal metabolic characteristics if stored in liquid paraffin at 6 degrees centigrade. Pieces of rabbit cornea stored in liquid paraffin for eight days were used successfully for transplantation and remained clear for a year. The new method has proved successful in one human eye. The oil adherent to the donor cornea is carefully removed by means of filter paper and the graft placed on a gauze sponge moistened with saline until its "bed" has been made ready. Peter C. Kronfeld.

Bursaux, M. **A case of conjunctivitis petrificans.** Ann. d'ocul. 180:749-757, Dec., 1947.

Small pearly concretions were discharged from the conjunctiva of the right eye at about two week intervals in an 11-year-old girl. The eye became red and painful preceding attacks, but between them was almost normal. The number discharged in an attack varied from one to six and the size ranged from that of a pin head to a grain of rice. The concretions were white, dry, friable and irregularly crystalline. Chemically they were found to be calcium phosphate. Somewhat similar concretions were observed in the urine. Otherwise bodily examinations were normal. Conjunctivitis petrificans is believed to be due to a bodily alkalinosis with a tendency to precipitation in predisposed tissues. Because of the increased alkalinity of the tears, the conjunctiva is a frequent location. The concretions apparently become an irritant and the resulting vasomotor reaction aids in their expulsion. Chas. A. Bahn.

Dean Guelbenzu, Manuel. **An operation for pterygium which eliminates recur-**

rence. Arch. Soc. oftal. hispano-am. 8:137-142, Feb., 1948.

The well illustrated technic, which was used without a recurrence in 117 cases, is as follows: the head of the pterygium, including the invaded superficial corneal layers is dissected with a sharp knife, beginning in clear cornea. Two incisions, parallel to the pterygium, are made with scissors in the healthy conjunctiva as far as the internal canthus, the pterygium is excised with scissors by two slightly convergent cuts at the internal canthus, leaving a rhomboidal raw surface, and all episcleral tissue is thoroughly removed from this surface. Two triangular conjunctival flaps are fashioned above and below and brought down to cover the raw area, with the superior triangle adjacent to the limbus and the inferior behind it. The flaps are anchored by one suture to the episclera and the conjunctival wounds closed with two rows of vertical sutures. A small piece of conjunctiva is excised adjacent to the limbus to leave a small area of sclera uncovered. (12 illustrations.) Ray K. Daily.

Franklin, H. C. **Penicillin in drops for prophylaxis against ophthalmia neonatorum: a single instillation method.** South. M. J. 41:320-325, April, 1948.

Almost 1200 infants were studied in the nursery and home during the first two weeks of life, as to the effectiveness of one instillation of penicillin for prophylaxis against ophthalmia neonatorum. It was found that 1.1 percent had pus in the eyes while in the nursery. Twice as many had pus in a previous series wherein penicillin had been given in four doses, and about six times as many have been previously reported after the routine use of silver nitrate.

The crystalline sodium salt was used, 2,500 units per cc. in sterile isotonic sodium chloride. The solution was kept refrigerated constantly, it was never out of the refrigerator for more than five minutes at any time, and was made fresh every five days. The sodium chloride was autoclaved twice weekly. The lids of the infant were wiped with sterile cotton, the eyes were irrigated with sodium chloride solution and then four drops of penicillin were put into each eye. Any pus was carefully noted and cultured. (2 figures, 4 tables, 1 chart, discussion, references.)

Bennett W. Muir.

Franklin, H. C., and Loeb, L. N. **Bacterial flora in eyes of newborn infants during first forty hours of life after single instillation of penicillin and silver nitrate.** J. Pediat. 32:251-256, March, 1948.

The bacterial flora in the eyes of 200 infants was studied during the first 48 hours of life. In 100 a single instillation of penicillin had been used for prophylaxis and in the others a single instillation of silver nitrate. The number of positive cultures was slightly less after penicillin prophylaxis (41 percent) than after silver nitrate (45 percent). That anaerobic organisms are encountered in the conjunctiva only during the first hours of life is to be expected. The oxygen tension in the conjunctival sac produces conditions unsuitable for growth.

This study indicates that a single instillation of penicillin compares favorably with silver nitrate as a prophylactic agent. In this series penicillin was slightly better than silver nitrate in depressing the bacterial flora of the newborn conjunctiva during the first 40 hours of life. Further study is required for interpretation of the observed increase of the bacterial flora with time in the conjunctiva of the newborn infant. Theodore M. Shapira.

Grignolo, A., and Bruna, F. **Importance of penicillin in the treatment of septic corneal ulcers.** Boll. d'ocul. 26:630-643, Oct., 1947.

Forty-eight patients of the Rome Eye

Clinic were treated for pneumococcic corneal ulcer with penicillin in drops, ointments, baths, subconjunctival injections, injections into the anterior chamber, and application as powder, to ascertain the most efficacious way of administration. Eye drops and ointments were sufficient in mild cases only; for more advanced ulcers, penicillin in substance was better, but in some cases, even the most aggressive therapy was helpless. Among 17 slight ulcers, only one did not respond to the treatment; among 15 of medium gravity, three remained uncured, and among 16 severe ulcers, 11 were failures. (5 tables, 27 references.) K. W. Ascher.

Hallermann, W. **The question of the intrauterine origin of the brown saucer-shaped lens opacity in congenital lues.** Klin. Monatsbl. f. Augenh. 112:222-225, 1947.

A woman with old interstitial keratitis and luetic choroiditis exhibited a brown saucer-shaped opacity in the region of the posterior external embryonal lens nucleus. The border of the nucleus was seen as a fine line behind this opacity. The author concludes that this opacity was formed during intrauterine development of the lens and was a direct result of the lues in the mother. Max Hirschfelder.

Hilgartner, H. L., Wilson, R. T., and Wilson, J. D. **Surgical treatment of pterygia followed by X-ray therapy to prevent recurrence.** Am. J. Ophth. 31:667-670, June, 1948. (1 colored plate, 1 figure, references.)

Kant, Alfred. **An unusual case of leptothricosis conjunctivae.** Am. J. Ophth. 31: 607-608, May, 1948.

Larsen, Victor. **Luetic keratitis caused by an operation.** Acta ophth. 25:195-199, 1947.

To clarify the role of trauma in the development of interstitial keratitis, Larson reports a case occurring several days after the extraction of a congenital cataract in a woman, 32 years old. It was then discovered serologically that she had congenital lues. She gave a history of poor vision since childhood. Syphilis had never been suspected before operation. The interstitial keratitis was cured in three to four months, leaving a large corneal opacity, which reduced vision to 3/60; the eye subsequently developed a secondary cataract, and a rise in ocular tension which required the use of miotics. Four years later she came to Larson for an operation on the right eye. He did an intracapsular extraction without an iridectomy and she made an uneventful recovery, with a final visual acuity of 6/12, because of a congenital choroiditis. The interesting features of the case are the occurrence of congenital cataracts in lues, the role of surgery in initiating an interstitial keratitis, and the favorable postoperative course in the second eye. The latter is attributed to antiluetic therapy, and to the avoidance of trauma to the iris. Larsen believes that trauma is a factor in the etiology of interstitial keratitis. When conditions for its development are favorable, trauma acts as a catalyzer in starting the pathologic process. Ray K. Daily.

Meader, G. and Danis, T. **A new form of corneal dystrophy associated with keratoconus.** Ophthalmologica 114:246-248, Oct.-Nov., 1947.

The author describes a system of fine "filiform" opacities in the deepest layer of both corneas of a patient with pronounced keratoconus in one eye and a questionable one in the other.

Peter C. Kronfeld.

Mattos, R. B. **Primary complex of conjunctiva.** Arq. brasil. de oftal. 11:7-9, 1948.

The author describes, in a girl child aged four years, a granulating mass in

the lower palpebral conjunctiva, presenting necrosis and surrounded by cell groups including giant cells and lymphocytes, and to which the diagnosis of productive tuberculuosis was given. The child was placed on treatment with vitamins A and D, in combination with mineral salts, but disappeared from observation too soon for the final result to be recorded. W. H. Crisp.

Moretti, Ezio. **Efficiency of penicillin in herpes zoster; uselessness in interstitial keratitis.** Boll. d'ocul. 26:717-719, Nov., 1947.

Four illustrative case histories are given to confirm the conclusion mentioned in the title. K. W. Ascher.

Nataf, R. **On the etiology of trachoma.** Arch. d'opht. 7:589-598, 1947.

In this report Nataf reviews his own previous studies, made with the collaboration of Cúenod, on the etiology of trachoma and answers the criticisms which have been levelled against a number of his conclusions. He considers first his cytological conceptions which center mainly around the term "plastilles" (described as granular formations occurring in the trachoma follicles), and vigorously defends their specific trachomatous nature. He states that they occur only in trachoma but that he is still unable to conclude as to their nature. Other cytological findings which he considers to be of importance include the Prowazek bodies in the conjunctival epithelium and the epithelioid cells of the follicles which show necrotic changes and contain coccobacillary bodies. He concludes that these bodies are identical with those observed in the inclusions of Halberstaedter and Prowazek. He denies that he and his collaborators ever considered Rickettsia Rocha-Lima as the cause of trachoma but states again his belief that the agent of trachoma might be related or adsorbed on to the Rickettsia. He also denies the conclusion attributed to him by certain authors that the louse was the sole vector and reservoir of trachoma virus but still affirms his belief that the louse could be a possible vector or reservoir of the infection. In support of this hypothesis he reports an experiment in which lice were inoculated with trachomatous material. After three passages in lice, the right conjunctiva of a human volunteer was inoculated with ground louse intestine. A mild follicular conjunctivitis developed and was interpreted by the author as an abortive trachoma. Because of the war he was unable to follow the patient beyond the fourth month.

Nataf concludes that the agent of trachoma is a corpuscular virus intermediate between the ordinary viruses and the rickettsiae and that it appears in such different forms as the elementary and initial bodies of the Prowazek-Halberstaedter inclusion and the rickettsioid bodies. For this agent he proposes the name of Prowazekia trachomatis.

Phillips Thygeson.

Pascheff, C. **New histological proofs of follicular pannus.** Arch. d'opht. 7:599-603, 1947.

Pascheff reaffirms his previous statements that in the pannus of trachoma there form follicles with germinal centers just like those in the trachomatous conjunctiva. To this pannus rich in follicles he gives the name "follicular pannus." When these follicles become hyperplastic, as a result of proliferation or confluence, they give rise to small hyperplastic tumors which might be called folliculomas. On the cornea this condition can be called folliculomatous pannus. Pascheff concludes that true trachomatous pannus is not an exudative inflammation, nor a simple granulomatous inflammatory process, but that it is a follicular hyperplasia of reticulo-endothelial lymphatic tissue.

He recommends for treatment of follicular pannus either the use of skin grafts or removal of the pannus by superficial keratectomy. Phillips Thygeson.

Venco, L., and Rosso, L. **The evolution of corneal grafts in syphilitic parenchymatous keratitis.** Ann. d'ocul. 181:199-212, April, 1948.

The most successful results in keratoplasty are obtained in corneas with opacities due to syphilitic parenchymatous keratitis. This is attributable to the minimal vascularization as compared with that in ulcerative diseases. Subsequent uveitis is three times more frequent, however, in syphilitic eyes than in all others combined, due apparently to a toxic reaction from bodily spirochetes. The basic reaction in syphilitic parenchymatous keratitis is largely of the allergic type and is precipitated by a variable trauma to a cornea which contains inactive spirochetes. A complicating cicatrizing uveitis will produce greater corneal opacification and other uveal sequellae. The primary stage of healing involves a traumatic non-granulomatous type of reaction somewhat similar to the traumatic allergic reaction in syphilitic parenchymatous keratitis. Early and slight vascularization favors a local immunity of the transplant against foreign protein reactions. In the second stage the transplant has survived the initial traumatic reaction and the proteins of the host are no longer toxic to the implant. This is followed by slight vascular invasion which bridges the cornea of the host and that of the implant.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Bamatter, F. **Toxoplasmic chorioretinitis.** Ophthalmologica 114:340-358, Oct.-Nov., 1947.

The paper is based on the clinical and anatomic findings in a premature female infant who during her life of 27 days showed symptoms of encephalomyelitis with hydrocephalus and a large chorioretinal lesion in one eye. This combination of symptoms suggested the diagnosis of toxoplasmosis which was verified by the demonstration (and photomicrography) of the toxoplasma photozoon in the chorioretinal lesions. The baby's twin brother died of severe ulcerative, probably also toxoplasmic, enterocolitis at the age of 30 days. Peter C. Kronfeld.

Cunningham, E. R. **A study of (1) attenuation of the iris root; (2) attachment between the dilatator and ligamentum in the Chinese eye.** Chinese M.J. 66:22-28, Jan., 1948.

The anterior limiting layer of the Chinese iris is very dense and tough. There are few crypts and hollow spaces. The innermost part of the iris in this case was attenuated and consisted only of the posterior layer of pigment epithelium and a delicate strand connecting the dilatator muscle and the pectinate ligament.

Irwin E. Gaynon.

Richardson, Shaler. **Diffuse malignant melanoma of the iris. Report of two cases.** Tr. Am. Ophth. Soc. 45:327-342, 1947.

The salient features of this unusual and rare condition are presented in considerable detail and with good illustrations. Two cases of the diffuse type, primary in the iris are reported.

David O. Harrington.

9

GLAUCOMA AND OCULAR TENSION

Elwyn, Hermann. **Nature of glaucoma.** Arch. Ophth. 38:506-520, Oct., 1947.

According to the author's concept, normal intraocular pressure is maintained in the following manner: There is a unit mechanism consisting of an effector organ

(tissues of the angle of the anterior chamber with Schlemm's canal, the ciliary body and the vessels of the choroid) and a central control from a center in the brain mediated by means of cholinergic nerves of the parasympathetic nervous system. Primitive peripheral regulation is maintained by the activity of the ciliary body and that of the angle of the anterior chamber by means of a constellation of electrolytes. The volume of blood in the choroid is regulated by the vessel walls. The primitive peripheral regulation is not sufficient and is superseded by a central regulation. This central regulation is effected from a center in the brain, probably situated in the brain stem near or in the Edinger-Westphal nucleus.

Glaucoma is a heredoconstitutional functional disease, involving primarily the function of central regulation of the intraocular pressure. When insufficient impulses from the central regulation reach the units of the effector organ, either the constant volume of the blood in the choroidal vessels is increased or the constant volume of the aqueous is increased. The result is glaucoma with a shallow chamber when an increase in the constant volume of blood in the choroidal vessels predominates, or glaucoma with a normal anterior chamber when the increase in the volume of the aqueous predominates. Primary glaucoma is one disease only. Secondary glaucoma is the increase in intraocular pressure which results when the outflow of aqueous or the choroidal blood volume is interfered with by organic changes in the eye.

John C. Long.

Kronfeld, P. C., and McGarry, H. I. **Five year follow-up of glaucomas.** J.A.M.A. 136:957-965, April 10, 1948.

Glaucoma is divided into early, moderately advanced, and far advanced, depending upon the perimetric findings. The authors report 225 cases of wide angle glaucoma and 100 of narrow angle glaucoma. These cases had remained in their respective states for at least five years.

The course of the disease after normalization of tension showed a strong dependence on the stage of the disease when normalization became effective in wide angle glaucoma. Semi-normalization of tension preserved the existing vision in two-thirds of the patients. The late stage of glaucoma showed a tendency to progress in the wide angle glaucomas in spite of normalization of tension. The center of the visual field seems to exhibit a specific resistance to the glaucoma in these eyes.

The narrow angle glaucomas remain stationary after normalization of tension in approximately 90 percent of the cases. These patients usually presented themselves early. (6 figures, 3 tables.)

H. C. Weinberg.

Posner, A., and Schlossman, A. **Mild glaucoma.** Am. J. Ophth. 31:679-686, June, 1948. (11 references.)

Thomassen, Thore Lie. **The venous tension in eyes suffering from simple glaucoma.** Acta Ophth. 25:221-241, 1947.

The author reviews the literature and reports his own investigations of 30 glaucomatous eyes. He made 71 series of measurements of the diurnal variation of the intraocular and the episcleral venous tension. The intraocular tension was measured with a tonometer, and the tension of the episcleral veins taken by a modification of Seidel's method. The tension necessary to compress an episcleral vein was measured with a water manometer; the water from the manometer was conducted into a transparent chamber 8 mm. in diameter and 7 mm. deep of

which one side is covered with a thin, nonelastic, soft cellophane paper, which bulges with pressure. Through the chamber the moment of collapse of the vein could be observed, and the tension read on the manometer. A careful analysis of the plotted data shows that the venous tension in the eye is high in proportion to the ocular tension, when the ocular tension is in an increasing phase, it is medium when the ocular tension remains constant, and low when the ocular tension is in a decreasing phase. The changes in the venous tension are primary. Pilocarpine produces a fall first in the venous tension of the eye, then in the ocular tension. The outstanding result of this study is the demonstration of considerable oscillations that arise spontaneously in the venous tension of the eyes and precedes changes in the ocular tension. (7 curves.)

CRYSTALLINE LENS

Franceschetti, A. **Congenital cataract due to German measles during pregnancy. The digito-ocular phenomenon.** Ophthalmologica 114:332-339, Oct.-Nov., 1947.

The literature is reviewed and two pertinent cases are described. In these two, as well as in other cases of complete congenital cataract, the author has observed the "digito-ocular phenomenon," that is a natural tendency of these children to press against their eyeballs with one or several fingers placed against the closed lids close to either the upper or the lower orbital rim. The author recommends surgery at the earliest possible date, before the nystagmus which occurs several months after birth, becomes firmly established. The idea of therapeutic abortion, which is considered a legitimate form of prophylaxis by some, has met opposition on legal, religious and social grounds. For the time being, one should investigate the following possibilities of prophylaxis: vaccination, premarital voluntary contraction of the disease, isolation of the mother during the first three months of pregnancy.

Peter C. Kronfeld.

RETINA AND VITREOUS

Ayberk, Nuri F. **Two cases of obstruction of the central artery of the retina treated with Heparin.** Göz Kliniği 5:129-135, 1947.

One patient who had received inadequate amounts of the drug because enough was not available was not improved. In the other patient the visual acuity improved for light perception to 5/10 after he had received 600 mgms. of Heparin in six days and no other treatment.

F. H. Haessler.

Bedell, A. J. **Ophthalmoscopy and the hypertensive state.** Mississippi Doctor 25: 347-349, April, 1948.

Patients with hypertensive disease in whom the fundus is devoid of retinal edema and shows only moderate blood vessel changes, are favorable for splanchnicectomy. Those with mild retinopathy as evidenced by cotton wool exudates, hemorrhages and narrow arteries with irregular lumen may be done after a thorough study of the response to rest, cold, drugs and kidney function tests. Those with papilledema, fulminating retinopathy and extensive hemorrhages are least likely to be benefited by surgery.

Irwin E. Gaynon.

Bedell, A. J. **The diagnosis of retinoblastoma.** Tr. Am. Ophth. Soc. 45:282-291, 1947.

Six case histories with description of the ocular signs which led to enucleation in five and in the sixth, to the diagnosis of angiomatosis are presented. Differential diagnosis, the difficulty of early diagnosis, and the implications of birth control in affected families are discussed.

David O. Harrington.

Braveman, B. L., Koransky, D. S., and Kulvin, M. M. **Quinine amaurosis.** Am. J. Ophth. 31:731-733, June, 1948. (1 figure, references.)

McFarland, C. B. **Vascular changes of the eye associated with diabetes mellitus.** J. Indiana St. M.A. 41:487-488, May, 1948.

The earliest change is a non-uniform dilatation and tortuosity of the veins of the retina. Small micro-aneurysms occur in the smallest capillaries of the inner nuclear layer and are usually situated beneath the larger retinal vessels and on or near the small perimacular arterioles.

Irwin E. Gaynon.

Pignalosa, G. **Examination of hypermetropic maculas in red-free illumination.** Boll. d'ocul. 26:672-682, Nov., 1947.

There is no correlation between the degree of hypermetropia and of amblyopia; some eyes with very high hypermetropia may have an excellent visual acuity, and sometimes, in a case of strabismus, the eye with greater hypermetropia may be the leading one and have better acuity than the one with lesser hypermetropia. Among 447 hypermetropic patients examined with the red-free ophthalmoscope of Zeiss, there were 21 patients with abnormal appearence of the yellow spot. In some of them the area of yellow coloration or its intensity was reduced, and in others the macular reflex was modified or missing. All these eyes were more or less amblyopic. The finer structure of the retina in amblyopic eyes is probably altered in all eyes showing a not otherwise explainable diminution of their visual acuity. (4 colored fundus pictures, 1 table, bibliography.)

K. W. Ascher.

Rutherford, C. W. **Hemorrhages of the retina; newer treatment.** J. Indiana St. M.A. 41:494-495, May, 1948.

Retinal hemorrhages occur because of increased capillary fragility and permeability. Fragility is tested by the method of Göthlin and premeability by the method of McMaster. Rutin decreases capillary fragility. The initial dose of rutin is 20 mg. three times daily and may be increased to 400 mg. daily. It is nontoxic and noncumulative. In venous thrombosis, dicumeral has almost replaced heparin. The patient must be hospitalized, frequent prothrombin time taken, and only after the dosage has been calculated to make the prothrombin time 50 percent normal, can the patient be ambulatory.

Irwin E. Gaynon.

Verhoeff, F. H. **Successful diathermy treatment in a case of recurring retinal hemorrhages and retinitis proliferans.** Tr. Am. Ophth. Soc. 45:194-201, 1947.

Observations on a patient are reported in considerable detail in whom vision in the right eye was apparently hopelessly lost from vitreous hemorrhage arising from retinal periphlebitis and in whom retinitis proliferans indicated the same fate for the left eye. No improvement had occurred either with tuberculin therapy or with treatment with diazone, and accordingly surface diathermy was applied to the affected region in the left eye. When the reaction had subsided the foci of periphlebitis had apparently subsided and hemorrhages had disappeared. A series of new retinal hemorrhages in the left eye nine months later was treated with diathermy, again successfully, and vision has remained normal.

The author suggests the use of dia-

thermy treatment as a means of establishing communication between retinal and choridal vessels, thus restoring retinal circulation in all cases of impending blindness from retinal vessel obstruction.

David O. Harrington.

Wagener, H. P., Clay, G. E., and Gipner, J. F. **Classification of retinal lesions in the presence of vascular hypertension.** Tr. Am. Ophth. Soc. 45:57-73, 1947.

This report to the American Ophthalmological Society by the committee on the classification of hypertensive disease of the retina is a comprehensive evaluation of the retinal complications of cardiovascular renal disease with hypertension. In outline form the report deals with the terminology of lesions of retinal vessels, the grading of lesions of retinal arterioles and the terminology of retinopathies associated with vascular hypertension. More detailed consideration is given to lesions of the retinal arterioles, retinal arteries, retinal veins and choroidal arteries and to the retinopathies of acute hypertension, chronic progressive hypertension, terminal malignant hypertension, and the retinopathies of glomerulo nephritis. David O. Harrington.

Weber, E. **The asymptomatic retinal hole.** Ophthalmologica 114:304-311. Oct.-Nov., 1947.

The asymptomatic hole in the retina, that is, a complete hole without retinal separation, is not as rare as is generally assumed. The author describes four cases of this condition. From the excellent fundus drawings it is evident that chorioretinitic tissue alterations surrounded the tears in at least three of the cases. Jess has recommended immediate operation whereas Amsler advocates observation to determine the natural course of the process (stationary or progressive). The author bases his decision upon the following factors: (1) the condition of the other eye, (2) the position of the tear (tears in the upper half call for early operation), (3) stationary or progressive course of the degenerative retinal changes, (4) presence or absence of detachment of the vitreous, (5) the refractive error and (6) the incidence of degenerative eye conditions in other members of the patient's family.

In the discussion Amsler recommends immediate surgical treatment of complete retinal tears without separation if there are no visible signs of spontaneous demarcation or walling-off of the diseased portion. It happens only very exceptionally that a retinal tear without visible demarcation does not lead to a detachment.

Peter C. Kronfeld.

12

OPTIC NERVE AND CHIASM

Bruetch, W. L. **Surgical treatment of syphilitic primary atrophy of the optic nerves (syphilitic optochiasmatic arachnoiditis).** Arch. Ophth. 38:735-754, Dec., 1947.

Recent theories have attributed the cause of primary syphilitic atrophy of the optic nerves to optochiasmatic arachnoiditis, and surgical intervention has been recommended. On the basis of a histologic study of 12 cases of syphilitic primary atrophy of the optic nerves, the propriety of surgical intervention is discussed. In four cases of syphilitic atrophy no arachnoidal adhesions were present at all, and in two others the slight arachnoidal thickening could be considered as still within normal limits. In the others there was definite syphilitic arachnoiditis in the optochiasmatic region. Microscopic examination revealed that the thickened arachnoid passed harmlessly over the optic nerves and chiasm, leaving no signs of pressure. Primary syphilitic optic nerve atrophy is essentially the result of an

inflammatory process in the intracranial portion of the optic nerves and in the chiasm. The inflammation has its origin in a basilar syphilitic meningitis, which in some instances produces an optochiasmatic arachnoiditis and in others leaves the basilar arachnoid grossly unaltered. Surgical removal of the arachnoidal adhesions will be of little, if any, benefit because the inflammatory process within the optic nerves and chiasm remains unaltered by the operative procedure. The most efficacious treatment of primary syphilitic optic atrophy is malarial therapy aided by a course of concomitant and subsequent injections of penicillin, with 5,000,000 units in each course.

John C. Long.

Focosi, M. and Grignolo, A. **Two cases of acute optic neuritis occurring in acute, benign lymphocytic meningitis.** Rassegna ital. d'ottal., 17:11-23, Jan.-Feb., 1948.

The authors report two cases of acute optic neuritis developing during attacks of an acute, benign lymphocytic meningitis, one in a man of 31 years, the other in a woman of 23. After discussion of the clinical aspects and the etiology it was assumed that both developed from the same agent, possibly a virus, which had caused the meningitis. It is suggested that the optic neuritis may, at times, be the only evidence of this infection, or that the other symptoms are so slight as to escape observation.

Finally, a group of five other instances of acute optic neuritis without recognizable extraocular symptoms, is described. These developed in the same period during which the first two were seen.

E. M. Blake.

Hamburg, J. **The treatment of toxic amblyopia by raising the oxydative cell metabolism.** Ophthalmologica 114:358-368, Oct.-Nov., 1947.

The oxygen consumption of the optic nerve in a state of early ascending or descending degeneration after mechanical trauma (in cats) is markedly lower than under normal conditions. In acute or chronic poisoning with quinine or methyl alcohol the oxygen consumption of the retina of cold-blooded animals has been found diminished. On this and similar evidence the author bases his concept that the mechanism of most forms of toxic amblyopia is a specific diminution of the oxydative cell metabolism, caused by the direct action of the toxic substance on nerve tissue. Specific treatment of toxic amblyopia should, therefore, consist of abstinence, the administration of a high-caloric diet with large amounts of vitamin B and an oxydation-raising agent. For the latter purpose the author uses manganese chloride in 0.02 molar solution in daily doses of from 1 to 3 cc. (intramuscularly). Manganese intoxication can be prevented by watching the pulse rate which should not go up more than 10 beats per minute. Several cases of combined alcohol-nicotine amblyopia were first treated with total abstinence plus high-caloric, high-vitamin diet for several weeks. If only minimal improvement in visual acuity occurred the manganese treatment was instituted. In three such cases the visual acuity started to improve "almost suddenly" on the fourth to sixth day of the manganese therapy.

In the discussion F. P. Fischer reports negative results with a similar, cell metabolism-raising treatment by means of intramuscular injections of potassium permanganate (1 cc. of a one-percent solution) in cases of "camp eyes."

Peter C. Kronfeld.

Lin, Chang-yuin, and Tao, Kuo-tai. **Neuromyelitis optica in a Chinese.** Chinese M.J. 66:18-25, Jan., 1948.

A case of neuromyelitis optica in a 25-year-old woman is presented. Within a few days she lost light perception in

both eyes. Three and seven years later the patient developed myelitis in the form of a brown sequard syndrome. There was a complete remission of spinal symptoms between attacks. Irwin E. Gaynon.

Man, H. X. **Diagnostic etiology of a case of unilateral optic atrophy.** Ann. d'ocul. 181:106-110, Feb., 1948.

A 22-year-old man with a primary optic atrophy in the left eye only, had noted gradual failing sight for two years. The right pupil was somewhat larger, but both direct and indirect light reactions were normal in both eyes. The fields were normal, except for a concentric contraction to one-half in the left eye and a bitemporal chromatic contraction in both eyes. Radiographically, the sella appeared abnormally calcified. In addition to failing vision the patient had also noticed increased somnolence and decreased virility during two years. Otherwise he was clinically and serologically normal, except for slight clinical indications of hypothyroidism and sexual hypopituitarism. After cystic drainage and partial removal of an intrasellar craniopharyngioma the bitemporal chromatopsia improved. The differential diagnosis of the mechanism that produces monocular primary optic atrophy with bitemporal chromatopsia is discussed at some length.

Chas. A. Bahn.

Missiroli, Giuseppe. **A new congenital familial syndrome: hypoplasia of the optic nerve and binasal hemianopia.** Boll. d'ocul. 26:683-698, Nov., 1947.

Two daughters and one son showed the syndrome named in the title. In otherwise normal eyes of physically normal individuals, the optic nerves showed an extremely small diameter, about one-fourth of the usual size, sharp outlines, and normal color. There were no other children in this family, and both parents had normal eyes, and there was no consanguinity of the parents. Similar but not identical cases have been previously reported by Schwarz (1915) and Velhagen (1930) (1 colored fundus picture, 2 visual fields, bibliography.) K. W. Ascher.

Verzella, M. **The injection of nicotinic acid "juxta forum opticum" in some forms of optic neuritis.** Rassegna ital. d'ottal., 17:24-77, Jan.-Feb., 1948.

Since 1937, when Goldberg isolated nicotinic acid and its amide from a liver extract, there has been much effort to explain the complex biological action of this substance. Of particular interest to the ophthalmologist is the effect upon the blood vessels, especially the arterioles, capillaries and venules. Here its action has been seen to produce hyperemia, increased velocity of the blood stream, with resulting increased oxidation. Condorelli has suggested that these results are due to stimulation of the cerebrospinal vegetative centers. Intramuscular injection of 60 mmgr. of nicotinic acid produces a dilatation of the retinal veins lasting 45 minutes.

Verzella gives minute directions for the introduction of the hypodermic needle into the orbit so that the solution of nicotinic acid is made close to the optic foramen. Ten injections of 15 mmgr. were given in each orbit. Sixteen patients, with various types of optic nerve disease were treated, eleven with very good results. An elaborate discussion of the action of the nicotinic acid, especially at the site of injection, follows. (18 figures)

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
601 Union Trust Building, Cincinnati 2

News items should reach the editor by the 12th of the month

ANNOUNCEMENTS

ARGENTINA CONGRESS MEETS IN DECEMBER

The 4th National Argentinian Congress of Ophthalmology will convene in Mar del Plata, a beach resort 250 miles south of Buenos Aires, from December 13 to 18, 1948. The congress meets every four years. Prof. Diego M. Arguello is president and any correspondence concerning the meeting should be addressed to him at Casilla Correo 4097, Buenos Aires.

WANTED

The Ophthalmic Publishing Company will pay $1.50 for copies of the January, 1947, and January, 1948, numbers of the *American Journal of Ophthalmology*. Send copies to the Manager of Subscriptions, Ophthalmic Publishing Company, 664 North Michigan Avenue, Chicago 11, Illinois.

CALIFORNIA POSTGRADUATE COURSE

A postgraduate course in ophthalmology will be given by the University of California Medical School, September 6th through 11th. The course, under the direction of Dr. Frederick C. Cordes, will be held at Toland Hall, University of California Hospital, San Francisco.

Officers of instruction include the following:

Dr. Samuel D. Aiken, Dr. Crowell Beard, Dr. George S. Campion, Dr. Frederick C. Cordes, Dr. Joseph W. Crawford, Dr. C. Allen Dickey, Dr. Owen C. Dickson, Dr. David O. Harrington, Dr. Margaret Henry, Dr. Michael J. Hogan, Dr. Warren D. Horner, Dr. Robert N. Shaffer, Dr. Joseph G. Smith, and Dr. Phillips Thygeson.

On Friday evening, September 10th, the third annual Francis I. Proctor Lecture will be delivered by Dr. David G. Cogan, associate professor of ophthalmic research and director of the Howe Laboratory of Ophthalmology, Harvard University Medical School. His subject will be "The Physio-Pathologic Basis for Some of the Signs and Symptoms of Corneal Disease."

The schedule of classes is:

Monday, September 6

8:30-8:40 a.m.—Opening Address—*Dr. Cordes*
8:40-9:30 a.m.—Diagnosis and Treatment of Blepharo-Conjunctivitis—*Dr. Crawford*
9:45-10:45 a.m.—Practical Observations in Refraction, Part I—*Dr. Cordes*
11:00-12:00 noon—Practical Observations in Refraction, Part II—*Dr. Cordes*
1:30-2:30 p.m.—Thyrotropic and Thyrotoxic Exophthalmos—*Dr. Dickson*
2:45-3:45 p.m. Emergency Treatment of Eye Injuries—*Dr. Smith*
4:00-5:00 p.m.—Diagnosis and Pre-Operative Management of Retinal Detachment—*Dr. Dickson*

Tuesday, September 7

8:30-9:30 a.m.—Optic Atrophies in Children and Adults—*Dr. Dickson*
9:45-10:45 a.m.—Etiology and Treatment of Uveitis, Part I—*Dr. Thygeson*
11:00-12:00 noon—Etiology and Treatment of Uveitis, Part II—*Dr. Thygeson*
1:30-2:30 p.m.—Congenital Ocular Anomalies—*Dr. Henry*
2:45-3:45 p.m.—Diagnosis and Management of Lid and Conjunctival Tumors—*Dr. Hogan*
4:00-5:00 p.m.—Preparation, Sterilization, and Care of Ophthalmic Solutions—*Dr. Hogan*

Wednesday, September 8

8:30-9:30 a.m.—The Office Treatment of External Diseases—*Dr. Horner*
9:45-10:45 a.m.—X-ray Localization of Intraocular Foreign Bodies—*Dr. Smith*
11:00-12:00 noon—Routine Testing of Eye Muscles (Demonstration)—*Dr. Dickey*
1:30-2:30 p.m.—Congenital Anomalies of the Eye Muscles—*Dr. Campion*
2:45-3:45 p.m.—Diagnosis and Treatment of Paralytic Squint—*Dr. Dickey*
4:00-5:00 p.m.—Physiology of the Extraocular Muscles—*Dr. Campion*

Thursday, September 9

8:30-9:30 a.m.—Pediatric Ophthalmology—*Dr. Henry*
9:45-10:45 a.m.—Neuro-Ophthalmology, Part I—*Dr. Harrington*
11:00-12:00 noon—Neuro-Ophthalmology, Part II—*Dr. Harrington*
1:30-2:30 p.m.—Medical Ophthalmology, Part I—*Dr. Aiken*
2:45-3:45 p.m.—Medical Ophthalmology, Part II—*Dr. Aiken*
4:00-5:00 p.m.—The Importance of the Pupil in Diagnosis—*Dr. Beard*

Friday, September 10

8:30-9:30 a.m.—Diagnostic and Differential Diagnostic Problems in Early Glaucoma—*Dr. Cordes*
9:45-10:45 a.m.—Glaucoma, Part I—*Dr. Shaffer*
11:00-12:00 noon—Glaucoma, Part II—*Dr. Shaffer*
1:30-2:30 p.m.—Ocular Allergies—*Dr. Crawford*
2:45-3:45 p.m.—Toxoplasmosis—*Dr. Hogan*
4:00-5:00 p.m.—Virus Diseases of the Cornea—*Dr. Thygeson*

Saturday, September 11

8:30 a.m.—Clinical Conference—*Dr. Cogan*

This course is open only to qualified physicians and requests for registration should be addressed to:

Dr. Stacy R. Mettier, Medical Extension, University of California Medical Center, San Francisco 22. The fee for the course is $60.00 payable at the time of enrollment.

Miscellaneous

Luncheon for Journal staff

The editorial staff and collaborators of the Journal were entertained at a luncheon given by the Ophthalmic Publishing Company at the Kungsholm restaurant, Chicago, on June 24th.

Those present were: Dr. Charles A. Bahn, New Orleans; Dr. Alston Callahan, Birmingham; Mrs. Katherine Chalkley, Lake Geneva; Dr. F. M. Crage, Chicago; Dr. Beulah Cushman, Chicago; Dr. Ray K. Daily, Houston; Dr. Orwyn H. Ellis, Los Angeles; Dr. Irwin E. Gaynon, Milwaukee; Dr. and Mrs. F. Herbert Haessler, Milwaukee; Dr. Max Hirschfelder, Centralia, Illinois; Dr. Peter C. Kronfeld, Chicago; Dr. Donald J. Lyle, Cincinnati; Dr. William A. Mann, Chicago; Dr. Lawrence T. Post, Saint Louis; Dr. A. B. Reese, New York; Dr. Ernst Schmerl, Toledo; Dr. Theodore M. Shapira, Chicago; Mrs. Mildred Skinner, Chicago; Dr. Phillips Thygeson, San Jose, California; Dr. Derrick Vail, Chicago; and Dr. Alan C. Woods, Baltimore.

Lions Club scholarships

At a luncheon at the Savoy Plaza Hotel, New York, on June 2nd, the Lions Club of New York presented a check for $2,000 to the New York University College of Medicine to finance four scholarships for graduate training in ophthalmology.

The scholarships were awarded to Dr. Goodwin M. Breinin and Dr. Walter J. Maher of New York, Dr. Edwin H. Kent of Riverside, Connecticut, and Dr. Charles H. Toomey of Lakewood, Ohio. They will study special phases of eye conservation at Bellevue Hospital under the direction of Dr. Daniel B. Kirby, chairman of the ophthalmology department at the College of Medicine.

Honored guests at the luncheon were: Mr. William E. Cotter, guest speaker; Mr. Benet Polikoff, president of the Lions Club; Dr. E. M. Bernecker, commissioner of city hospitals; Mr. E. R. Fryxell, chairman of the Eye Conservation Committee of the Lions Club; Dr. Currier McEwen, dean of the New York University College of Medicine; Dr. Daniel B. Kirby, professor of ophthalmology, New York University College of Medicine; Dr. Townley Paton, technical adviser for the Eye-Bank for Sight Restoration, Inc.; Dr. F. M. Foote, director of the National Society for the Prevention of Blindness; Mrs. Grace Harper, director for the Bureau of Service for the Blind, New York; Dr. Philip S. Platt, executive director, New York Association of Blind.

Societies

Research Association scientific program

The Association for Research in Ophthalmology, Inc., met at Thorne Hall, Northwestern University Medical School, Chicago, on June 21st and 22nd. The program follows:

Monday, June 21

Alston Callahan, M.D.———Aniridia, Ectopic Lenses, and Congenital Glaucoma: Genetic, Pathologic, and Surgical Considerations

Harold F. Falls, M.D.———A Gene Producing Various Defects of the Anterior Segment of the Eye

William T. Kruse, M.D., Harold F. Falls, M.D. ———Three Cases of Marcus-Gunn Phenomenon in Two Generations

Harold G. Scheie, M.D., Jerome Bourne, M.D. ———Electrocoagulation of the Sclera: Reduction in Ocular Volume and Pathological Changes Produced

J. Lloyd Burns, M.D., W. Stanley Hartroft, M.D. ———Intraocular Hemorrhage in Young Rats on a Choline-Deficient Diet

Edward P. Danforth, M.D.———The Fate of Transplanted Ciliary Body Tissue

R. K. MacDonald, M.D.———Changes Observed in the Eyes of Animals Following Prolonged Administration of Testicular Extract

Donald T. Hughson, M.D.———The Use of Alkyldimethyl-benzyl Ammonium Chloride for Maintenance of Sterility in Solutions

Dorland J. Davis, M.D., Margaret Pittman, Ph.D. ———Streptomycin in the Treatment of Experimental Conjunctivitis due to *Hemophilus sp.*

Murray Sanders, M.D., Alson Braley, M.D.——— Aureomycin in Ocular Infections, A Study of Its Spectrum

J. K. Frenkel, M.D.———Uveitis and Toxoplasmin Sensitivity

John C. Locke, M.D.———Experimental Studies with Antibiotics (Bacitracin, Streptomycin, Penicillin) and Antibiotic Mixtures in Intraocular Infections with Penicillin-resistant Staphylococci

Henry A. Imus, Ph.D., Lt. Comdr. (MC) U.S.N.R. ———Industrial Vision Testing Techniques

Tuesday, June 22

Irving H. Leopold, M.D., Joseph Smolens, Ph.D., James H. Parker, Jr., M.D.———Some Physical, Chemical, and Biological Properties of Normal Human Tears

Frank W. Newell, M.D., John A. D. Cooper, M.D., Chester J. Farmer, M.D.———Effect of BAL (2, 3 Dimercaptopropanol) on Intraocular Copper

John E. Harris, Ph.D., Leta Gehrsitz, M.S.——— Movement of Monosaccharides into and out of the Aqueous Humor

V. Everett Kinsey, M.D., Ernst Barany, M.D.——— The Rate of Flow of Aqueous Humor and its Significance for Intraocular Fluid Problems

Jonas S. Friedenwald, M.D.———Proctor Address: Formation of the Aqueous

T. D. Duane, M.D.———The Steady State of Corneal Hydration

W. A. Robbie, Ph.D., P. J. Leinfelder, M.D.——— The Use of Isolated Retinal Tissue in Studies of the Metabolism of the Central Nervous System

Lawrence Ely, M.D.———Respiration of the Crystalline Lens

Paul W. Miles, M.D.———Flicker Fusion Frequency in Amblyopia ex Anopsia
John W. Henderson, M.D., Ph.D.———The Anatomical Basis for Certain Reflex and Automatic Eye Movements
K. W. Ascher, M.D.———The Compression Test of Aqueous Veins of Glaucomatous Eyes

Section on Ophthalmology program

The Section on Ophthalmology, American Medical Association, met at Thorne Hall, Northwestern University, Chicago, on June 23rd, 24th, and 25th, under the chairmanship of Dr. Everett L. Goar, Houston, Texas.

The program included: Chairman's Address, with lantern demonstration, Dr. Everett L. Goar; Address, Dr. John A. MacMillan, Montreal, Canada; "Retrolental Fibroplasia and Persistent Hyperplastic Primary Vitreous: Two Entities," Dr. A. B. Reese, New York; "The Epidemiology of Encephalo-Ophthalmic Dysplasia," Dr. Theodore H. Ingalls, Southborough, Massachusetts; "Treatment of Glaucoma Associated with Iridocyclitis," Dr. Adolph Posner and Dr. Abraham Schlossman, New York; "The Use of Strips of Orbicularis Oculi Muscles in Surgery of the Eyelids," Dr. William B. Clark, New Orleans; "Verified Refraction," Dr. S. Judd Beach, Portland, Maine; "Intraorbital Tumors," Dr. Arnold W. Forrest, New York; "The Use of D.F.P. in Glaucoma," Dr. P. Robb McDonald and Dr. Irving H. Leopold, Philadelphia; "The Blindspot Syndrome," Dr. Kenneth C. Swan, Portland, Oregon; "Nonmedical Problems in Industrial Ophthalmology," Dr. Ralph S. McLaughlin, Charleston, West Virginia; "The Use of Streptomycin and Streptomycin Plus Promizole in Experimental Ocular Tuberculosis," Dr. Alan C. Woods, Baltimore; "A Method of Retrobulbar Anesthesia which Produces an Associated Muscle Block of the Extraocular Muscles," Dr. Harold Gifford, Jr., Omaha, Nebraska; "Basic Principles of Ocular Muscle Surgery," Dr. Watson Gailey, Bloomington, Illinois; "A Further Exceedingly Delicate Test for Astigmatic Axis," Dr. William H. Crisp, Denver, and Dr. George H. Stine, Colorado Springs.

Scientific exhibits at A. M. A. convention

The Section on Ophthalmology exhibits at the A.M.A. convention included: "New Type Movable Implant," by Dr. William Stone, Jr., Massachusetts Eye and Ear Infirmary, Boston, awarded the bronze medal; "Tumors of the Orbit," Dr. Raymond G. Ingalls, Institute of Ophthalmology, Presbyterian Hospital, New York; "Diseases of the Fundus Oculi," Dr. Bertha A. Klien, Department of Ophthalmology, Northwestern University Medical School, Chicago, awarded the gold medal; "Prevention of Ophthalmic Neonatorum: Antibiotics Replace Silver Nitrate," Dr. Louis Lehrfeld, Wills Eye Hospital, Philadelphia; "Treatment of Ocular Infections: Use of Chemotherapeutic Agents," Dr. John G. Bellows and Dr. Chester J. Farmer, Northwestern University Medical School, Chicago, awarded the certificate of merit; "Ocular Toxoplasmosis: Clinical Observations," Dr. Lorand V. Johnson, Western Reserve University School of Medicine, Cleveland; "Observations on the Course of Glaucoma," Dr. Adolph Posner and Dr. Abraham Schlossman, New York.

Better Vision Institute officers

At the annual meeting of the Better Vision Institute the following men were chosen to serve two-year terms ending in June, 1950: manufacturers—Beverly Chew, J. E. Hansen, B. A. Ramaker, G. B. Wells; supply house representatives—T. A. Byrne, Roy Martin, L. W. Myers, C. N. Shelden; optometrists—John F. Hill, John Hughes, W. E. Malinka, J. A. Palmer; ophthalmic dispensers—W. A. Blocker, William Cook, J. A. T. Obrig, A. F. Weber.

At the meeting of the board of directors, officers and members of the executive committee were elected for one-year terms as follows: officers—M. J. Julian, president; E. E. Williams, treasurer; Carl Hallauer, George Nagel, Roy Martin, H. B. Carpenter, and John F. Hill, divisional directors; executive committee—M. J. Julian, chairman; E. E. Williams, Herbert Eisenhart, C. N. Shelden, John F. Hill, and J. A. T. Obrig.

Reading meeting

The 82nd meeting of the Reading Eye, Ear, Nose, and Throat Society was held June 9th. It consisted of surgical and dry eye and ear, nose and throat clinics. The speakers were Dr. F. L. Philip Koch, chief surgeon, Glaucoma Clinic, Manhattan Eye and Ear Hospital, New York, who spoke on "Glaucoma"; Dr. Karl M. Houser, professor of otology, University of Pennsylvania, who spoke on "The Diagnosis and Treatment of Meniere's Disease." There was a study club conducted by Dr. Robert R. Impink, chief of general surgery, St. Joseph's Hospital, on "General Principles of Surgery."

Carolinas meeting

The South Carolina Society of Ophthalmology and Otolaryngology and the North Carolina Eye, Ear, Nose, and Throat Society will hold a joint meeting in Charleston, South Carolina, from September 13th through 16th. Headquarters will be at the Francis Marion Hotel. Invitations will be sent to specialists in Virginia, Tennessee, Georgia, and Florida. The first two days of the meeting will be devoted to ophthalmology; the last two days to otolaryngology.

Personals

Awarded Lucien Howe prize

Dr. Jonas S. Friedenwald of Baltimore, has been awarded the Lucien Howe Prize in Ophthalmology by the University of Buffalo for his basic research work in ophthalmology. The prize is awarded only when, in the opinion of the committee, a man is worthy of such recognition. It has been several years since the last award was made.

PAN-AMERICAN NOTES

Edited by M. URIBE TRONCOSO, M.D.
500 West End Avenue, New York 24

Communications should reach the editor by the 12th of the month

SYMPOSIUM ON OCULAR ONCHOCERCOSIS

The Mexican Ophthalmological Society, with the coöperation of some foreign oculists, held a symposium on onchocercosis on August 5, 1947. Guests were: Dr. Thomas R. Yanes and Dr. Miguel A. Branly of Cuba and Dr. R. Pacheco Luna of Guatemala. The papers read were: "A brief history of the Mexican Society of Ophthalmology and its journal, *Anales de Oftalmologia,*" Dr. R. A. Chavira; "History of onchocercosis, especially in Guatemala," Dr. R. Pacheco Luna; "Parasitology of onchocercosis," Dr. L. Mazotti; "Transmission of the disease," Dr. Luis Vargas; "Synthesis of the studies on the entomology of onchocercosis," Dr. I. Ochoterena; "Cutaneous lesions in the disease and frequency of blindness as a complication," Dr. L. Benitez Soto: "Histopathological examination of the affected eyes," Dr. Bertha Riveroll; "Report of a trip through the zone where the disease is prevalent," Dr. R. Nettel; "The presence of microfilaria in the human eye and the tissue changes which it produces," Dr. A. Torres Estrada; "New statistics on the frequency of onchocerosis," Dr. M. Puig Solanes.

At the conclusion of the meeting several members brought up the idea of founding a Pan-American society of tropical ophthalmology. The idea was discussed and approved, and a committee was formed to organize the society. On the committee are Dr. Pacheco Luna, Dr. Puig Solanes, and Dr. Palomino Dena.

IV PAN-AMERICAN CONGRESS OF OPHTHALMOLOGY

This congress will convene in Mexico City in January, 1952. The ophthalmological societies in Mexico sent representatives to a meeting at which the organization and preliminary work were started. A permanent committee was appointed: President, Dr. A. Torres Estrada; vice-president, Dr. M. Puig Solanes; general secretary, Dr. L. Sanchez Bulnes; treasurer, Dr. F. Palomino Dena; secretary of scientific activities, Dr. Raul A. Chavira; secretary of surgical activities, Dr. Lino Vergara Espino; secretary of organization; Dr. F. Martinez Hinojosa; secretary of propaganda, Dr. Teodulo Agundis; secretary of social activities, Dr. Daniel Silva; secretary of technical exhibits, Dr. M. Rivas Cherif; director of courses, Dr. Abelardo Zertuche. The official address of the committee is: Dr. A. Torres Estrada, Gomez Farias No. 16, Mexico, D.F.

FIRST NATIONAL CONGRESS OF OPHTHALMOLOGY IN MEXICO

This congress will convene from January 9 to 15, 1949. The committee has made the following appointments: Honorary presidents: Dr. Manuel Uribe Troncoso, Dr. Manuel Marquez, Dr. Antonio F. Alonso, Dr. Ricardo Tapia Fernandez, and Dr. Carlos Bauer; president, Dr. Lino Vergara Espino; vice-president, Dr. Raul Arturo Chavira; general secretary, Dr. M. Puig Solanes; treasurer; Dr. F. Palomino Dena; secretary of scientific activities, Dr. A. Torres Estrada; secretary of technical exhibits, Dr. M. Rivas Cherif; director of courses, Dr. Abelardo Zertuche. Addresses are as follows: Dr. Lino Vergara Espino, president, 5 de Mayo No. 40-106, Mexico, D.F., and Dr. M. Puig Solanes, general secretary, Av. Lopez Cotilla No. 811, Mexico, D.F.

PROCEEDINGS OF THE II PAN-AMERICAN CONGRESS OF OPHTHALMOLOGY

The Transactions of the II Pan-American Congress have been published in Montevideo under the editorship of Dr. A. Vazquez Varriere and Dr. R. Rodriguez Barrios. The three well-printed and illustrated volumes contain all the papers and discussions presented to the congress and also a brief history of the foundation and development of the I and II Pan-American meetings.

PERSONALS

Dr. Moacyr Alvaro, of Sao Paulo, Brazil, read a paper on "Pathogenesis of Uveitis" before the Mexican Ophthalmological Society.

Dr. David C. Cogan of Harvard University gave a series of lectures on physiopathology of the cornea in Mexico City, under the auspices of the Mexican Ophthalmological Society.

OPTIC NEUROPATHIES: A SIMPLIFIED CLASSIFICATION AND OUTLINE FOR ETIOLOGIC DIAGNOSIS*

THE ESTELLE DOHENY EYE FOUNDATION LECTURE

ALAN C. WOODS, M.D.
Baltimore, Maryland

The confusion in the etiologic diagnosis of diseases of the optic nerve is due to two factors: first, the complexity of the subject and, second, to the fact that the subject lies in several fields—ophthalmology, neurology, and internal medicine. As a result, there has gradually been developed a welter of terms, some highly descriptive, many others highly confusing, all of which have been used both discriminantly and indiscriminantly by various authors. Many of the classifications proposed are so comprehensive and formidable that the average practitioner, confronted with a case of optic-nerve disease, scarcely knows where to begin his investigation. The diagnostic approach to the problem proposed in this paper has at least the advantage of relative simplicity and works out well in actual practice.

GENERAL CLASSIFICATION OF OPTIC-NERVE DISEASE

Primarily, from the viewpoint of etiology, diseases of the optic nerve may be divided into two general classes:

1. Degenerations of the optic nerve secondary to local ocular disease, circulatory failure, local malformations, local accidents or infections, or hereditary in basis.
2. Diseases of the optic nerve due to central nervous system disease, intracranial anomalies, systemic disease, and various intoxications.

GROUP 1

The first group lies predominantly in the field of the ophthalmologist, and requires little comment. A thorough ophthalmic examination by a competent specialist will almost invariably reveal the true nature and cause of the neuropathy. As a rule, little further investigation is required, although in some cases confirmatory evidence may be sought, and in others certain special examinations may be indicated for the exclusion of remote possible etiologic factors.

In this large group are included: (a) atrophies secondary to glaucoma and retinal degeneration (pigmentary degeneration, and so forth); (b) those associated with congenital retinal and often cerebral degeneration (Tay-Sachs's disease, juvenile cerebroretinal degeneration, familial retinal degeneration); (c) atrophies secondary to circulatory failure—embolus of central retinal artery, sclerosis of the nutrient vessels of the optic nerve (atherosclerosis, arteriolar sclerosis, vascular spasm); (d) atrophies secondary to such bony changes as oxycephaly, abnormalities of the optic foramina, fractures of the orbit; (e) neuropathies secondary to orbital conditions—hemorrhage, infections, tumors, and so forth (Leber's disease).

The one essential common denominator of this entire group is that a careful history, a

* From the Wilmer Ophthalmological Institute of The Johns Hopkins University and Hospital. Delivered at Los Angeles, December 18, 1947.

thorough ophthalmic examination including all visual and motor functions, and local or radiographic examination of the orbit will usually reveal the cause of the optic neuropathy. This group of neuropathies therefore offers no general diagnostic problem.

Group 2

The second group of optic diseases includes those associated with central nervous-system disease, intracranial anomalies, systemic disease, and intoxications of one sort or another. When the ophthalmologist is confronted with cases of this type, it becomes his duty: (1) to exclude etiologic factors belonging to the first group; (2) to analyze and to evaluate all the information obtained by the ophthalmic examination and to classify the disease as far as possible; (3) to direct the consultant services of the neurologist, internist, otolaryngologist, and radiographer along the indicated lines; and (4) in the light of all the assembled information, to arrive at the diagnosis and direct the patient to the proper channels for treatment.

Classification of an optic neuropathy

In the classification of an optic neuropathy, the initial step is to decide whether the neuropathy belongs to the primary or secondary group of optic-nerve disease. This requires a word of explanation. It is of course admitted that, in the etiologic sense, there is no such thing as a primary atrophy. The application of the words primary and secondary neuropathies refers only to the ophthalmoscopic examination. Since all diseases of the optic nerve—inflammations, degenerations, and pressure changes—will, if of sufficient severity and duration, ultimately produce either a primary or a secondary atrophy of the nerve, they may first be considered from this viewpoint. "Primary" neuropathy implies that the optic nerve shows no ophthalmoscopic evidence of present or past inflammation or pressure change. "Secondary" neuropathy implies that the optic nerve shows evidences either of present or past inflammation or pressure changes.

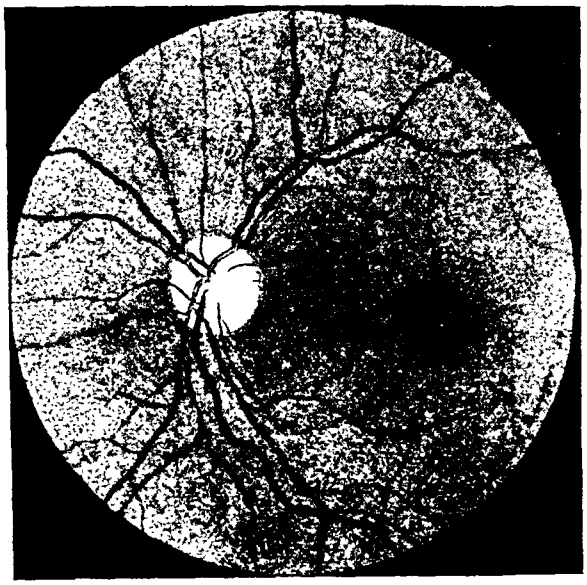

Fig. 1 (Woods). Complete primary optic atrophy.

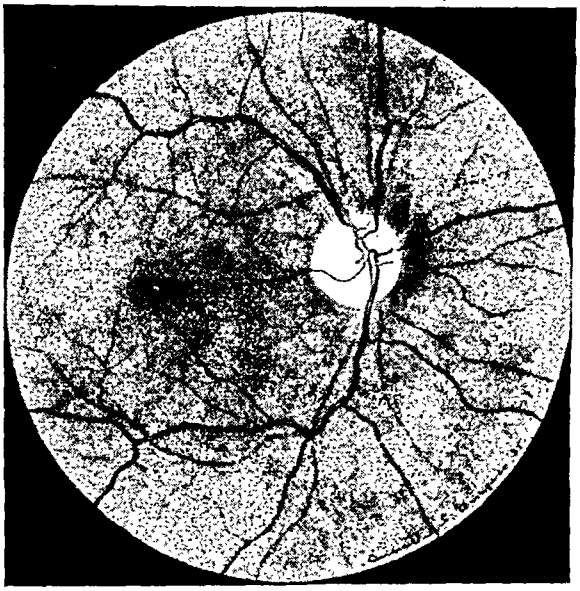

Fig. 2 (Woods). Atrophy of the papillomacular bundle.

Primary neuropathy

A primary optic atrophy may be complete (fig. 1), involving the entire nerve, or may be partial, involving the papillomacular bundle (fig. 2). The abnormality is confined to the optic nerve, the edges are normally outlined, the physiologic cup and lamina cri-

brosa are normal, there is no evidence of edema, congestion, exudation or hemorrhage, or distortion of the neuroretinal outlines. A whitish or bluish-white color, involving either the entire nerve or the temporal sector occupied by the papillomacular bundle, is the one abnormal finding. As the disease progresses, the degree of atrophy increases. Attenuation of the vessels, due to fibrosis in the nerve and up-stream traction, is a late development.

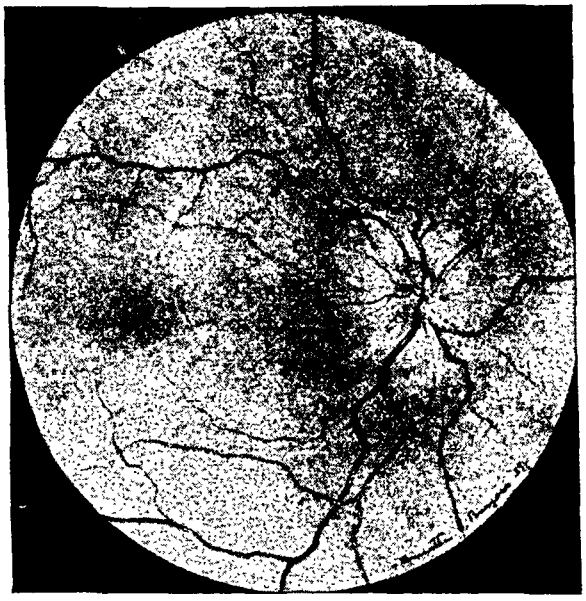

Fig. 3 (Woods). Papilledema.

Secondary neuropathy

The early picture of secondary neuropathy is edema of the nervehead (fig. 3). This may be due either to increased intracranial pressure or to actual inflammation of the nerve. The picture of early pressure changes are edema, actual elevation of the nervehead, blurring of the neuroretinal margins, loss of the physiologic cup from edema, overfilling of the veins, with bending of the vessels at the edge of the edematous papilla (fig. 4).

Hemorrhages and exudates occur later, usually in the peripheral retina, as a result of capillary stasis and local anoxemia (fig. 5). If increased intracranial pressure is established as the cause of the papilledema, the term "choked disc" is used. Actual visible

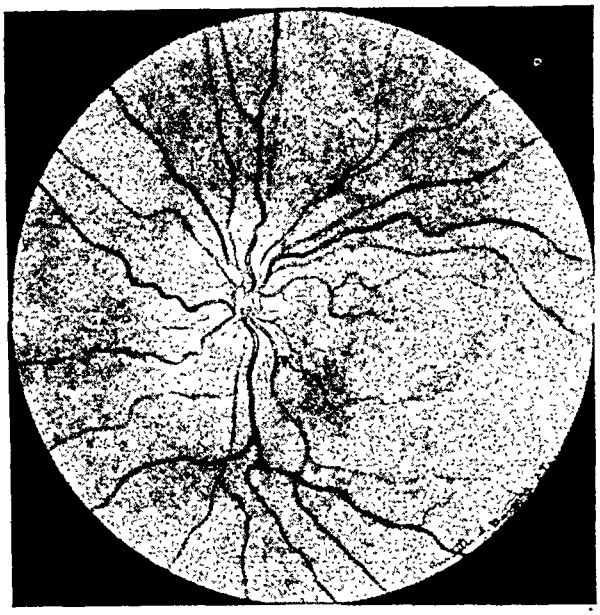

Fig. 4 (Woods). Choked disc—early.

inflammation in the nerve is termed "optic neuritis." In optic neuritis the same edema of the papilla occurs, although often of less degree than in choked disc (fig. 6). There are often other evidences of inflammation, hemorrhages and exudates usually occurring over the nervehead or in the immediately adjacent retina (fig. 7).

The final picture, ophthalmoscopically, is secondary atrophy. The disc is gray, dirty-

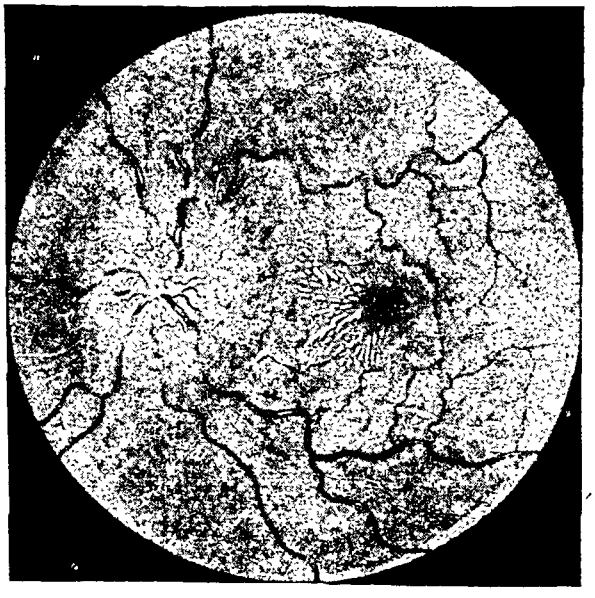

Fig. 5 (Woods). Choked disc—late with beginning secondary atrophy.

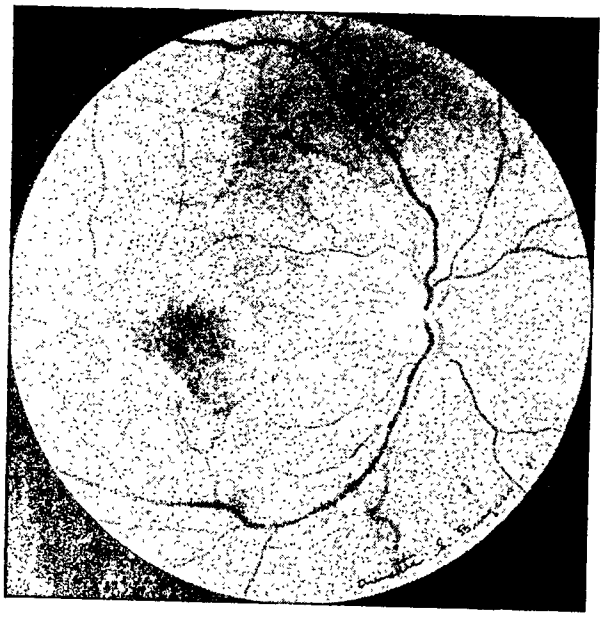

Fig. 6 (Woods). Early optic neuritis.

gray, or reddish-gray in color. The neuroretinal outlines are irregular and slightly distorted with glial tissue. The physiologic cup is lost and the lamina cribrosa is veiled with fibrous or glial tissue which often extends a short distance along the perivascular spaces of the retinal vascular bed as it emerges from the disc and fans out over the retina. This marks the extent of the former pressure or inflammatory changes (fig. 8).

Primary optic atrophy and secondary neuropathies usually arise from distinctly different etiologic factors, although, as will presently be seen, certain conditions may cause either clinical picture, depending on the location of the lesion in the nerve (retrobulbar neuritis and optic neuritis), or on the severity of the intoxication.

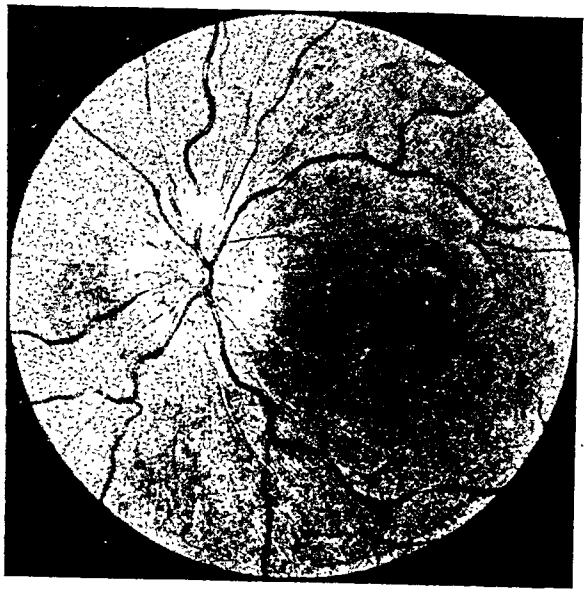

Fig. 7 (Woods). Advanced optic neuritis.

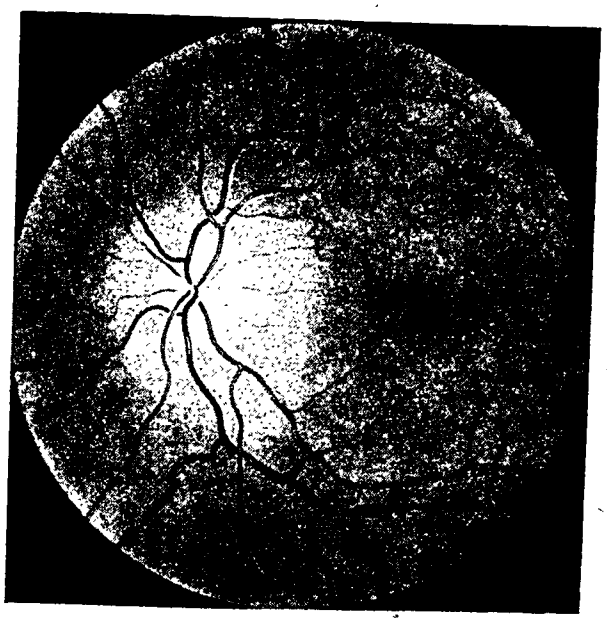

Fig. 8 (Woods). Secondary optic atrophy.

I. Primary Optic Neuropathies

Primary optic atrophy may be total, including the entire nerve in the atrophic process, or partial, including either the peripheral fibers, the papillomacular bundle, or a nerve fiber bundle. The degree of involvement depends in the main on the extent and severity of the underlying lesion, although certain etiologic factors tend to produce total nerve involvement, and other more localized lesions affect especially the papillomacular bundle. The ophthalmologist determines the degree of the nerve involvement by the appearance of the disc, the determination of the visual acuity, and by the visual field changes.

The more important causes producing primary atrophy of the optic nerve may be listed as follows:

1. Central nervous system syphilis: tabes, taboparesis
2. Breaks in the line of conduction: tumors, aneurysms, hemorrhages, trauma

3. Retrobulbar neuritis:
   a. Inflammation in the nerve posterior to the papilla
   b. Demyelinizing disease
   c. Toxic amblyopias

Central nervous system syphilis and large tumors tend ultimately to affect the entire nerve, although in early stages only the peripheral fibers or the papillomacular bundle may be involved. Small tumors and aneurysms often involve a portion of the nerve, the papillomacular bundle, or peripheral sectors. Retrobulbar neuritis usually affects only the papillomacular bundle, although if the local inflammation or the area of demyelinization is large, the entire nerve may be involved. The greater number of the toxins with a selective action of the optic nerve involve the papillomacular bundle only, the pentavalent arsenicals only affecting the peripheral fibers primarily. In massive intoxications the entire nerve may be affected by either group.

Ophthalmic examination does not, as a rule, give sufficient information to differentiate between primary atrophies due to syphilis and those due to breaks in the line of conduction. In general, if the degree of visual failure is slight and the ophthalmoscopic picture of atrophy marked, syphilitic atrophy of the nerve without involvement of the papillomacular bundle is at once suspected. Conversely, if the failure of vision is marked and the picture of atrophy slight, breaks in the line of conduction are suspected. The picture of sharp visual failure, central scotoma, and a normal optic nerve is of course diagnostic of retrobulbar neuritis.

1. Central nervous system syphilis

The primary optic atrophy of syphilis has certain peculiarities. Primarily, in the overwhelming majority of cases, it is associated with a single form of the disease, tabes or taboparesis. It rarely, if ever, occurs in pure paresis. The peculiarities which differentiate it from other forms of syphilis are:

a. Long incubation period
b. The extraordinary selectivity for certain parts of the brain and spinal cord
c. The relative refactoriness to treatment
d. The low reagin content of the blood serum and spinal fluid—the tendency to negative serology
e. The relative paucity or absence of T. pallida in the lesions

The pathogenesis of the primary atrophy of syphilis has long been a problem both to syphilologists and ophthalmologists. Various theories have been proposed. These fall in three general groups.

The first set assumes that the atrophy is due to some form of circulatory failure of the nutrient vessels of the nerve, assumed by some to be related to a disturbance between the retinal and systemic blood pressure. Suffice to say there is no scintilla of evidence in favor of such theories, and there is a wealth of established evidence against them.

The second group of theories attributes the atrophy to adhesions around the chiasm involving the optic nerves—the so-called adhesive chiasmoarachnoiditis. While this condition does occasionally exist, as testified by reputable and trustworthy neurosurgeons, nevertheless it is rarely found in central nervous-system syphilis and when present usually produces a picture midway between primary and secondary atrophy. There is no evidence that it is the cause of the optic atrophy of tabes.

The third group of theories is based on certain experimental evidence and attributes the atrophy to a combination of central nervous-system syphilis and vitamin deficiency, involving both vitamin A and the B-complex. This evidence, which has been fully presented elsewhere, is highly intriguing, fits most of the known facts, and may ultimately be proved to be either the underlying cause or closely related to it. About all we can say at present is that the riddle of syphilitic primary optic atrophy is probably the riddle of tabes itself.

There is much misconception about the

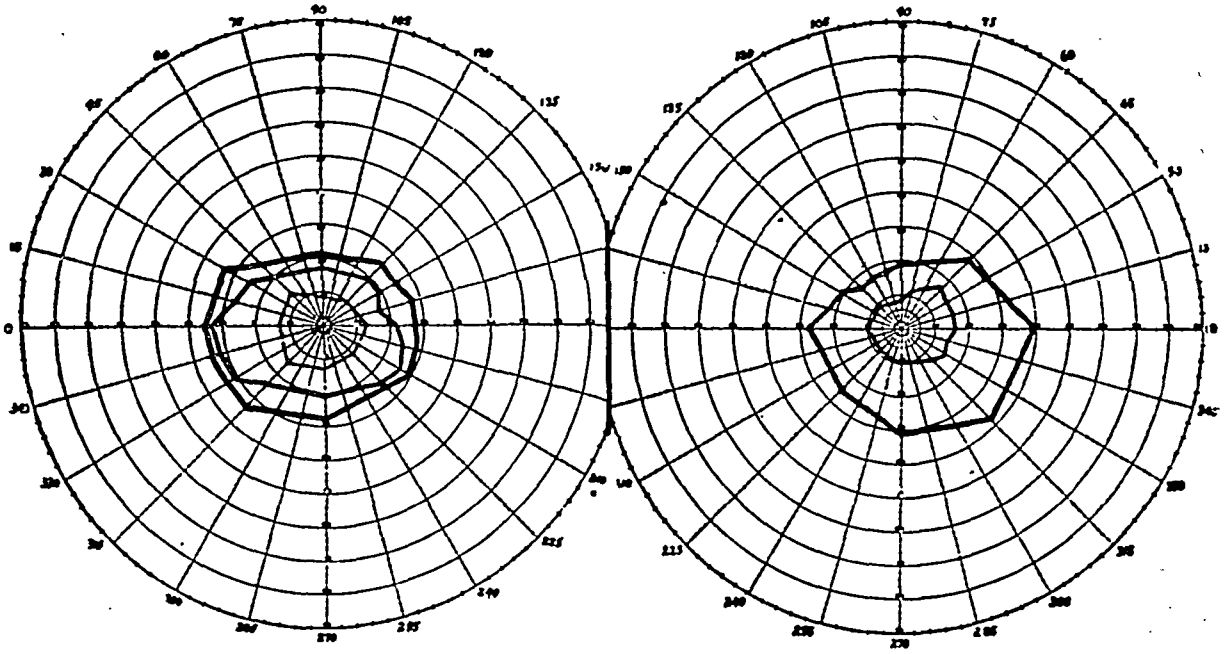

Fig. 9 (Woods). Concentric contraction of visual fields in syphilitic primary optic atrophy.

involvement of the optic nerve in tabes and the resultant visual-field changes. It was formerly supposed that the peripheral fibers were as a rule first involved, and the papillomacular bundle much later, Uthof reporting central scotomas in only two percent of the cases.

This question has been recently investigated and it was found that the visual fields in this group of patients fell into four general classes. These are:

1. Concentric constriction of the field, late loss of vision, occurring in 12.5 percent of the cases (fig. 9).

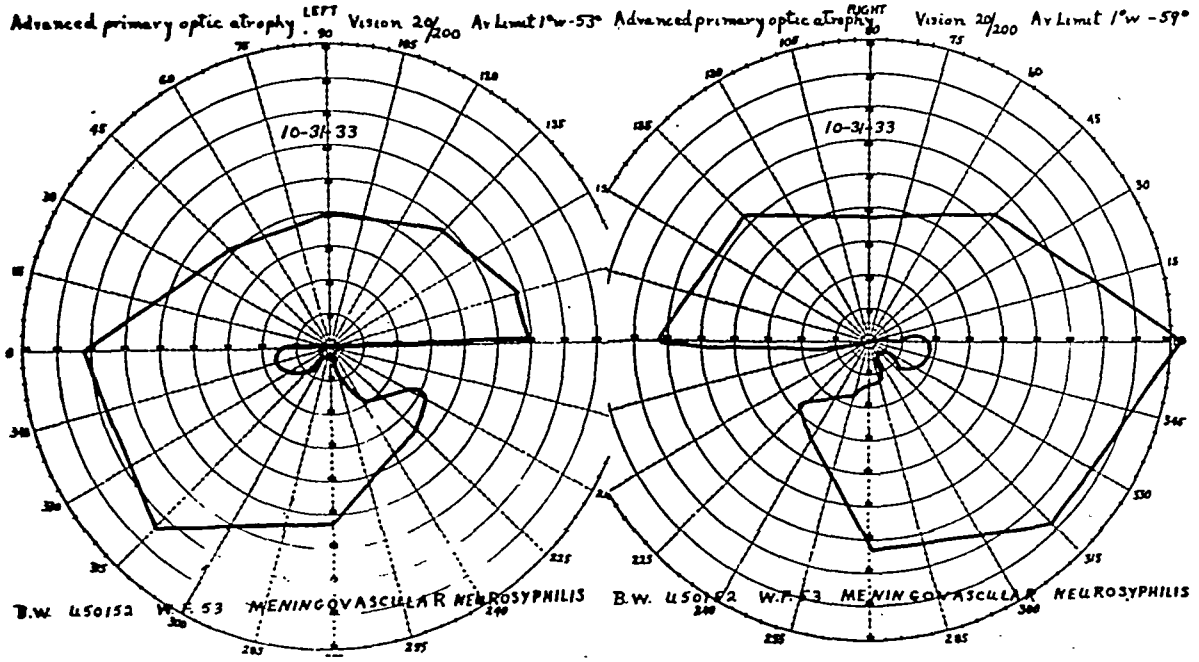

Fig. 10 (Woods). Sector defects in syphilitic primary optic atrophy.

2. Sectorlike defects, due to nerve-bundle involvement. The loss of vision in these cases might be early or late, depending on the involvement of the papillomacular bundle. This type of field occurred in 34 percent of the cases (fig. 10).
3. Central, or cecocentral, scotomas, with normal peripheral fields and early loss of vision. This was present in 14 percent of the cases (fig. 11).
4. Central or cecocentral scotomas, associated with changes in the peripheral fields, and early failure of vision, occurring in 40 percent of the cases (fig. 12). Thus, in the series as a whole, 54 percent of the patients had central or cecocentral scotomas with early failure of vision.

Course. The course of syphilitic primary atrophy has been the subject of several studies. Whether the visual failure be early or late, the course is the same. Untreated cases progress to total blindness in from 7 to 9 years, with atrophy of the entire nerve and loss of all light perception (fig. 13).

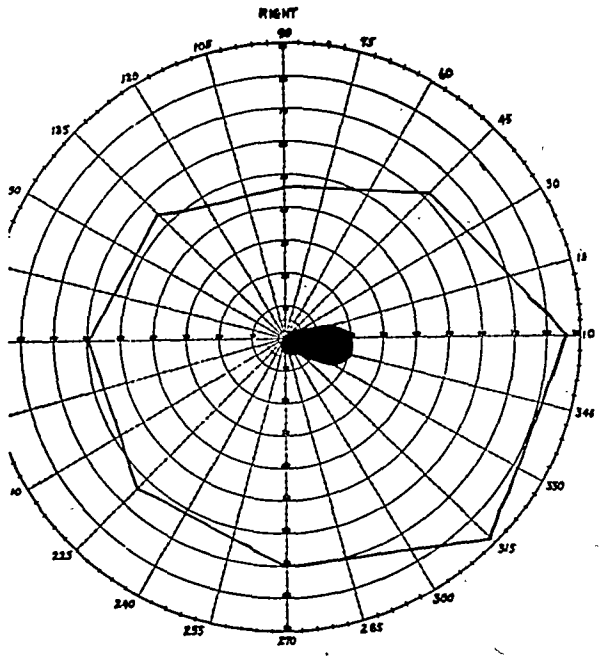

Fig. 11 (Woods). Central and cecocentral scotomas in syphilitic primary optic atrophy.

Treatment. It is traditional that the treatment of syphilitic primary optic atrophy has always been regarded with extreme pessimism by both syphilologists and ophthalmologists. This pessimism is, however, unjustified.

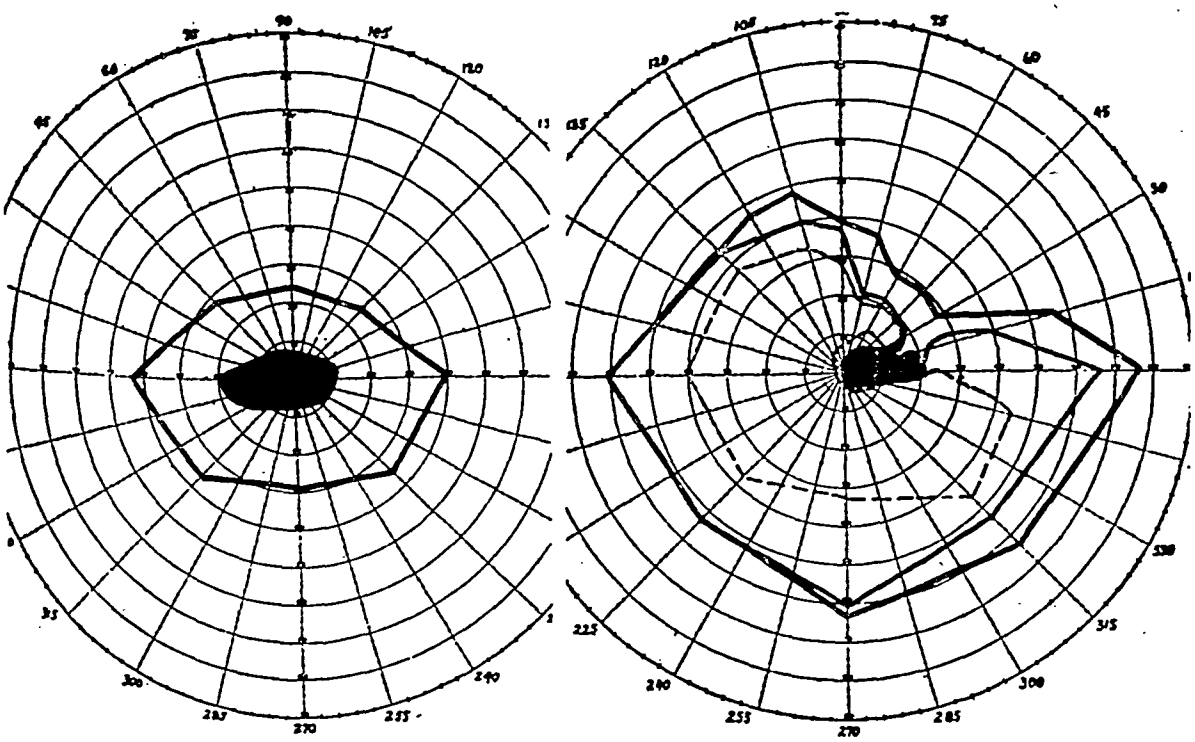

Fig. 12 (Woods). Central scotomas with peripheral field changes in syphilitic primary optic atrophy.

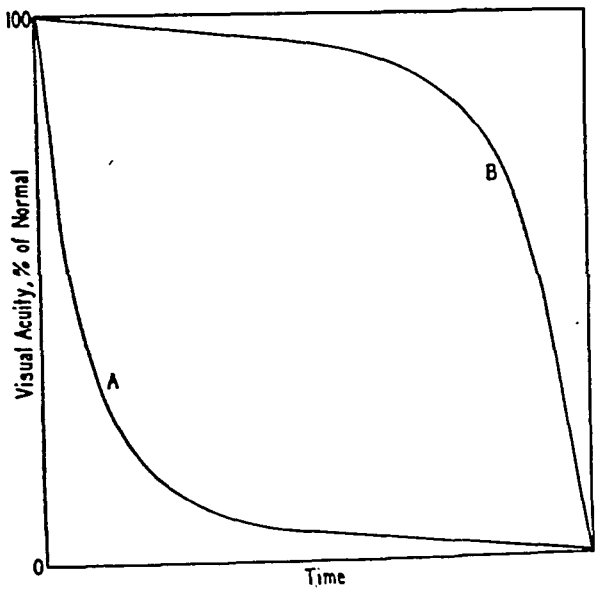

Fig. 13 (Woods). Course of syphilitic primary optic atrophy. Hypothetical curves showing rate of loss of central visual acuity in (A) patients with central and cecocentral scotomas and (B) patients with peripheral constriction of the visual fields only.

No one yet knows what will be the effect of the early treatment of syphilis by penicillin on the later development of primary optic atrophy and tabes. There is some evidence that penicillin is of value in arresting primary optic atrophy, although the results are not uniform. Klauder concludes that since "penicillin does not uniformly benefit the optic atrophy of all patients, the wisdom of its exclusive use in treating the disease is questionable."

The effect of malaria treatment is known. Our earlier experiences with this have already been reported, and our later experiences confirm our first impressions. With this form of treatment only 14 percent of the patients treated lost their vision in the first two years. Thereafter the curve flattened out and 86 percent of the patients retained their remaining vision, of whatever degree it might be (fig. 14).

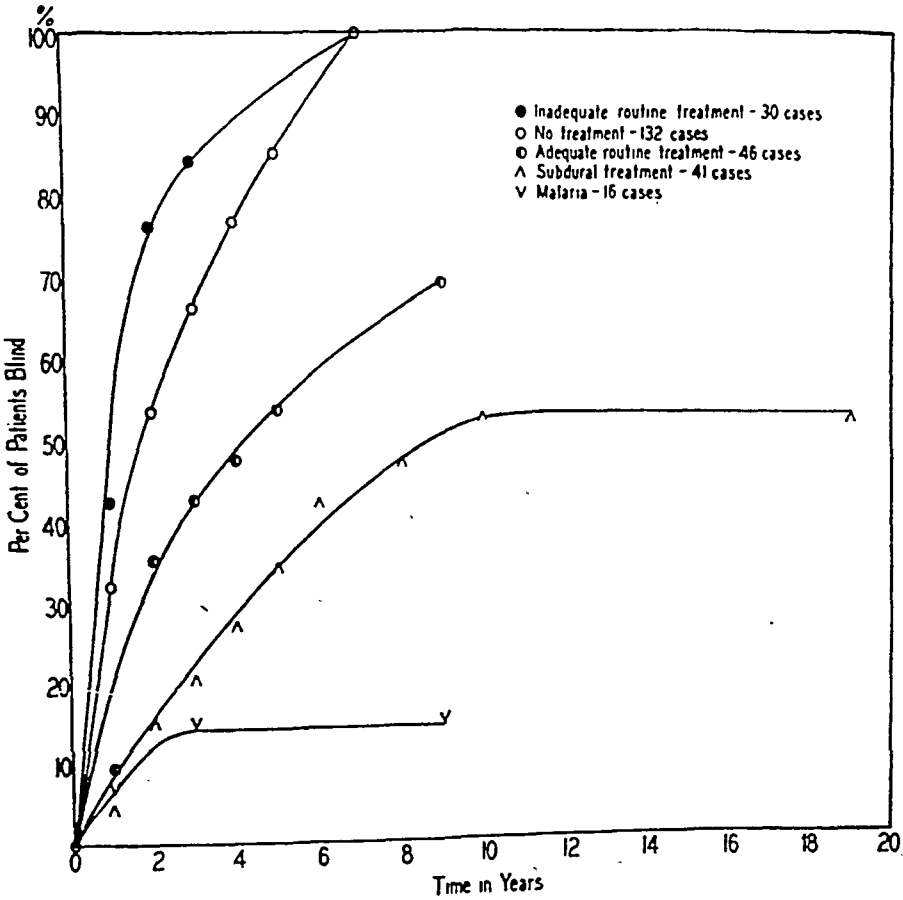

Fig. 14 (Woods). Results of treatment of syphilitic primary optic atrophy.

In his recent book on *Penicillin in Syphilis,* Moore recommends the combination of penicillin and malaria treatment, believing that this form of treatment, capable of completion in about five weeks, may give as satisfactory lasting results as malaria alone followed by prolonged chemotherapy.

2. BREAKS IN THE LINE OF CONDUCTION

By atrophies due to breaks in the line of conduction is implied mechanical pressure on the optic nerves either anterior to the chiasm or in the neighborhood of the chiasm, which produce either total or partial primary atrophy of the optic nerves. The most frequent conditions in this category are:

a. Prechiasmal tumors
b. Pituitary tumors
c. Suprasellar tumors (chiasmal syndrome—Cushing's syndrome)
d. Sclerosis of vessels impinging on the chiasm

Prechiasmal tumors. Nothing can be more difficult than the preoperative diagnosis of these tumors. The optic atrophy is usually unequal and of slow development; the visual-field changes are bizarre and unpredictable. Prechiasmal tumors should be suspected only when no other cause for the atrophy can be found and when the field changes are unequal and bizarre. The actual diagnosis can only be made by exploratory craniotomy by the transfrontal route and direct examination of the optic nerves. The usual prechiasmal tumors are meningiomas, dural endotheliomas, and olfactory-groove tumors. They frequently undergo psammoma body changes.

Pituitary tumors. The classic picture of pituitary tumors is destruction of the bony walls of the sella, bilateral primary optic atrophy, bitemporal hemianopia, and radiographic changes in the sella. The older literature occasionally states that the primary optic atrophy secondary to pituitary tumors has a faint yellowish tinge. This is probably incorrect. In appearance the atrophy from pituitary tumors is indistinguishable from

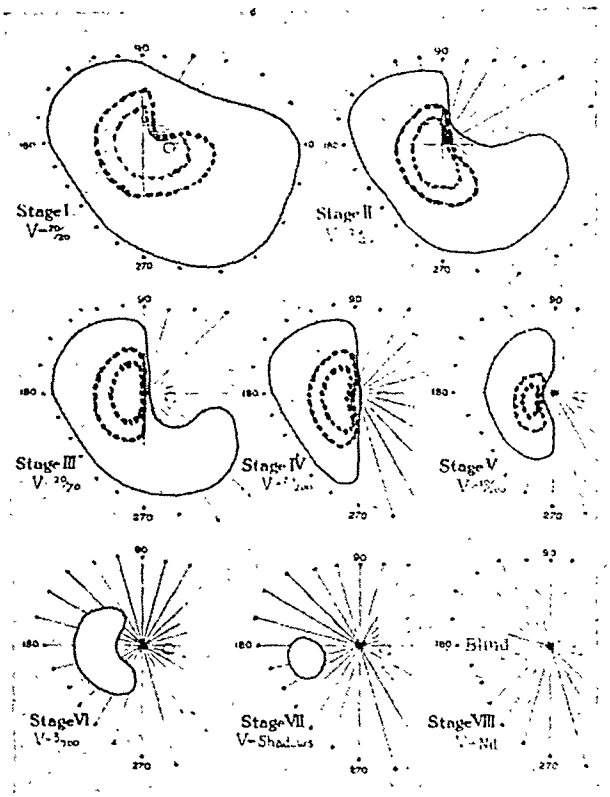

Fig. 15 (Woods). Visual fields in pituitary tumors. (From Cushing and Walker.)

other forms of primary optic atrophy. It should be emphasized that pituitary tumors rarely if ever cause choked disc or papilledema. Hypothetically, this could only occur if the tumor is so placed and of such size that it blocks off the entire intravaginal space.

Despite the volumes which have been written on pituitary tumors, practically nothing has been added to the visual-field studies since the classic paper of Cushing and Walker. These authors divided the perimetric changes into eight grades, from the upper bitemporal slant to total blindness (fig. 15). They emphasized the early loss of the upper temporal color fields, the development of a complete bitemporal hemianopia with involvement of the papillomacular bundle, the gradual limitation of the white fields to the lower nasal quadrants, and the ultimate blindness if the pressure on the nerves was not relieved. Up to and including Stage 4, the condition was reversible, and improvement in the fields and vision might be ex-

pected to follow successful operation.

One additional point should be stressed. In a small percentage of cases, the chiasm is prefixed; that is, instead of lying above and slightly posterior to the sella, the chiasm lies somewhat anteriorly. In such cases an enlarging pituitary might not press on the lower nasal aspects of the optic nerves or on the anterior chiasm but on the posterior portion of the chiasm. Here it might first impinge on the crossed macular fibers and so produce a central scotoma as the cardinal symptom, mimicking the picture of a suprasellar tumor. These cases are rare, but they do occur.

The suprasellar meningiomas tend to press on the lower posterior surface of the chiasm, where the crossed nasal fibers lie, thus producing a bitemporal hemianopia.

Adenomas of the pituitary stalk and Rathke's pouch tumors usually press on the posterior lip of the chiasm where they impinge on the crossed macular fibers and so cause a central scotoma. Since there is some intermingling of the lower nasal fibers in the posterior chiasm, they may also produce more or less associated bitemporal hemianopia. Since they all lie centrally, they do not involve any of the nerves going to the extraocular muscles.

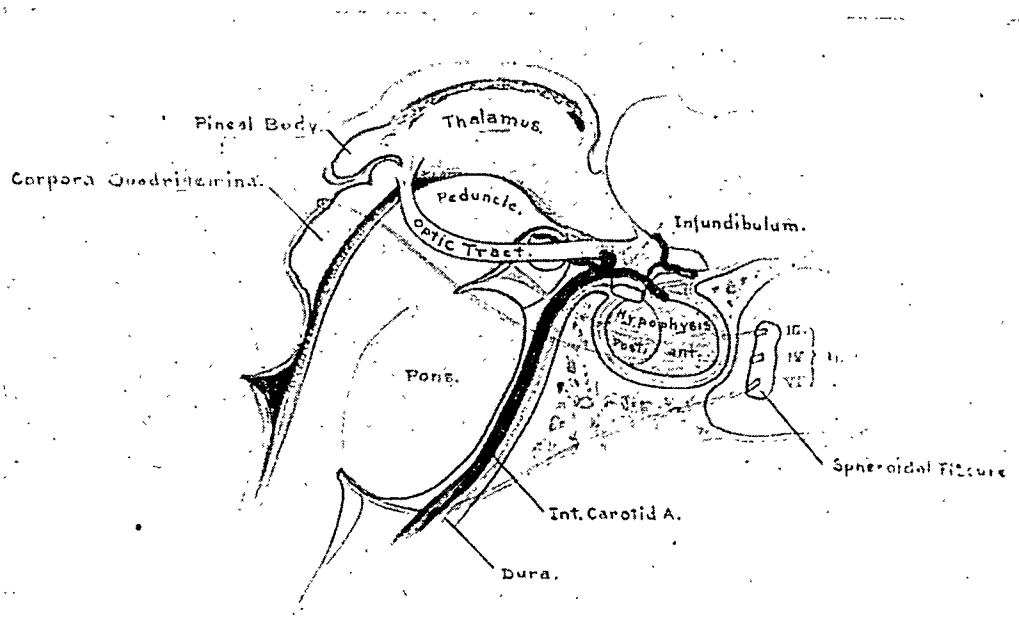

Fig. 16 (Woods). Diagram of relations at chiasm.

Chiasmal syndrome. The chiasmal syndrome is primary atrophy of the optic nerves, or the picture of retrobulbar neuritis, with bitemporal hemianopia or central scotoma and no radiographic evidence of destruction of the sella.

The most frequent tumors causing this syndrome are suprasellar meningiomas, adenomas of the pituitary stalk, craniopharyngiomas (Rathke's pouch tumors), and aneurysms of the anterior portion of the circle of Willis.

Aneurysms of the circle of Willis produce visual-field changes according to their location. The most frequent picture is a central scotoma due to pressure in the papillomacular bundle fibers. Since they lie laterally, they often involve the third cranial nerve.

The actual diagnosis of these tumors is made on the presence of the chiasmal syndrome and exploratory craniotomy. Unfortunately, X-ray examination and ventriculography are of little or no assistance, although at times in the Rathke's pouch tumors the

areas of calcified and keratinized epithelium cast definite shadows in the roentgenograms.

Sclerosis of the vessels, especially the carotids, impinging on the chiasm may produce a primary optic atrophy simulating the so-called "soft glaucoma," with visual-field changes affecting primarily the nasal fields. In his 1916 Bowman lecture, de Schweinitz called attention to the various vascular anomalies which might occur around the circle of Willis, and pointed out how sclerotic vessels might impinge either on the chiasm, the tracts, or the optic nerves and produce bizarre and unusual field changes.

While such changes, binasal hemianopias and bizarre field changes associated with primary optic atrophy, are somewhat rare, in all such cases where no other obvious explanation is present, sclerotic changes in the carotids of the circle of Willis should be considered.

Especially suggestive of pressure changes from sclerosis or aneurysms of the circle of Willis are the altitudinal or unilateral quadratic hemianopias. This is readily understood when one recalls Walker's description of the position of the vessels in relation to the optic neuropathways; the anterior cerebrals passing "over the toes" of the optic nerves, while the posterior communicating pass "under the heels" of the tracts (fig. 16).

The pressure changes from anterior cerebral vessels would produce inferior or altitudinal hemianopia, which might be unilateral if only one nerve is affected. Pressure from the posterior communicating would produce a superior hemianopia, and if only on one side, a quadratic superior defect.

3. Retrobulbar neuritis

Retrobulbar neuritis implies a pathologic process in the optic nerve so far posterior to the papilla that not until a descending atrophy becomes evident at the nervehead is any ophthalmoscopic change evident. Thus in the early stage, Parsons' definition "that neither the patient or the doctor sees anything" is singularly apt.

In general, all the various conditions which cause inflammatory changes at the papilla may likewise cause a retrobulbar neuritis—the essential question is whether the lesion in the nerve is anterior to the lamina so the inflammatory changes are visible, or so well posterior to it that there is no ophthalmoscopic change. However, there are certain conditions which usually produce the clinical picture of retrobulbar neuritis, and others which usually produce the picture of optic neuritis, with visible swelling and inflammation at the nervehead.

The clinical picture of retrobulbar neuritis is as follows:

a. Failure of vision
   1. Acute—sudden loss of central vision
   2. Gradual loss of central vision with fluctuations
b. Ophthalmoscopic picture
   1. Early stages—clear media and normal fundus
   2. Late stages—clear media, atrophy of temporal sector of disc
c. Visual fields
   1. Normal outlines for white and color
   2. Central scotoma varying from relative to absolute white

The more frequent causes of retrobulbar neuritis may be grouped as follows:

1. Intracranial lesions—suprasellar tumors, and so forth
2. Direct involvement of nerve from infections of posterior ethmoids and sphenoids
3. Demyelinizing disease—usually multiple sclerosis
4. Endogenous toxins—diabetes (avitaminosis) and alcohol-tobacco amblyopia
5. Toxic amblyopias

The intracranial lesions, suprasellar tumors, aneurysms of the circle of Willis have already been discussed.

Posterior nasal infection. Retrobulbar neuritis from infection of the posterior nasal sinuses was formerly a fashionable diagnosis. At present it has fallen into disrepute,

and its clinical entity is seriously questioned. While giving full credence to the various clinical studies which have thus cast doubt on it as an actual clinical entity, nevertheless there do appear to be occasional cases of retrobulbar neuritis secondary to infection of the posterior nasal sinuses. Quite probably the changes in the optic nerve are pressure changes only rather than actual infection. Certainly, however, clinical experience indicates that posterior nasal infection must be considered in the search for the etiologic factor in retrobulbar neuritis.

Demyelinizing disease presents a unique problem. The various recognized demyelinizing processes: disseminated sclerosis, acute disseminated encephalomyelitis, neuromyelitis optica, and Schilder's disease of diffuse periaxial encephalitis, may all affect the optic nerve, producing either a retrobulbar neuritis or an actual optic neuritis, according to the location of the lesion. Nevertheless, disseminated or multiple sclerosis usually causes the clinical picture of retrobulbar neuritis while the other demyelinizing diseases tend to give a visible optic neuritis.

It is well recognized that the early retrobulbar neuritis of multiple sclerosis may precede by years the other characteristic changes of the disease, the loss of the abdominal and cremasteric reflexes, the scanning speech, the nystagmus, the ataxia, and other evidences of central nervous-system involvement.

Ophthalmologists are therefore confronted with a group of cases of early retrobulbar neuritis, the attacks beginning with periodic blurring of central vision, the only positive finding being a fluctuating, gradually intensifying central scotoma. There are long remissions between the attacks, which gradually become more severe.

No other etiologic factor can be discovered or suspected; the early neurologic examination is negative; laboratory tests show nothing. Only after several years do the development of the other neurologic manifestations of the disease cement the diagnosis. Few cases can be more exasperating, and all too frequently these patients are subjected to exploratory craniotomies and drainage of the posterior nasal sinuses. No blame can be directed to the ophthalmologist, the neurologist, the neurosurgeon, or the otolaryngologist for such mistakes. The intrinsic baffling nature of the disease is responsible, and until some more accurate method of early diagnosis is developed, such mistakes will continue to be made in the best clinics.

Endogenous toxins. The retrobulbar neuritis from endogenous toxins is interesting. For a long time tobacco-alcohol amblyopia has been recognized as a clinical entity, with the peculiar dumb-bell scotomas involving the blindspot. It has also been recognized that individuals with some debilitating disease, especially diabetes, are especially prone to this type of amblyopia. Only in recent years has it been recognized that the underlying cause is an avitaminosis involving the B-complex, especially thiamine chloride. Fortunately, a form of therapy other than total abstinence is thus afforded sufferers with this unfortunate condition.

The toxic amblyopias affect vision in difference ways. The majority of the known poisons which act on the optic nerve affect primarily the papillomacular bundle. Chief of these are methyl alcohol, carbon disulphide, lead, iodine, thallium, aspidium, salicylates, and aniline dyes.

Methyl alcohol in the commercial form is a universal poison. The others usually produce symptoms only in certain individuals, after varying degrees of exposure.

Quinine amblyopia, on the other hand, results from degeneration of the ganglion cells of the fovea, in individuals with an idiosyncrasy, with resultant ascending atrophy of the papillomacular bundle.

Most important of these especially selective drugs are the pentavalent arsenicals, especially tryparsamide. These arsenicals act first on the peripheral fibers of the optic nerve sparing the papillomacular bundle until the last stages of intoxication. The visual

fields are characteristic with marked constriction above and below (fig. 17). Again, only a small percentage of the population appear susceptible to the toxic action of tryparsamide, and in these, if the field changes are detected early and the drug stopped, central vision can be saved. If, however, the drug is continued and the early visual symptoms ignored, total blindness inevitably results.

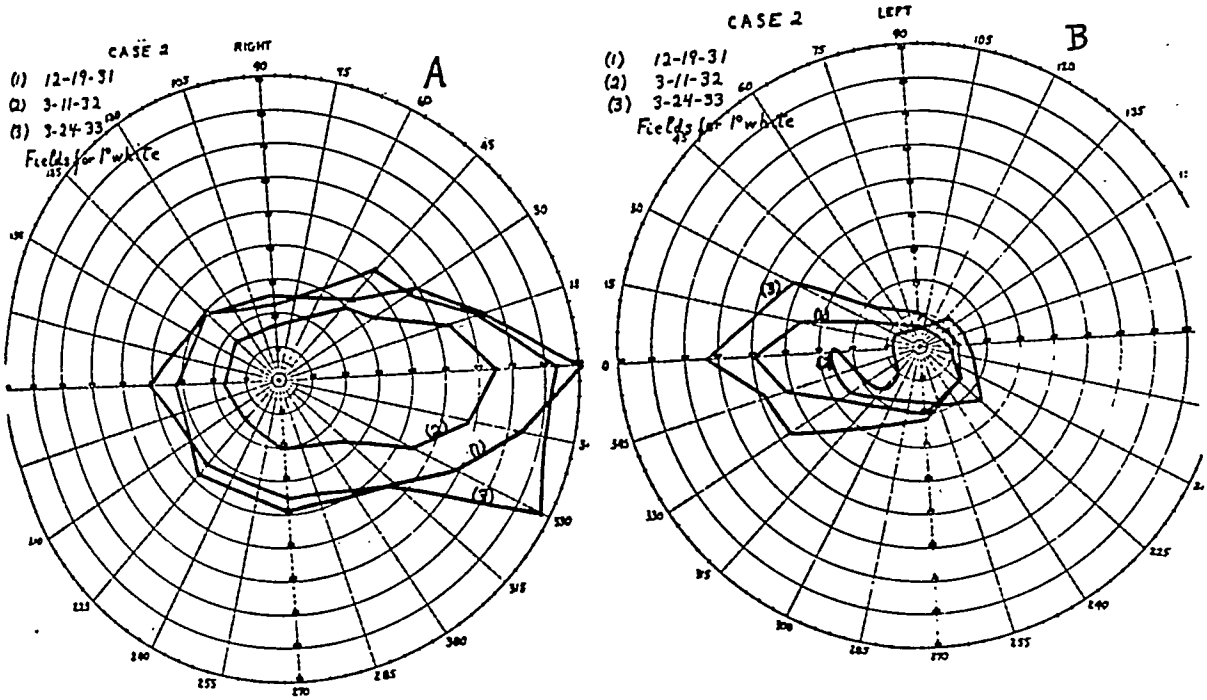

Fig. 17 (Woods). Visual fields in tryparsamide poisoning.

In any event, the usual end-picture of retrobulbar neuritis, unless the cause is early determined and removed when possible, is the same—temporal pallor of the optic nerve from papillomacular-bundle atrophy, with an absolute central scotoma and greatly reduced central vision.

II. Secondary Optic Neuropathies

Optic neuritis and choked disc—two distinct conditions—both produce the same end-picture of secondary optic atrophy. If the patient is encountered in the early stages of papilledema, every effort must be made to differentiate between optic neuritis and choked disc. If the patient is encountered in the final stage of secondary atrophy, the possibility of either primary condition must be considered.

In general, in optic neuritis the inflammatory symptoms are more marked; there is a greater tendency to hemorrhages and exudates over the disc; there is a greater tendency for the inflammatory process to extend out over the immediately adjacent retina; the actual elevation of the disc is usually moderate, usually two diopters or less; and the visual loss may be either slight, if only the peripheral fibers are involved, or severe if the papillomacular bundle is involved.

In the early stages of choked disc which is, by definition, the ophthalmoscopic evidence of increased intracranial pressure, the edema is first manifested at the upper and lower poles of the disc, where the fibers supplying the upper and lower retina are crowded together (fig. 18). In the latter stages, the elevation of the disc becomes high, the physiologic cup is lost, the veins become engorged, edema vesicles form beneath the internal limiting membrane of the retina in the macular area (fig. 19), and ultimately there is a

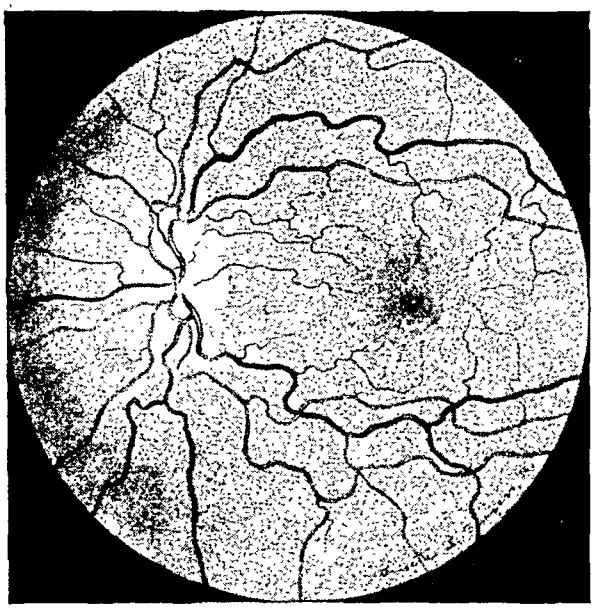

Fig. 18 (Woods). Early choked disc.

full macular figure, with areas of degenerated nerve fibers and hemorrhage, the result of prolonged anoxemia and capillary stasis (fig. 20). While the edema alone may spread out a short distance into the adjacent retina, the maximum elevation is over the papilla itself. The actual elevation of the disc is usually high, often up to 4 to 6 diopters. The visual loss in the early stages, even with high degrees of swelling, may be minimal. Indeed, it is amazing how long the optic-nerve fibers can stand high degrees of pressure from edema alone without atrophy.

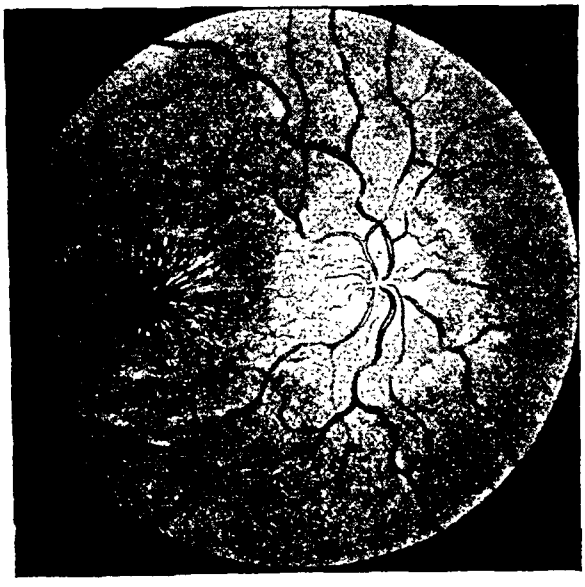

Fig. 19 (Woods). Moderately advanced choked disc.

These are the general criteria which guide the ophthalmologist in the differentiation of optic neuritis and choked disc. Admittedly, in many cases, the differentiation is presumptive, and in other cases, cannot be made at all. When this is the situation, the etiologic study must proceed upon both presumptions until the actual underlying cause of the papilledema is established.

Optic neuritis is commonly found in the following conditions, excluding such orbital

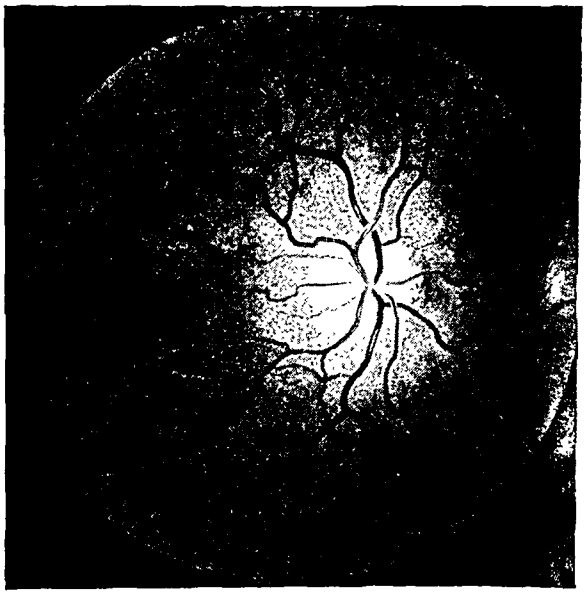

Fig. 20 (Woods). Advanced choked disc.

conditions as infections, periostitis, and so forth:

1. Intracranial infections
2. Acute febrile disease
3. Severe toxic amblyopias—especially methyl alcohol
4. Early syphilis
5. Demyelinizing disease—especially neuromyelitis optica
6. Tuberculosis of the sheaths of the optic nerve—(a hematogenous infection or extension of a tuberculous meningitis)

Few of the conditions require special comment. The optic neuritis complicating a meningitis is obviously the result of direct

extension of the inflammation to the sheaths of the nerve. The optic neuritis of acute febrile disease is an expression of a general toxemia. In severe methyl-alcohol poisoning, with a manifest optic neuritis, the symptoms of systemic intoxication are so marked there is no doubt of the diagnosis. The most interesting conditions in this category are the optic-nerve inflammations of early syphilis, neuromyelitis optica, and tuberculosis.

Early syphilis. The incidence of actual optic neuritis in early syphilis is unknown. The Coöperative Clinical Group reported optic-nerve changes in 11 percent of 3,244 patients with early syphilis, the changes varying from simple hyperemia of the nerve up to an outspoken neuritis.

The one amazing thing about the optic neuritis of early syphilis is how intense the optic neuritis may be without provoking any marked visual symptoms. For this reason it is often detected only as a result of a thorough physical examination. If only the peripheral fibers are involved, as is often the case, there may be no visual changes other than a slight peripheral constriction of the field. If the papillomacular bundle is involved, which is frequent, the visual failure will of course be marked.

Irrespective of the degree of early visual failure, the general rule is that the patients recover from the optic neuritis of early syphilis with little or no loss of vision; some irregularity of the neuroretinal outlines and gliosis over the cup being the only ophthalmoscopic residua. Only in extremely severe cases does secondary optic atrophy and serious impairment of vision result.

Neuromyelitis optica presents a distinct problem, much like that of multiple sclerosis. Indeed the similarity is such that neuromyelitis optica is considered by some to be an acute disseminated sclerosis, although various clinical and histologic differences have been pointed out (Walsh).

Essentially, the disease is a spotty demyelinizing disease with scattered lesions throughout the gray matter especially, with a marked tendency to affect the optic nerves and the spinal cord. In the classic form, the picture is optic neuritis with loss of vision, and a preceding, concomitant, or following paraplegia. In the early stages, there is orbital pain and in the cases with paraplegia often severe root pain. At the onset there is usually a mild fever and pleocytosis of the spinal fluid. The tendency is to recovery both of vision and limb function, although some patients are permanently blind, and some die.

Thus, in the classic form of the disease there is no diagnostic problem. However, there are an appreciable number of cases that show only the eye signs, orbital pain, especially on movement of the eyes, followed by the development of low-grade papilledema without marked evidences of hemorrhage or exudation, loss of vision, usually a central scotoma and sector defects from nerve-bundle involvement, and only minimal evidences of spinal irritation or associated systemic reaction. The disease may be unilateral or bilateral. The most profound investigation reveals no other cause for the optic neuritis.

Gradually, over a period of weeks, the patients slowly recover, without the later development of the expected paraplegia. How these cases are classified—as acute disseminated sclerosis or neuromyelitis optica or by some other name—is an academic question. The essential thing is to realize these cases are a definite clinical entity and recurrences may follow, even years after apparent total recovery.

Tuberculosis is a rare cause of optic neuritis. When it does occur, it is the result either of an extension of the tuberculosis process along the sheaths of the nerve, and into the nerve itself along the pial septa, or the result of a tuberculous periphlebitis of the central retinal vein. In either case the process is destructive. Secondary glaucoma usually results from thrombosis of the posterior veins, and destruction of the optic nerve with secondary atrophy follows. Fortunately the condition is rare and the patients usually die from the concurrent infection.

Comment. These are the main causes of optic neuritis. It may also occur in a variety of rarer conditions, some fungus infections, encephalitis of various causes, Friedreich's ataxia, systemic allergic reactions, Pick's disease, and so forth. These are, however, rare occurrences, and usually present no diagnostic problem.

If optic neuritis is excluded by ophthalmic and clinical examination, the diagnosis of the papilledema as a choked disc is justified. Choked disc must be regarded as the ophthalmoscopic evidence of increased intracranial pressure, and the clinical investigation of the patient extended to establish and determine the course of such pressure.

Examination. The immediate examinations are full perimetric studies and examination of the extraocular muscles to determine any present or latent paralyses. A complete neurologic examination is then indicated to detect any associated neurologic changes. This should be followed by lateral stereoroentgenograms of the skull to detect any pressure changes or abnormal shadows. Lastly comes the serologic examination, cell count, and manometric pressure reading of the spinal fluid. The one caution to be remembered in relation to the spinal puncture is that, in high degrees of choked disc, care should be exercised in the release of spinal fluid pressure, on account of the danger of damage to the brain stem at the foramen magnum.

Diagnosis. On the basis of this ophthalmic and neurologic information, the diagnosis can usually be made between intracranial tumor, which accounts for approximately 75 percent of all choked discs; central nervous system syphilis, which accounts for probably 10 to 15 percent of the cases; and the various other rarer causes (pseudotumor, brain abscess, hydrocephalus, subdural hemorrhage, meningitis, and so forth), which account for the remaining 10 or 15 percent of the cases.

If brain tumor is the underlying cause, a knowledge of the various syndromes caused by tumors at various intracranial levels may greatly help to localize the lesions. These various syndromes have been outlined elsewhere.* They are the pituitary syndrome, the chiasmal syndrome, the Foster-Kennedy syndrome for frontal-lobe tumors, the indefinite changes produced by parietal-lobe tumors, the often more precise changes which accompany temporal-lobe tumors, the characteristic pineal-gland syndrome, the well-known occipital and angle syndromes, and the exact changes produced by tumors at various levels of the brain stem—the so-called Benedikt's, Weber's, Nothnagel's, de Raymond's, Millard-Gubler, and Foville's syndromes. However, only in a limited number of cases, especially those of the chiasmal area, can an exact location be made by the ophthalmic, neurologic, and radiographic examinations. Ventriculography is, of course, the final resource in cerebral localization.

There remains one perplexing class of cases to mention briefly. These are the cases of pseudopapilledema and pseudoneuritis.

Pseudopapilledema occurs usually in hyperopic individuals. The disc margins are blurred, the physiologic cup indistinct, and at times the veins may appear overfilled. The absence of symptoms and the usual presence of hyperopia should put the ophthalmologist on guard. Examination with the binocular ophthalmoscope reveals there is usually no actual elevation of the papilla. There are, however, a few such cases in which the disc may be slightly elevated and still the most exhaustive investigation reveals no organic lesion, the ophthalmoloscopic picture remains unchanged over years of observation, and the patients develop no symptoms. The condition has been attributed to narrowing of the porus opticus.

Pseudoneuritis optica is a somewhat similar picture, but in addition there is usually glial tissue over the disc, and it may resemble a secondary atrophy in color. The condition is due to excessive formation or

---

*Woods, A. C.: Ocular manifestations of intracranial tumors. South. Surgeon, 5:91-114, 1936.

defective atrophy of the tissue which formed Bergmeister's papilla and the hyaloid system. A careful ophthalmoscopic examination usually raises suspicion of the true nature of both of these conditions, but even to the most meticulous ophthalmologist, they remain a source of worry. Fortunately both conditions are comparatively rare.

Conclusion

In this discussion I have endeavored to present a simplified approach to the etiologic diagnosis of optic neuropathies, to give a general classification of the more important causes, and to comment briefly on some of the more interesting points. There remains the question of how such cases should be handled by the ophthalmologist in actual practice. Here I think the answer is fairly obvious.

First, the ophthalmologist should have a clear concept of the various conditions which produce changes in the optic nerves.

Second, his ophthalmic examination should be precise and exhaustive and should enable him, in the majority of instances, to place the individual case in one or the other of the two large groups I have outlined early in this paper, and to classify it as a primary or secondary neuropathy.

Third, if the case falls into the second group, or if there is any question latent in his mind, he should outline the investigation to be followed. This investigation should routinely include a neurologic examination, a general physical examination with serologic and routine examination of the blood and spinal fluid, a lateral stereo of the head, and a clinical and radiographic examination of the posterior nasal sinuses.

Fourth, the ophthalmologist should remain captain of the team until the indications are definite where the patient should be referred for treatment or further investigation.

It is amazing that in the overwhelming majority of cases the information derived from the above examinations permits an immediate and exact diagnosis and establishes the underlying cause of the optic neuropathy.

To my mind the most important point in the etiologic diagnosis of optic neuropathies is that the ophthalmologist should not evade his responsibility. To content himself with the diagnosis of an optic neuropathy secondary to some systemic or intracranial disease and thereupon turn the case over *in toto* to a consultant is an evasion of duty. The neurologist, internist, and neurosurgeon are of necessity and training largely ignorant of the many and diverse causes of optic-nerve disease. While each consultant may be preëminent in his own field, the basic problem is an ophthalmic one; the investigation should be directed by the ophthalmologist; the diagnostic survey assembled by him and correlated with the ophthalmic examination. I believe it is only by this means that the correct diagnosis will be reached in the greatest number of cases.

Johns Hopkins Hospital (5).

THE USE OF BACITRACIN IN OCULAR INFECTIONS*

PART I. TOLERANCE AND PERMEABILITY IN THE RABBIT EYE

JOHN G. BELLOWS,† M.D., AND CHESTER J. FARMER,‡ PH.D.
(With the technical assistance of F. W. Kraft and H. J. Reingold.)
Chicago, Illinois

Following the successful application of penicillin and streptomycin in ocular infections, the reported results following the use of a relatively new antibiotic, bacitracin, in various surgical infections stimulated our interest as to its applicability to infections of the eye. Meleney and his coworkers[1, 2] have shown that in general bacitracin is effective against the same bacteria as penicillin and, in addition, report that, where a difference in susceptibility exists, the organisms are more often susceptible to bacitracin than to penicillin in a ratio of 5 to 1. Furthermore, there is no evidence that bacteria can inactivate bacitracin, as is the case with penicillin (penicillinase).

These reports seemed of sufficient importance to warrant undertaking the studies reported here to ascertain the applicability of this antibiotic to ocular infections.

A. THE EFFECT OF BACITRACIN ON THE CORNEAL EPITHELIUM

Saline solutions containing 1,000 and 5,000 units bacitracin per ml. were applied to a series of 12 normal rabbit eyes as drops at one-half hour intervals for six doses, and also in 6 other animals as a constant corneal bath for periods up to one hour. In no case was there any gross evidence of irritation. Upon staining the corneas with fluorescein, no staining areas were visible.

When bacitracin was applied to the corneas for periods up to 30 minutes as a dry powder, then washed out with water, no gross evidence of irritation was apparent. However, upon staining with fluorescein, micropunctate areas became visible. These represented but a transitory injury since, in 24 hours, the eyes were normal in all appearances, and the corneas failed to give a staining reaction.

Another method employed in the study of local toxicity is to observe the effect of the drug upon the regeneration of the corneal epithelium. In a series of 15 rabbits, 5-percent cocaine was applied to both eyes to anesthetize and to facilitate the denudation of the epithelium. The epithelium was removed by rubbing with sterile dry gauze and checked for completeness of abrasion by staining with fluorescein.

Five rabbits received in one eye, 2 drops of the saline solution containing 5,000 units bacitracin per ml., 3 times daily, while the other eye serving as a control received a similar amount of saline. The control eyes healed completely without scarring in 3 to 4 days; whereas, only one receiving the bacitracin healed by the 4th day, and the other 4 remained unhealed when observed on the 9th day. Eventual healing occurred with vascularization and opacities of the corneas. Eyes similarly treated with the solution containing 1,000 units bacitracin per ml. showed no difference in healing rate from that of the saline controls.

Since the rabbit cornea is more sensitive to irritating substances than the human cornea, it is evident that bacitracin in saline solution of a concentration of 1,000 units per ml. may safely be applied to the surface of the human eyeball under any condition. However, if the corneal epithelium is intact,

* Read before the Ophthalmic Section, New York Academy of Medicine, November, 1947. This research was done under a contract between the Office of Naval Research and Northwestern University.

† Of the Department of Ophthalmology, Northwestern University Medical School.

‡ Of the Department of Chemistry, Northwestern University Medical School.

bacitracin in any concentration, or even as the dry powder, is well tolerated.

B. Permeability of the cornea to bacitracin

For these studies, penetration was observed in a group of 24 albino rabbits under various conditions: (a) where the cornea remained intact, (b) was traumatized, or (c) was inflamed as a result of induced infection.

Rabbits were first anesthetized by the intravenous injection of nembutal. The bacitracin solution was applied as a constant corneal bath by means of a plastic eyecup for periods ranging from 4 to 60 minutes. At the end of the respective periods, the excess of bacitracin was removed from the surface of the eyeball and the adnexa by thoroughly washing with a stream of normal saline. The aqueous was then withdrawn through a limbal puncture by means of a sterile 27-gauge needle. The bacitracin content was determined by the serial dilution method, using the Chanin-Strain Streptococcus hemolyticus, kindly furnished by Dr. Frank L. Meleney. The results of these experiments are shown in Table 1.

TABLE 1

Penetration of bacitracin (1,000 units per ml. saline) through the cornea

Condition of Cornea	No. of Eyes	Duration of Therapy Corneal Bath (Minutes)	Bacitracin Units* per ml. of Aqueous	Remarks
Intact	3	30	0, 0, 0	Non-irritating
Abraded (Amt.)				
100%	2	60	40, 40	Healed within 4 days
100%	2	30	20, 20	Healed within 4 days
50%	2	30	20, 20	Healed within 4 days
25%	3	4	0, 0, 0	Healed within 4 days
25%	2	30	4, 8	Healed within 4 days
Stippled	2	15	0, 0	Healed within 4 days
Stippled	4	30	0, 0.66, 1.0, 2.0	Healed within 4 days
Inflamed (Vaccinia virus)	8	30	2–16 (Av. 6.6)	
Ion transfer				
Intact Cornea	2	15	0, 0	Punctate stippling
Intact Cornea	4	30	0, 0, 0.5, 1	Corneal edema
25% Abrasion	3	4	0, 0, 0	
25% Abrasion	2	30	4, 8	Corneal edema
Aerosol O. T. (1 Drop in 1.0 ml. Bacitracin)				
0.5%	1	60	8	
0.5	1	5	0.12	Staining of cornea, chemosis, and corneal edema
0.1	2	30	4, 4	
0.05	2	30	2, 4	
0.01	2	30	0.5, 1	

* Hemolytic serial dilution method, using the Chanin-strain Streptococcus hemolyticus, kindly furnished by Dr. Frank L. Meleney

From the data presented it will be seen that bacitracin does not penetrate the normal cornea in a period of 30 minutes when applied in a concentration of 1,000 units per ml. In our previous studies on streptomycin,[3, 4] it was shown that, although penetration does not occur in the intact cornea, it readily penetrates following corneal damage.

Similar studies were therefore conducted using bacitracin. It was found that bacitra-

cin behaves in a similar manner. As shown in Table 1, the amount of penetration varies somewhat but not in an absolute manner with the degree of denudation and period of application.

In studies with the inflamed cornea, resulting from the application of the vaccinia virus, penetration in two cases with a 30-minute application of the corneal bath was similar in amount to that occurring in a 25-percent abrasion of the cornea. It is of interest to note that the infected lesion produced by the vaccinia covered about 25 percent of the corneal area.

As observed from Table 1, no detectable amount of bacitracin was found in the aqueous of an eye with intact cornea subjected to ion-transfer (iontophoresis) therapy for a period of 15 minutes. Small amounts of the antibiotic were present after 30 minutes. Application of fluorescein to the cornea following ion-transfer of 15 to 30 minutes in nearly all cases showed punctate staining.

The amount of bacitracin found in the aqueous after ion-transfer was no greater than after a corneal bath containing the same concentration of bacitracin applied for the same time to a cornea which had previously received a similar amount of damage by mechanical means. (Compare amounts for stippled cornea and ion-transfer intact cornea 15 and 30 minutes.)

It was also shown that the passage of bacitracin was no greater with 25-percent abrasion plus ion-transfer than with 25-percent abrasion plus corneal bath alone. From the above data, we conclude that the passage of bacitracin through the cornea does not depend upon ion-transfer per se so much as upon associated epithelial damage. Furthermore, since increased permeability was observed to occur with lesions produced by various means—scraping, a surface-active chemical agent, vaccinia, and during ion-transfer (iontophoresis)—we are led to conclude that the mechanism effecting an increase in penetration through a damaged cornea is essentially the same irrespective of the agent employed.

C. Effect of intraocular injection of bacitracin

Since at present bacitracin cannot be administered parenterally because of its toxicity and, as already shown, it does not penetrate the normal cornea, it was decided to study the effect of direct injection into the vitreous.

For this purpose, 0.1 ml. of a saline solution containing 100 units bacitracin was injected by means of a 27-gauge needle in the region of the equator of the eyeball, taking care to deposit the bacitracin as near the center of the vitreous as possible. The eyes were observed daily with the ophthalmoscope and with the slitlamp.

Minimal to moderate degrees of vitreous opacities were observed immediately following the injection. Usually these disappeared over the course of several weeks. In only 2 of 8 eyes were opacities observed at the termination of the experiment one month later.

At this time two small linear vitreous opacities were observed in one eye, and several fine vitreous opacities in the second. Since no histologic sections were made of these eyes, minute lesions may have escaped observation.

Lens opacities in these early experiments were present in four eyes and were attributed to injury occurring as a result of contact with the needle. In a later series of infected eyes treated by similar injection of bacitracin, rarely was a lens opacity observed. On the basis of size, it is postulated that injection of bacitracin into the human eye should be well tolerated.

In the second part of this report which will be published next month the effect of bacitracin therapy in experimental and clinical ocular infections will be considered.

SURGERY OF CONGENITAL CATARACTS*

FREDERICK C. CORDES, M.D.
San Francisco, California

The advent of the rubella cataract has served to stimulate a new interest in the surgical treatment of congenital cataracts. During the past 25 years only a few scattered papers on the subject have appeared in the literature. Of the more recent ones, that of Falls[1] is the most comprehensive. In the present paper no attempt will be made to present a statistical study but rather the procedures that have seemed most efficacious in my hands. In addition, certain types of congenital lens anomalies that warrant special consideration will be discussed.

INTRODUCTION

A thorough knowledge of congenital cataracts is essential for the intelligent discussion of the case with the patient or the patient's parents. It is also of importance in reaching a decision as to whether or not the cataract should be operated upon and the type of surgical procedure that may be indicated.

As Duane[2] points out, it is only in exceptional cases that the congenital cataracts are discovered immediately after birth, the rule being that they are not noticed until the child is some weeks or months old. This is due to the fact that newborn children have very narrow pupils, that they sleep so much, and keep their eyes closed most of the time. Moreover, they do not fix objects, an additional factor in not making it apparent that they do not see. Partial congenital cataracts may be overlooked for a longer time as the child will have sufficient vision to carry on.

Certain forms of congenital cataract show an hereditary tendency, primarily of a dominant type, although the type may not always be consistent. Therefore, lamellar, polar, spindle, and central cataracts all may occur in the same family. In some instances, however, the type may be the same in all members of the family involved. Haro,[3] for example, observed a family of 59 persons, covering four generations, in which 16 members had ring or disk-shaped cataracts. Nettleship[4] found coralliform cataract in 35 members of one family over five generations. Franceschetti[5] has listed as types with an hereditary tendency: Congenital total cataract, lamellar cataract, embryonal nuclear cataract, coralliform cataract, spear cataract, floriform cataract, axial fusiform cataract, stellate cataract and disk-shaped cataract.

PRODUCTION OF CONGENITAL CATARACTS

As Falls[1] pointed out, ophthalmologists, to a large extent, are ignorant of the primal causes of congenital cataracts, especially in regard to the mechanism of their production

* Presented at the III Pan-American Congress of Ophthalmology, Havana, Cuba, January, 1948. From the Division of Ophthalmology, University of California Medical School, San Francisco.

and the rationale of their transmission from one person to another. Mann[6] states that a certain number of congenital abnormalities can be explained as abnormal persistence of a normally transient condition.

It must also be borne in mind, however, that a greater part of so-called developmental anomalies do not represent any normal stage, but are pure aberrations of growth. The most that can be said in regard to the production of these developmental anomalies is that it is possible to deduce from their location the time at which the fibers involved were formed. Whether the opacities occurred at this time or whether they occurred as the result of a subsequent degeneration, it is impossible to say.

Intra-uterine trauma may at times produce lens changes as seen in the reduplication cataract. In addition, as Mann[7] has stated, we know experimentally that toxic substances administered to the mother during pregnancy may cause lens changes. It is known that interference with calcium metabolism and parathyroid secretion will produce the same opacities produced by avitaminosis.

The recent work of Gregg,[8] Swan and his co-workers,[9] Reese,[10] and others on rubella cataract would tend to show that infection in the mother, particularly during the early part of pregnancy, is capable of producing lens changes.

In addition, lens changes may be secondary to abnormalities of the vascular capsule which produce such changes as retrolental fibroplasia (persistence and hyperplasia of the primary vitreous).

From the above it seems apparent that some knowledge of the embryology of the lens, together with a thorough knowledge of its structure, particularly the zones of discontinuity, is essential for the proper diagnosis of the type of congenital cataract. As already stated, the correct diagnosis is essential in helping to make a decision in regard to the surgery of the case at hand.

Other anomalies are present

It is noteworthy that in approximately 50 percent of the cases of congenital cataract other ocular anomalies are present. These include strabismus, nystagmus, aniridia, choroidal and retinal changes, microphthalmus, subluxation of the lens, dissociated ocular movements, eccentric fixation, colobomas of the lens and optic nerve, muscle paresis, anomalies of the hyaloid artery system, and other changes. Falls[1] in his series of 313 cases found that 52.6 percent of the patients had other ocular defects in addition to congenital cataract.

In addition to ocular defects, a fairly high percentage of these cases have associated disturbances of a constitutional variety, either congenital or metabolic in nature. There is also a fairly high incidence of mental retardation. According to Krause[11] the mental deficiences may not make their appearance until the child is four or more years of age. The opinion has been expressed that the mental retardation is due to failure to perceive visual sensations. On the other hand all of us have seen instances of bilateral congenital blindness, uncorrectable by surgery, that have progressed very well mentally. While it is true that in many instances some of these cases do apparently show a marked improvement in their mental condition after restoration of vision, it must be kept in mind that frequently this does not occur. From what has been said it is obvious that the prognosis in the care of congenital cataracts must be guarded. As early as 1805, Ware[12] stated: "Operation is not so certain a cure for cataract in children, as in persons of a more advanced age."

General indication for surgery

The general indication for surgery in these cases is a visual acuity that has been reduced to the point of interfering with the normal use and development of the eyes. Inasmuch as most congenital cataracts are stationary it may at times be advisable to

leave the patient alone if his vision is 20/40 or better. It would seem advisable to make a general rule that patients with 20/40 vision should not be operated upon unless the visual acuity is further reduced. Consequently, it is never wise to tell a patient that he should never be operated upon, as the visual acuity may change in some of these cases. The zonular (lamellar) cataract, for example, has a tendency to increase in density so that, while the visual acuity may be adequate in youth, the vision in middle life may be sufficiently reduced to warrant surgery.

Age at which to operate

There has been a good deal of variance regarding the age at which congenital cataracts should be operated upon. In 1805 Ware[12] said, "Children, again, some of whom are born with cataracts, are in general so unmanageable that the operation becomes almost impracticable. For these reasons it is advisable to postpone it until they arrive at the age of reason and reflection, and feel by experience the necessity of submitting to it." It must be remembered this was before the days of anesthesia.

By 1830 we find that the opinion has changed. At that time Mackenzie[13] says, "In cases of congenital cataract, ought the operation to be delayed till the patient has attained an age sufficient to enable him to give his assent, or ought it to be practiced during infancy? The answer decidedly is to operate in infancy. About the age of from 18 months to 2 years, the tissues of the eye have attained a degree of resistance which enables the surgeon to operate with greater precision than at an earlier period, yet the capsule is not so tough and coriaceous as at a later period, and especially after the lens (as often happens in congenital cases) is completely absorbed."

Guthrie[14] in his lectures on the operative surgery of the eye, in 1830 states: "The proper period for operating has been and ever remains a disputed point, not as to the propriety of doing it at an early age, or within the first three years, that being fully established; but as to the best part of that time, some surgeons recommending 6 months, others 20 months to 3 years. If the child be healthy at 3, 4, and certainly 6 months, the operation ought to be performed with every hope of success. If the operation is delayed until the end of the third year, the child acquires . . . an irregular rolling motion of the eye, which it does not readily lose."

E. Fuchs,[15] in 1928, in discussing congenital cataracts said: "When I was still an assistant in the clinic, it was the rule that children with congenital cataracts were not to be operated upon until they were 10 years old. It was only later that it was discovered that the earlier the operation the better the visual result. One should not expect to obtain normal vision in such eyes as they also show other evidences of abnormal development. These eyes are usually smaller than normal and, if one waits until later to operate, the eye will have increased some in size, but the visual acuity will be much worse because the retina, due to lack of use, fails to develop normally."

Kirby[16] states that if operation is decided upon, it may well be performed early, as good results are obtained with careful needling at the age of a few months. If the lens opacities are allowed to obstruct the rays of light until after the fourth year of life, the best function obtainable after their removal will not be within the range of useful vision. He also states that in progressive congenital cataracts the visual function of the macula may be well developed in the early period of life and therefore the function will be good after the lens has been removed at a later date. Such patients obtain good vision after operation as late as 9 to 10 years of age.

Falls[1] suggests that in cases of complete bilateral cataracts, operation be performed on one eye after the patient reaches the age

of six months and on the other after the age of two years. If the cataracts are incomplete and the child has sufficient vision to get around, he feels surgery should be postponed until the 3rd or 4th year. Treacher Collins[17] prefers to wait until the child is at least 10 months old, as at that age the eye is larger and the anterior chamber is deeper.

From what has been said it is apparent that there can be no hard and fast rule as to the time of surgery. It has been my practice to operate the first eye at six months in those cases where the cataract is sufficiently dense to interfere with fixation, in the hope that the resultant fixation will prevent the establishment of nystagmus. The second eye is operated upon between the 2nd and 3rd years. In the interim, the eye has had the opportunity to develop and increase in size so that surgery is simpler. When the lens opacity is sufficient to interfere with the possibility of the child learning to read, the cataract should be removed before the school years.

Resultant postoperative vision

The prognosis as to the amount of resultant postoperative vision must be guarded. Fuchs[15] states that, "A visual acuity of one-fourth of normal certainly seems rather poor but must be considered a good result in these cases, especially where there is nystagmus, a smaller eye, and an abnormal development of the retina. One learns to appreciate such a result when one is asked to operate a case of bilateral congenital cataract after puberty. Immediately following operation the patient appears as blind as he did before surgery for he does not recognize objects, due to the fact that he lacks visual memories. This must be developed through experience but even then he will not obtain more than defective vision because of the fact that after a certain age the retina cannot entirely overcome the neglected development. One reads in romances how the congenitally blind person is operated upon and how at the first removal of the bandages he is surprised at the beauty or ugliness of his adored-ones. This must be regarded as purely poetic fantasy."

In Falls's[1] series 53.5 percent had a visual acuity of 20/100 or better; 9 percent were capable of 20/200 vision or possessed the ability to place accurately the Worth ball. For all practical purposes 17 percent were blind; 18.4 percent were capable of reading J4 to J7 print or better. It is interesting that in his series Falls found that no patient with pendular (ocular) nystagmus achieved better than 20/50 vision.

From the above it is apparent that in discussing the surgery of congenital cataracts with the parents it is well to explain in detail the visual prognosis and thus avoid a great disappointment on the part of the parents.

Surgical procedures reported in literature

The surgery of congenital cataracts has been limited to a relatively few procedures, all of which have their advocates. The ideal surgical procedure for the removal of congenital cataracts would seem to be one in which a single operative procedure would provide for the removal of at least the major portion of the lens so as to permit the remainder to absorb without further surgical interference. In addition, there should be no interference with the pupil and a minimum danger of iris incarceration or adherence to the operative wound. It is also highly desirable that, if possible, there be no interference with the posterior capsule and the vitreous. The danger of glaucoma should be minimized.

The use of visual iridectomy as advocated by Fox[18] and others in cases of incomplete cataract has been discarded. Bell[19] advocated an iridectomy as a preliminary procedure to either a later Ziegler discission or a linear extraction.

Discission

Discission in one form or another is the

most universally used operation for congenital cataract. The simple discission, repeated a varying number of times, has many advocates because of its simplicity and the fairly good results obtained. One of the disadvantages, a very real one from the parents' viewpoint, is that the procedure must be repeated a number of times. While complications are not common, as Spaeth[20] points out, they do occur and include cessation of the absorption as a result of postoperative irritation; postoperative low grade and prolonged iridocyclitis; organization of capsular tags and remnants into a dense membrane. Secondary glaucoma also occurs. As Wiener and Alvis[21] stated, discission or needling as many as 17 or 18 times has been necessary before a good opening or good visual results were secured.

In 1921 Ziegler[22] published his V-shaped through-and-through discission of the lens, which has many advocates. Wiener and Alvis[21] say that it is rarely necessary to operate these patients more than once and practically never more than twice. They feel that there is absorption of the softened lens in the anterior chamber and in the vitreous, "thus equalizing the pressure within the eye." The chief objections to the operation are delayed absorption and the presence of vitreous in the anterior chamber. Spaeth[20] says that a through-and-through incision of the lens into the vitreous is not a guarantee against the development of secondary glaucoma; instead, damage may occur to the vitreous with later development of a chronic iridocyclitis and even a retinal detachment.

Modification of discission

Recently, Moncreiff[23] has reported his modification of the discission. He makes an incision through the anterior capsule and into the cortex, and then makes multiple incisions in all directions down to the nucleus until the anterior cortex and capsule are reduced to shreds. The nucleus is then cut into several fragments. With an anterior-chamber irrigator he attempts to wash all of the cortical material from the remnants of the capsular sac into the anterior chamber. He feels this is the nearest approach to the ideal operation in these cases. The operation has only been done in both eyes of three patients and, as Moncreiff states, a large number of cases will have to be observed before the operation can be evaluated. It would seem that the possibility of glaucoma, due to the rapid swelling of all of the lens material in the anterior chamber, would be a definite risk.

Another rather frequently used procedure is the combination of discission and linear extraction. A fairly extensive discission of the anterior capsule of the lens is done. The eye is observed for several days postoperatively until the lens material is sufficiently disintegrated to permit easy removal through corneal or limbal keratome incision. Falls[1] found that this combined technique produced the best visual results. One does, however, have to keep in mind that in the older age group of children this may produce an acute glaucoma following the discission.

Modification of linear extraction

In 1932, Otto Barkan[24] reported his modification of a simple linear extraction in which the cataract extraction was done in one procedure. The chief modification consisted in several very important details, namely, the injection of adrenalin at the limbus and the making of the keratome incision inside the limbus. The absorption is rapid, and useful vision is obtained in a very short time, much sooner than with the discission. The difference in time between this and the combined method of discission and linear extraction is not very great, however, but it does not necessitate two operations. The chief objections that have been made to the procedure have been the tendency to anterior-synechia formation and the possibility of vitreous loss. The avoidance of these rather infrequent complications will be discussed later.

The intracapsular extraction also has a

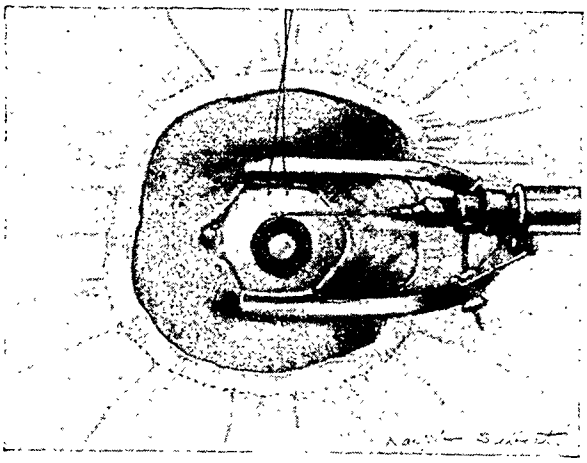

Fig. 1 (Cordes). Two drops of adrenalin (1: 1,000) are injected subconjunctivally at the limbus above. When introducing the needle, the open part should be directed toward the limbus.

very limited use in congenital cataract surgery. Falls[1] in his series limited this operation to the treatment of shrunken, dense, membranous, or hard cataracts in the very young.

Results in various operations

Horay's[25] observation on the results in the various types of operation for congenital cataract is of interest. He reported the results in 282 operations on congenital cataract. The cases were divided equally between discission, linear extraction (simple), and combined linear extraction. The age of the patient played no part in the decision as to the type of operation to be used.

From the survey it was concluded that the best results were obtained with a combined extraction, while the poorest results were obtained with the discission. The opinion that has been expressed that the operation should not be done until after the first year he felt was unfounded as the results were just as satisfactory during the first year as later in life. The failures in the patients operated upon during the first year of life were often the result of other congenital anomalies present. He concluded that an extraction, done in one sitting, was the operation of choice, irrespective of the age of the child.

Surgical procedures in congenital cataract

Except for certain types of congenital cataracts to be discussed later, I have employed a slightly modified Otto Barkan operation on all cases.

After the routine preoperative preparation and anesthesia, two drops of adrenalin (1: 1,000) are injected subconjunctivally at the limbus above (fig. 1). When introducing the needle, the open part should be directed toward the limbus. After 5 to 10 minutes the pupil is maximally dilated so as to almost disappear behind the limbus, especially above at the site of the incision. This dilation is due to a contraction of the sympathetic dilator fibers and thus is tonic, and results in maintaining the exaggerated dilation even after the anterior chamber is open, thereby preventing the iris from coming into contact with the incision before the anterior chamber is reformed. In addition, the hypotony is such that the tendency of the ocular

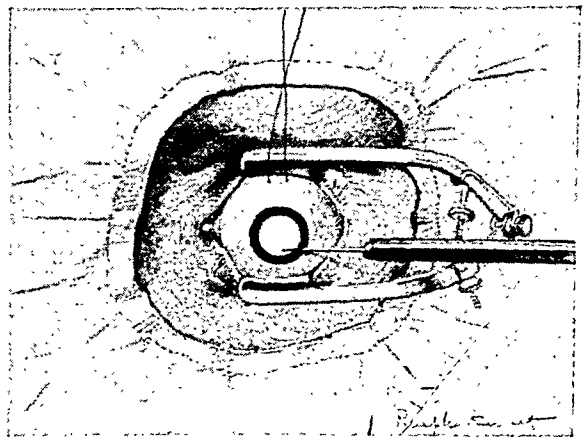

Fig. 2 (Cordes). Before making the incision, a puncture is made at the lower temporal limbus with a straight knife-needle to facilitate the injection of air into the anterior chamber after completion of the operation.

contents to prolapse is reduced to a minimum.

A suture is now placed through the superior rectus tendon. This is very helpful in fixing the eye downwards during the extraction, especially in infants where the small

area of the operative field makes it difficult to use fixation forceps.

Before making the incision, a puncture wound is made at the lower temporal limbus with a straight capsulotomy knife-needle to facilitate the injection of air into the anterior chamber after completion of the operation (fig. 2). The site of the puncture should be marked with gentian violet as an aid in finding it later. If the knife-needle is introduced into the chamber parallel to the iris surface, there will be no loss of aqueous

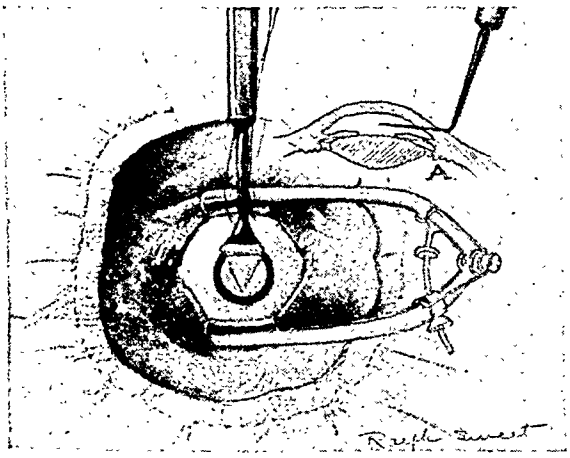

Fig. 3 (Cordes). A keratome incision is made inside the limbus and parallel to the iris plane.

and no collapse of the anterior chamber.

The incision is made 10 minutes after the injection of the adrenalin so as to allow ample time for the maximum effect. A keratome incision is made 1.5 to 2 mm. inside the limbus in the cornea. The incision is made oblique (parallel to the iris surface), thus forming a valvelike incision which tends to close more the greater the pressure within the anterior chamber (fig. 3).

The incision should be no larger than necessary for the extraction of the lens substance.

A capsulotomy is then performed with capsule forceps. As in the senile extracapsular extraction, it is desirable to obtain as large a capsulotomy as possible. In very young infants this must necessarily be small (fig. 4).

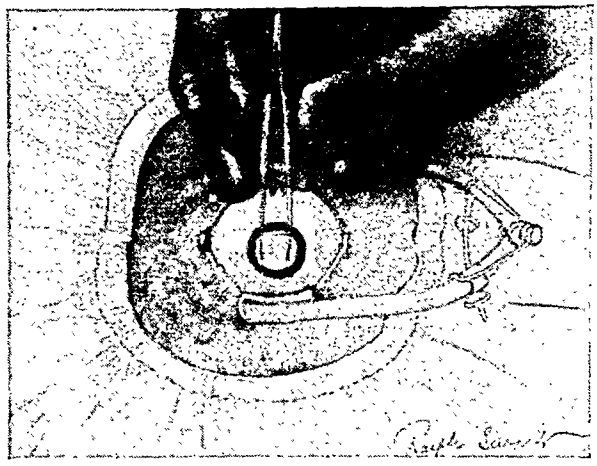

Fig. 4 (Cordes). A capsulotomy is done with Fuchs's forceps.

The lens substance is now expressed with spoons and the anterior chamber is washed out with normal saline solution (fig. 5). The wound is carefully inspected to be certain that there is no lens substance or capsule remnant in the wound.

With a small Luer syringe and a very fine needle (28 to 30 gauge), air is injected into the anterior chamber. This is done without difficulty through the small, previously made, stab puncture at the limbus below. The tip of the needle should be dulled a bit so that the point will not catch in the walls of the puncture wound. The injected air remains in the upper part of the anterior chamber for several days and prevents the iris from

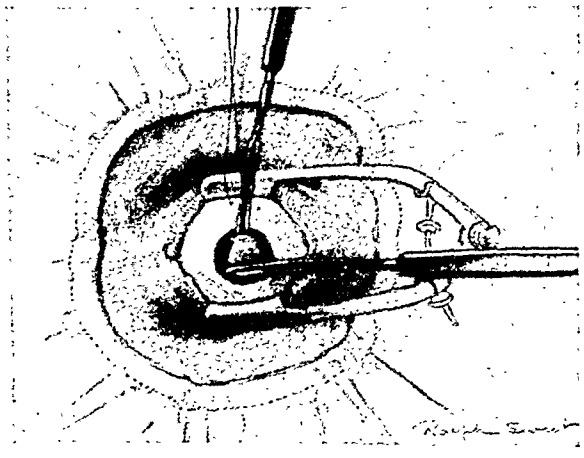

Fig. 5 (Cordes). The lens substance is expressed and the anterior chamber is washed out with normal saline solution.

coming into contact with the wound. Otto Barkan emphasizes the importance of a deep chamber before the patient leaves the operating table (fig. 6).

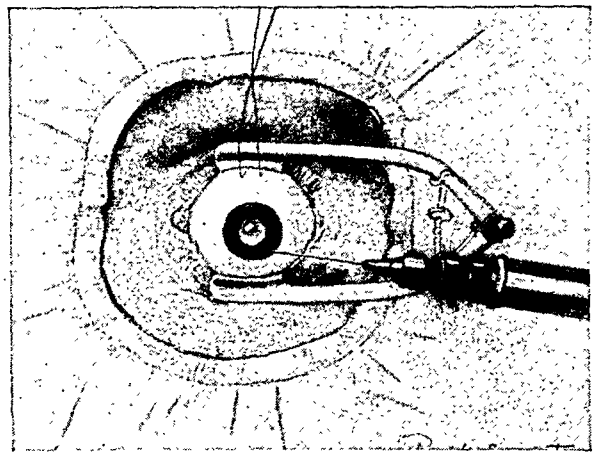

Fig. 6 (Cordes). With a small Luer's syringe and a very fine needle (28 to 30 gauge), air is injected into the anterior chamber. The tip of the needle should be dulled to facilitate the introduction of the needle into the previously made canal.

The usual postoperative atropinization is carried out.

Complications

The complications encountered are not many and can, to a great extent, be prevented. Of importance is the injection of adrenalin and the necessary wait of 10 minutes until the pupil is widely dilated so that the iris is not in the way.

The importance of the incision being parallel to the surface of the iris cannot be stressed too much, for it is this angle that produces the valvelike opening which seals firmly from the pressure within, and is a factor in preventing prolapse of the iris or opening of the wound by postoperative squeezing.

Vitreous loss is infrequent and, when it does occur, usually results from attempting to remove the last bit of lens substance. It is well to remember that when the major part of the lens has been removed there is little to absorb and this absorption occurs in a short time, even in those cases where the lens is relatively immature. It is important not to "do too much."

The most serious objection that has been made to the operation is the development of anterior synechias, or iris incarceration in the wound, with the resultant drawing up of the pupil which may at times be accompanied by glaucoma. The injection of air immediately following the operation seems to prevent this, as in no instance where this has been done has there been any iris incarceration.

Secondary glaucoma has occurred only once, and this in a 12-year-old boy whose lamellar cataract had increased in density to the extent that it caused sufficient loss of vision to necessitate surgery. No difficulty was encountered in opening the wound and washing out the lens debris. The final result in this eye was 20/30 vision.

Special consideration of certain types of congenital cataracts

Certain types of congenital cataracts warrant special consideration from the surgical viewpoint.

Posterior polar cataract. In this cataract, in addition to the posterior cortical opacity, the major opacity is confined to the posterior capsule and therefore, if a linear extraction is done, a later discission through this posterior capsule is necessary. Due to the fact that other anomalies are often present the prognosis must be guarded when surgery is considered.

Embryonal nuclear cataract. It must be remembered that in these cases the nucleus is dense and hard so that discission is very unsatisfactory. The cataract, however, causes very little interference with vision and Gifford[26] goes so far as to say that operation is never required for opacities limited to the embryonal nucleus.

Zonular (lamellar) cataract. In some of these cases, the disturbance continues until birth, or, is so unusually severe that the entire lens is opaque. Under these conditions

further growth of the lens fibers does not take place. This type of zonular cataract is usually associated with other serious congenital defects of the eye so that operative prognosis must be guarded.

Membranous cataract. In the membranous cataract, with the absorption of the lens parenchyma during intra-uterine life, the anterior and posterior capsules collapse to form a thin gray-white or chalky-white membrane. The condition is frequently bilateral and often associated with other anomalies including nystagmus and strabismus. In these cases the use of the discission advocated by Wheeler[27] has been found simple and effective.

Axial fusiform cataract. It is well to remember that in the axial fusiform cataract actual adhesion of the nucleus to the anterior and posterior capsules has been demonstrated.

Disk-shaped cataract. The surgical treatment of this cataract presents an interesting problem, due to the fact that for all practical purposes there are two types of cataract in one individual, namely a membranous (central area) and a soft cataract (the periphery of the lens). The literature contains relatively little on the subject.

Collins[28] was able to separate the central plaque in one of his patients. In both eyes the plaque fell into the lower part of the anterior chamber, where it remained without causing any reaction. Haro[3] reported his surgical experience in two cases. In one patient he attempted two discissions with rather poor results. After absorption of the lens substance, the central membrane was cut by means of de Wecker's scissors through a keratome incision. In the second case three discissions were performed but they were only partially successful. In the fourth operation, de Wecker's scissors were used to cut through the central membrane.

The first operation in these cases should be a discission through the existing lens substance and through the membrane, thus allowing the lens fibers to absorb. As Haro[3] has pointed out, in most cases the membrane is firmly adherent to the rest of the lens and is too tough to be cut with an ordinary discission needle. For this reason it would seem advisable to use the Wheeler knife-needle and to do the procedure in the manner described by Wheeler.[27] If this does not succeed it would seem that the use of the de Wecker or Berens scissors would be the next step.

Total extraction must be considered with caution as in some of these cases the central portion of the membrane is adherent to the hyaloid and extensive vitreous loss may follow this procedure as described by Malbran and Tosi.[29]

Rubella cataract. This type, which has been recognized as an entity in the last few years, deserves special consideration. It must be remembered that these cases often have other congenital anomalies and that microphthalmus is a common finding and therefore the prognosis must be guarded.

As Reese[10] has stated the anterior chamber is particularly shallow and in many cases the very dense central portion of the lens has proved resistant to the needle, sometimes separating off as a firm disk. If needling is employed this disklike opacity should be removed from within the confines of the capsule and, if possible, broken up to rest in the anterior chamber where it will absorb.

This characteristic of the embryonal nucleus in some of these cases has been observed by Goar and Potts[30] and others. In some of the cases the entire lens is opaque and here the usual operative procedure is employed. We have employed linear extraction as described above in these cases and have encountered only the complications of other anomalies seen in these cases.

Absorption of the lens substance has been slower than that of the usual congenital cataract. In most of these cases it is difficult to dilate the pupils with any mydriatic and this is especially true after operation, so

that in a certain percentage, there is an occlusion of the pupil in spite of all attempts at mydriasis. Glaucoma is one of the complications encountered.

Ether anesthesia has been used in these cases in spite of the presence of heart lesions. Goar and Potts,[30] Reese,[31] and Ellett[32] all agree that these patients stand general anesthesia well in spite of the presence of the heart lesion. Post[33] in one case used local anesthesia without difficulty. Cocaine was used as instillations as for a needling operation. The baby was firmly held and the operation performed on each eye without apparent pain to the infant and no operative difficulties were encountered.

The prognosis must always be guarded in these cases, as it is impossible to state whether or not other ocular defects are present or will develop.

Persistence and hyperplasia of the primary vitreous (retrolental fibroplasia). While this condition is, strictly speaking, not a cataract, it is associated with the lens and often is accompanied or followed by lens opacities and therefore warrants discussion here. On the theory that the condition resulted from failure of production of the aqueous, Terry[34] attempted to establish new vascular connections between the ciliary body and the episclera by scleral trephination over the ciliary body and reported some improvement in this condition.

The most important work on the subject is that done by Reese and Payne.[35] On a premise that some of these eyes might see, they made an effort to salvage 6 eyes in 6 cases. Their procedure was to remove the lens substance by repeated discissions and finally to make a vertical cut in the retrolental fibrous tissue with de Wecker's scissors.

Very little seems to happen when the lens capsule is opened, so that the capsule opening can be made extensive without fear of undue or too rapid swelling. After the lens substance had been dissipated for the most part, a central vertical incision was made through the remainder of the tissue with de Wecker's scissors. This was followed by hemorrhage in the anterior chamber with absorption in the due course of time.

In one instance they used three discissions and two incisions with de Wecker's scissors. In 2 of the 6 cases there was some vision, which it was believed came from the operated eye. While the results, according to the authors, leave a lot to be desired, the procedure may develop into one that may be helpful in these otherwise desperate cases.

Cataracts following intra-uterine inflammation. The prognosis is very bad in those cataracts with firm posterior synechias resulting from intra-uterine inflammation. Experience has shown that any operative procedure in these cases is "invariably followed by inflammation and fibrosis."[30]

Summary

In the surgical treatment of congenital cataract, it is important to remember that 50 percent of the patients have other ocular congenital anomalies and that therefore the prognosis must be guarded. In addition other general congenital anomalies are often present.

As a rule a visual acuity of 20/40 or better would seem to be a sufficient contraindication for surgery inasmuch as the wearing of the heavy disfiguring lenses is in itself a definite handicap to the growing child. In some instances, as in the lamellar cataract, the opacity may increase in density so that later surgery is necessary.

From personal experience, and from the literature, it would seem that in those cases of bilateral congenital cataract where the opacities are sufficiently dense to interfere with the development of fixation, the first eye should be operated upon at six months so that the child may develop this faculty and thus avoid nystagmus. The second eye should be operated upon between the 2nd and 4th year. When the cataracts are of

sufficient density to interfere with the child learning to read, they should be operated upon before the school age.

In discussing surgery of congenital cataracts with the parents, it is well to remember that only approximately 50 percent of the cases develop a postoperative vision of 20/100 or better.

The personal choice of operation in soft congenital cataracts is the linear extraction as modified by Otto Barkan. The important modifications are the injection of adrenalin (1:1,000) at the limbus at the site of the incision, to prevent the iris from becoming involved; and the making of the incision parallel to the iris surface and 1 to 2 mm. inside the cornea. In addition it has been found that the injection of air into the anterior chamber at the completion of the operation is an important factor in the prevention of the formation of anterior synechias or incarceration of the iris. The importance of a deep anterior chamber when the patient leaves the operating room has been stressed by Barkan and cannot be emphasized too much.

In certain types of congenital cataract, the discission as advocated by Wheeler is indicated, particularly in the congenital membranous cataract.

In the disk-shaped cataract where there are two types present (membranous central portion and peripheral soft cataract), a discission followed later by an incision through the membrane with Berens or de Wecker scissors is usually necessary.

In rubella cataract, in addition to the possibilities of other anomalies being present, it is well to remember that the absorption of the lens substance is slower than that of the usual congenital cataract and that in most instances it is difficult to dilate the pupil with mydriatics.

In persistence and hyperplasia of the primary vitreous it is possible that repeated discission of the lens substance, finally followed by making a vertical cut in the retrolental fibrous tissue may offer some hope in these otherwise hopeless cases.

The surgical treatment of congenital cataracts is a grave responsibility as the outcome of the operation is instrumental in determining the individual's future position in society. A thorough knowledge of the types of congenital cataracts, combined with a detailed study of the case in hand, is important in making the decision as to whether or not surgery is indicated. If surgery is indicated, this knowledge is useful in determining the age at which the operation is to be performed and the type of surgical procedure to be employed.

PREVENTION AND MANAGEMENT OF COMPLICATIONS OF CATARACT EXTRACTION*

JACK S. GUYTON, M.D.
Baltimore, Maryland

A comprehensive review of complications of cataract extractions was published by Berens and Bogart,[1] in 1938, and this study was supplemented by Kirby[2] in his 1941 paper on the practical aspects of both operative and postoperative complications.

Statistical analyses of the results and of the complications from senile cataract extractions performed in the Wilmer Institute between 1925 and 1943 have been recorded in careful detail by Hughes and Owens.[3, 4] They were able to divide the extractions performed during that period into five main types, with each subsequent type giving better results than the preceding one: (1) Combined extracapsular extractions with corneal sections and no sutures, (2) combined extracapsular extractions with conjunctival flaps and sutures, (3) combined intracapsular extractions with conjunctival flaps and sutures, (4) combined intracapsular extractions with one (rarely two) corneoscleral sutures, and (5) intracapsular extractions with peripheral iridotomy and two (rarely one) corneoscleral sutures. The last type of extraction gave significantly better final results than any of the first four types.

The statistical comparison of these groups is subject to one criticism; namely, each of the five types of extraction was in successive general preference during five successive eras of the period covered by the study and, therefore, minor refinements in operative technique, preoperative care, and postoperative care may have accounted for some of the improvements in results. Nevertheless, the conclusions of Hughes and Owens are certainly valid in general and the procedure of choice for extracting senile cataracts is intracapsular with peripheral iridotomy and two corneoscleral sutures.

This present report purposes to supplement the studies of Hughes and Owens by elaborating upon details of cataract extraction which do not lend themselves to ready statistical analysis. In most instances, the procedures herein advocated represent current preferences of the Wilmer Institute staff as a whole, such procedures having come into general usage as a result of cumulative experience.

PREOPERATIVE MANAGEMENT

PREVENTION OF PSYCHOLOGIC COMPLICATIONS

Prior to operation the patient should be told exactly what he must go through, what are the chances of a successful extraction, and what he can expect in terms of vision provided the operation is anatomically successful.

He should understand that (1) aphakic vision is so different from phakic vision as to require an appreciable period of adjustment (longer in elderly patients than in younger ones), (2) an aphakic eye can rarely ever be used together with a phakic eye with a correcting lens for each eye, (3) an aphakic eye is devoid of accommodation, and (4) when the initial correction is obtained for his aphakic eye he will be bothered by magnification, causing objects to appear closer than they really are, by peripheral distortion, and by limitation of the effective visual field. Limitation of effective field necessitates turning the head rather than the eyes. It is a permanent handicap, probably

* From the Wilmer Ophthalmological Institute of The Johns Hopkins Hospital and University. Presented before the Section on Ophthalmology of the American College of Surgeons, New York, New York, September 9, 1947.

the most unpleasant feature of aphakic vision.

The patient should be told of any abnormality, such as senile macular degeneration, which would impair the visual result, or of the possibility of any suspected but nonvisualized abnormality such as retinal detachment.

Choice of anesthetic

Local anesthesia is used except in special instances. Nembutal (0.1 gm.) is given by mouth two hours, and again one hour, before operation. Homatropine (2-percent solution) is instilled one hour before operation. Cocaine (4-percent solution) and neosynephrin (10-percent solution) are instilled alternately very two minutes preceding operation. About 5 minutes before operation, akinesia of the orbicularis is obtained with an O'Brien or van Lint block. My personal preference is for a slightly modified O'Brien block: This consists of injecting 4 cc. of 4-percent novocaine containing adrenalin (1:20,000) through a 2.0 cm., 25-gauge needle into both deep and superficial layers at the site preferred by Benedict, which is 1.5 cm. from the middle tragus on a line from the middle tragus to the upper lip. A retrobulbar injection of 1.5 cc. of 4-percent novocaine and 1:20,000 adrenalin is given deep within the muscle cone, using a 3.5 cm., 22-gauge needle.

A general anesthetic is indicated if the eye is unduly prominent or if there is increased intraorbital tension (resistance of the globe to being pressed back into the orbit). In these cases, a general anesthetic reduces the chance of loss of vitreous. General anesthesia is also indicated for uncooperative adults, and is of course necessary for children. Sodium pentothal is preferable in adults and ether in children.

Prevention of infection

Routine conjunctival cultures are of doubtful practical value, but care is taken that the lacrimal drainage apparatus is patent, that there is no clinically apparent conjunctivitis or blepharitis, and that there is no upper-respiratory infection.

Prevention of infection is dependent largely on the care with which the operative field is prepared, provided aseptic operative technique (including the use of drapes, gloves, gown, mask, and cap) is followed. Our present routine procedure is as follows: Two hours before operation, and again one hour before, argyrol (20-percent) is instilled (to coagulate mucous) and the conjunctival sac is irrigated with normal saline. The lashes are cut, the skin and brow are scrubbed with soap and water, the conjunctival sac is irrigated copiously with saline, and the lid margins, skin, and brows are painted with tincture of iodine followed by alcohol. Iodine is preferred because we found cultures of the skin of the lids at the close of operation rarely showed any growth when tincture of iodine was used, but frequently showed growth (usually staphylococci) when either tincture of merthiolate or tincture of metaphen was used.

Choice of operative techniques

The Parke lid speculum is most satisfactory, especially because a superior rectus bridle suture can be attached to the post on the upper arm of the speculum; more secure and dependable fixation is attained with a suture adjusted in this way than if it is clamped to the drapes or held by the assistant.

For uncomplicated cases a shallow incision, with a Graefe knife, of between two fifths and one half the circumference of the cornea is preferred. A mature or almost mature lens with a dense nucleus requires a slightly larger section than does an immature or hypermature lens. Also, in a very old patient the lens is generally larger and requires a larger incision than in a younger patient.

If there are many cornea guttata (endothelial dystrophy) there is an appreciable chance of persistent epithelial edema after operation. In these cases I believe the possibility of this postoperative complication is re-

duced by use of a small, deep section, and that such a section is indicated even though there is an increased risk of postoperative hemorrhage. Severe or prolonged diabetes, or purpura, indicates a section in clear cornea. A small incision with a knife or keratome, and enlarged with scissors, is preferable if the anterior chamber is very shallow.

If there is an elevated intraocular pressure which does not fall after the retrobulbar injection of novocaine and adrenalin, a posterior sclerotomy should be done before the incision is made. If there is an obliterated anterior chamber, either of two procedures may be used. The first, which I prefer, is the injection of air into the anterior chamber, followed by the usual Graefe section. The second, more generally used, is an incision ab externo with the Lundsgaard knife, enlarged to proper size with scissors.

If there has been an external filtering operation for glaucoma, with a filtering bleb at the 12-o'clock position, the incision may be made: (a) through the filtering bleb, (b) in clear cornea in front of the filtering bleb, or (c) below. I prefer a Graefe incision beneath a prepared flap below, with two corneoscleral sutures. In the presence of a luxated or dislocated lens, the incision is usually best made above and the method of delivering the lens varied according to the position of the luxation.

Two corneoscleral sutures appear necessary for optimal closure of the incision, and more than two are usually redundant. Sutures inserted before section (preplaced) are preferred. Corneoscleral sutures inserted immediately following section (postplaced) shortens the time required for operation, but coaptation of the incision does not appear to be as uniformly perfect as with preplaced sutures. The Lindner[5] or McLean[6] sutures give tighter closure than the Stallard[7] type of suture.

McLean sutures are preferred by most members of the Wilmer Institute staff. I personally like a slight modification of the Lindner or McLean suture: This modification consists in making a partially penetrating incision or slot in the limbus, passing the sutures through from the corneal surface, across the slot and out the scleral surface and overlying conjunctiva. The needle should be carried across the slot in a radial direction, with the point being first engaged in the cornea about 1.5 mm. in front of the slot, passing across the slot at a depth of 0.2 to 0.3 mm., and emerging from the sclera about 1.5 mm. behind the slot.

A round-pupil extraction with one peripheral iridotomy at the 12-o'clock position, is planned for all cases except those (1) with active anterior uveitis at the time of operation, (2) with an inflammatory membrane covering part of the pupillary space, (3) with marked fibrosis of the iris, (4) where a biopsy of the iris is desired, (5) where glaucoma is also present, or (6) where vitreous is already present in the anterior chamber (as with dislocated lenses). In these instances a complete iridectomy is performed. If congestive glaucoma is present, the iridectomy is made large and basal. Posterior synechias are broken loose with a spatula before the lens is delivered. If there is a postinflammatory pupillary membrane, it is separated from the lens with a spatula and excised with a blunt-pointed scissors; a radial iridotomy is performed at the 6-o'clock position before the lens is removed. Separation of inflammatory membrane from the lens is best accomplished, without rupture of lens capsule, if a smooth cyclodialysis spatula is used; this is true even if there has been a severe inflammation such as sympathetic ophthalmia.

An intracapsular extraction is attempted in every case except that of a traumatic cataract with the capsule already ruptured. Congenital cataracts in children are not generally supposed to be suitable for intracapsular extraction. However, while the zonule is quite strong, the capsule is also generally very strong, and contrary to the usual custom I prefer to attempt intracapsular extraction. The lens is grasped near the lower equator with forceps and pulled hard enough to stretch the ciliary processes and bring the

lower zonule into view; the zonule can then be stripped from the lens with an iris spatula as the lens is tumbled. No undue reaction appears to result from thus stretching the ciliary processes.

The incision

With preplaced corneoscleral sutures, it is important for the surgeon to have forceps in one hand for any necessary handling of the sutures as the section is completed. The assistant should therefore fix the globe. He should grasp the bulbar conjunctiva near the lower limbus with curved fixation forceps and pull the tips of the forceps gently downward, not pressing backward, and avoiding any pressure on the globe. A completely untrained assistant can perform this fixation without danger, if he is trustworthy. He should be directed simply to hold the fixation forceps in the one desirable position. The surgeon himself can then release the forceps after he completes the section.

Preplaced sutures predetermine the plane of the section and actually make a Graefe section easier than if no sutures are present. A sharp point on the knife is necessary for a proper Graefe incision. One with a double-edged point facilitates both engagement and counterpuncture. The knife is engaged at the limbus, in the same position as the slot for the preplaced sutures. The blade is pushed across the anterior chamber just in front of the iris until the tip begins to disappear behind the opposite limbus. The tip is then elevated anteriorly until it engages the cornea, the counterpuncture is made, and the section is completed. Care is taken to follow the slot and not to tilt the knife blade. The knife is carried past the preplaced sutures one at a time, the slot being spread at each of these points by lifting the suture close to the corneal lip as the knife goes by.

Intracapsular extraction of the lens

Extraction of the lens with capsule intact depends in large measure on the instrument with which the lens is grasped. Forceps are preferred in all cases except for dislocated lenses or where the capsule is so tense it cannot easily be grasped.

In my opinion the best forceps are Castroviejo's adaptation of Arruga tips to Sinclair's cross-section forceps. However, the presently available forceps of this type vary considerably in strength, curvature of shank, size and shape of blades ("tips"), and coaptation of blades. In the same hands, some forceps rupture a large percentage of capsules, while other supposedly identical forceps rarely break one.

If the cross-action spring closes the blades too tightly, the capsule is likely to be torn, while too little tension will often allow the capsule to slip out of the grasp of the blades. Forceps exerting a pressure of about 150 grams between the blades are most satisfactory.

The blades should have no superior lips, so the capsule can be grasped beneath the lower border of the pupil without the iris being caught. Blades about 3 mm. in length are optimal. Perfect apposition of the blades on closure, with heel and tip of each blade meeting in unison and maintaining an evenly distributed tension on complete closure, is essential.

The blades must have no sharp edges and no tiny nicks or spurs. When closed on a calling card they should slide smoothly both vertically and horizontally, with about the same resistance to sliding in either direction, and should not scratch either surface of the card. The blades should be inspected occasionally with a slitlamp for tiny defects. If such defects are found, these should be smoothed out with rouge paper or the forceps should be discarded.

In the delivery of a lens with forceps, the pupil should be moderately or widely dilated. With a moderately dilated pupil, the closed blades are inserted beneath the iris at the 6-o'clock position, opened, and closed on the capsule in a position two-thirds the distance from the anterior pole to the equator. During this maneuver the end of the forceps

handle is held with thumb and forefinger of the left hand and the opening and closing of the cross-action spring (which requires appreciable pressure) is worked with the right hand. The right hand is then readjusted so the forceps fit in it much as does a pencil, and have no tendency to wobble even with the fingers almost completely relaxed. The left hand is then removed and used to manipulate the Arruga expressor.

The forceps blades are lifted anteriorly and upward to the center of the cornea and the strength of the lower zonule is actually felt. The actual grasping of the capsule and this movement of the forceps often initiates rupture of the zonule. If it does not, rupture of the zonule is started by point pressure on the tense zonule just below the lower limbus.

Once dislocation has begun, the curved portion of the expressor is used to press the lower portion of the cornea against the junction of the lower border of the lens and the vitreous. By a combination of traction on forceps and counterpressure directed more upward than posteriorly, the lower border of the lens is tumbled upward into the incision. As the lens is tumbled, the forceps are rotated backward in order to keep the blades parallel to the grasped surface of the lens. Often a gentle side to side motion of the forceps assists in breaking the zonule along the sides as the lens is tumbled. After the lens is tumbled it is lifted out of the incision with the forceps, while the expressor, which is now actually behind the lens, is used to press the cornea upward and forward against the lens to complete delivery.

Occasionally with a very soft eye and a very anterior incision, final delivery of the lens can be facilitated by having the assistant press gently backward on the scleral lip of the incision until the lens is halfway through the incision. Also, should the upper zonule rupture before the lens is tumbled (a rare occurrence), the lens can more easily be pulled out without tumbling if the assistant retracts the upper iris with a spatula or blunt hook. However, if the assistant is not thoroughly trustworthy, it is better to exert more traction with the forceps in lieu of having him execute these maneuvers.

Use of an erisophake is indicated when the capsule cannot easily be grasped with forceps, and for dislocated lenses. One bugbear about erisophakes should be dispelled: Some surgeons fear that if the erisophake should slip, vitreous may be sucked out. Actually, formed vitreous will not pass through the lumen of an erisophake even if tremendous negative pressure is applied.

Of the various suction devices, my personal preference is for the Dimitry erisophake because of its simple light construction, and the fact that the amount of negative pressure can be varied. The more fragile the capsule, the less suction should be used. The tip or suction cup of any erisophake should have no sharp edge and should be free of nicks or spurs, just as with forceps.

For removal of a cataract which is not luxated, the erisophake is manipulated in much the same way as forceps, grasping the lens in the same position and tumbling it with a combination of traction and counterpressure. In cases of partially dislocated lenses, the erisophake is applied adjacent to the dislocation (whether above, below, or on the side) and the lens delivered either by tumbling or by sliding, depending upon the site of the dislocation. This maneuver may be assisted by the insertion of a spoon behind part of the lens after it has been lifted anteriorly with the erisophake.

Operative complications

Probably the most frequent cause of disastrous complications in cataract extractions is nervous tension on the part of the surgeon. Some degree of nervousness is a perfectly natural reaction of any surgeon faced with the responsibility of a patient's vision, but it generally decreases as self-confidence is gained.

A number of authors have emphasized the importance of nervous tension to the point

even of laying down rigid rules of conduct for the operator. However, no set rules can apply to all individuals. Some surgeons are more at ease after much sleep, others after little sleep; much physical exercise (especially shortly before an operation) usually increases nervousness, but occasionally has the opposite effect; many surgeons are made tense by caffeine and therefore do not drink coffee on operating days, while others are calmed by caffeine. These and many other factors can only be evaluated by each man.

Observation by a colleague frequently causes some nervous tension, if the surgeon has great respect for the observer's opinion, and observation by a relative of the patient will often have the same effect. The surgeon is usually more at ease if he sits down and makes himself as comfortable as possible while operating, takes advantage of every available rest to steady his hands while undertaking the more delicate maneuvers, and uses those techniques for cataract extraction he believes will in his hands give the least chances of complications. Thus a surgeon who does not feel confident with a Graefe knife can make equally satisfactory incisions, at the expense of very little additional time, by the use of keratome and scissors; and one who is not ambidextrous can use the better hand for performing the section or grasping the lens in either eye.

The complications of cataract extraction which actually become apparent during operation are as follows, in order of their importance:

A. Vitreous loss

Loss of strictly fluid vitreous is of no consequence. Such loss can generally be inferred rather than seen. It is manifested by immediate reformation of the anterior chamber as the lens is delivered. In most eyes with "fluid" vitreous only the anterior vitreous is strictly fluid (by virtue of partial collapse posteriorly of the normal vitreous structure, or sheets), and if more than a certain amount of the truly fluid vitreous escapes from the eye, formed vitreous will then begin to emerge.

Loss of any formed vitreous causes some degree of vitreous opacities, renders impossible the preservation of a round pupil, and greatly enhances the probabilities of postoperative inflammation ("uveitis"), of postoperative glaucoma, or of late detachment of the retina. These undesirable sequelae follow in more or less direct ratio to the amount of formed vitreous which is lost. By "formed" vitreous is meant any vitreous which possesses recognizable structure, as contrasted with strictly "fluid" vitreous, which is indistinguishable from aqueous except for being slightly more viscous.

The unfortunate sequelae of vitreous loss are dependent not on the eye's actually being devoid of some vitreous, but on distortion of the remaining vitreous structure and especially on incarceration in the incision of the remaining vitreous sheets, which are still attached to the posterior segment of the eye. This incarceration results in delayed complete healing of the incision, with connective-tissue proliferation (and subsequent contracture) extending from the incision for some distance along the vitreous sheets. This fibrosis may block part of the angle, irritate the adjacent ciliary body, and exert traction on the retina via the vitreous sheets.

Vitreous loss is very seldom encountered if there is no pressure on the eye. Thus in a "soft" eye there is little or no danger of vitreous loss unless there is grossly improper counterpressure on the eye, or actual instrumental removal of vitreous. Although some surgeons have expressed a dislike for a "soft" eye because of difficulty in delivering the lens, this has not been our experience.

Avoidance of pressure depends on (1) akinesia of the orbicularis, (2) akinesia of the extraocular muscles, (3) an adequate palpebral fissure, and (4) lack of excessive retrobulbar bulk.

1. Complete akinesia of the orbicularis can be attained in a very high percentage of

cases by the slightly modified O'Brien block. Closure of the lids is tested just prior to beginning the operation; should akinesia be imperfect, a van Lint injection of novocaine should be given just outside the lateral orbital margin.

2. *Complete akinesia of the extraocular muscles* is only occasionally attained with a retrobulbar injection of novocaine, but partial akinesia is the rule if the injection is given deep in the muscle cone. In a series of cases where 1 cc. of 2-percent pontocaine solution was used for retrobulbar injection, better akinesia resulted than with 4-percent novocaine. However, such injections of 20 mg. of pontocaine are probably inadvisable as a routine procedure because of the very occasional idiosyncrasy to the drug.

Adrenalin or some other vasoconstrictor should always be a part of the retrobulbar injection. Otherwise, slight edema of the posterior orbit is likely to result.

Ballooning the bulbar conjunctiva by the injected novocaine indicates the retrobulbar injection was not in the muscle cone. In such an instance, a further injection of 1 cc. more of novocaine may be given, provided the eye is not unduly prominent.

3. *A tight palpebral fissure* should be remedied at the start of operation by a large, deep lateral canthotomy. A Parke lid speculum holds the lids open better than any other speculum we have found. Also, it does not slip out of place and the blades do not press on the globe. Some surgeons insist on lid sutures in lieu of a speculum, or on a speculum which can be removed very quickly in the event of vitreous loss. The logic of this contention is not clear. When corneoscleral sutures are used, the lids must certainly be held open until the incision has been properly closed. After the incision is closed, the speed with which the speculum is removed is of no consequence.

4. *Lack of excessive retrobulbar bulk.* If the eye is very prominent, or if there is excessive intraorbital resistance, a retrobulbar injection will cause a further increase in the orbital contents with increased pressure on the globe. In such patients general anesthesia is preferable.

Orbital hemorrhage from retrobulbar injection is very rare, but may occur if the needle is inserted too close to the globe and hits the inferior oblique muscle. Hemorrhage in the orbit, manifested by proptosis and by ecchymosis of the conjunctiva, is usually evident before the operation is started. In such cases operation should be postponed.

After section has been made, if there is increased orbital pressure, it is manifested by forward prolapse of the lens-iris diaphragm against the back of the cornea. Extreme pressure even causes bulging of the iris into the incision, and spells danger of vitreous loss. When this happens, the speculum blades and superior rectus suture should be readjusted to give as little pressure as possible. As the lens is tumbled and delivered, the cornea should be kept pressed against the back of the lens with an Arruga expressor, thus holding back the vitreous. The sutures should be tightened immediately following delivery, before repositing the iris.

If there is actual loss of vitreous and the lens is delivered with intact capsule, the sutures should be tightened as quickly as possible. The iris will then either be prolapsed into the incision or folded backward. If it is prolapsed, a complete iridectomy should be performed and the pillars reposited. If it is folded backward, nothing should be done to the iris; the final pupil will be displaced upward and have the appearance of an iris coloboma, but the folding back of the iris does not in itself cause irritation.

B. Rupture of lens capsule

Rupture of the capsule during delivery makes complete removal of the lens material more difficult. Retained lens material may necessitate subsequent discission or capsulectomy, procedures far from benign. Also, the chances of postoperative "uveitis" and/or glaucoma are considerably enhanced. Reten-

tion of much lens cortex is rare except when the capsule of an immature lens is ruptured. Fortunately this is a rare occurrence. The capsules most easily ruptured are those of densely white, swollen, mature, or slightly hypermature cataracts.

When the capsule ruptures, as it will in a variable percentage of cases, the method of extraction varies according to the position of the lens when the rupture occurs. If the lens has already tumbled, it may often still be delivered in toto by taking another larger grasp with the forceps. If it has not started tumbling, the nucleus should be expressed and as much as possible of the cortex removed by irrigation. Then, if the eye is "soft," the residual capsule can usually be removed, without appreciable danger of rupturing the anterior hyaloid membrane, by sliding Arruga forceps in with the faces of the blades *parallel* to the iris plane and grasping the capsular remnants (fig. 1). Removal of capsule is then often facilitated by using two Arruga forceps, taking successive bites in the capsule as it is pulled out through the incision. If there is any pressure on the eye, with apparent danger of vitreous loss, residual capsule had best be left alone. An iridectomy is not necessary.

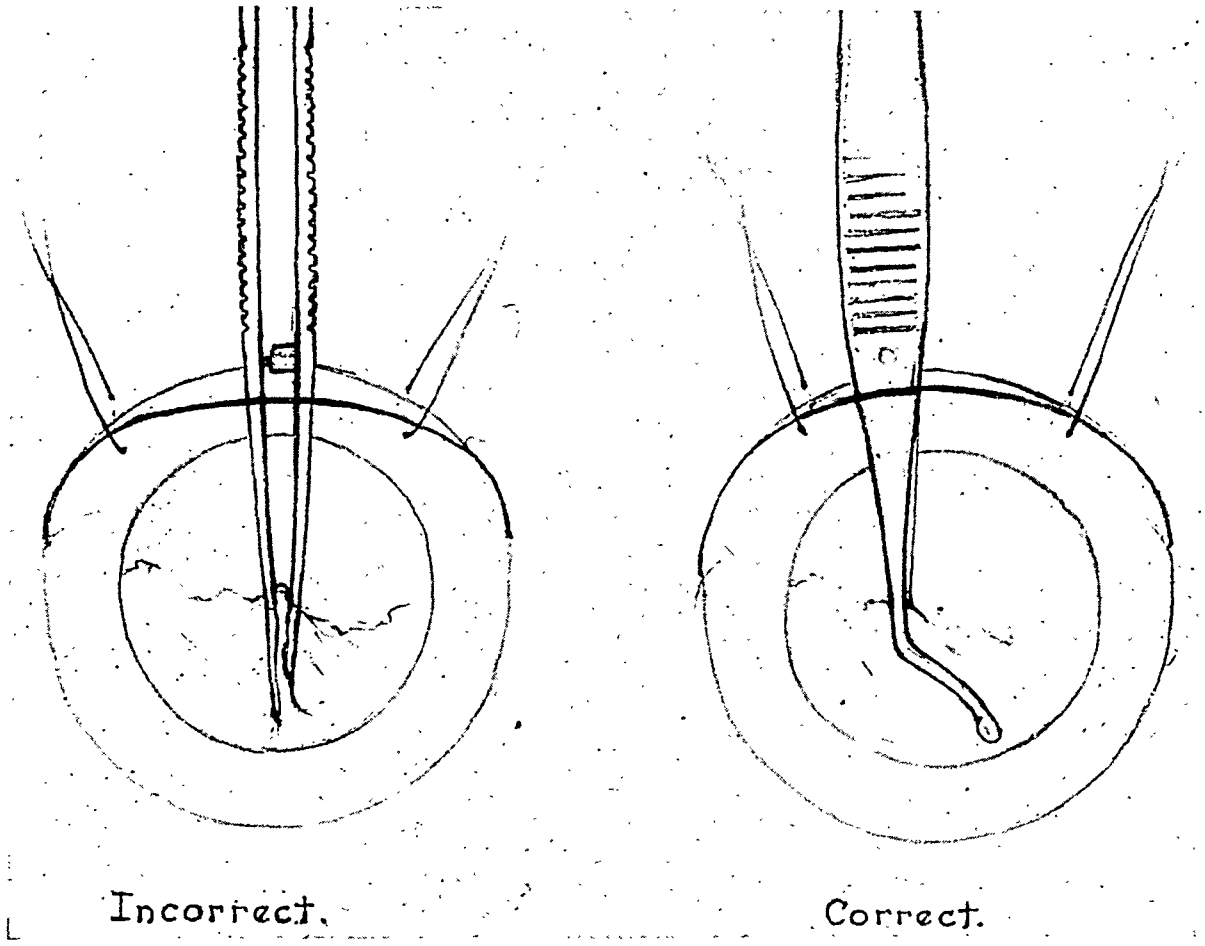

Fig. 1 (Guyton). Removal of capsular remains after rupture of lens capsule.

C. Vitreous loss plus rupture of capsule

If the lens capsule ruptures and vitreous begins to emerge at about the same time, the iridectomy usually should be completed. Lens material should then be removed by means of forceps and/or spoon, avoiding irrigation. The bulk of the lens material must be removed, but it is not advisable to

remove all lens capsule if such a maneuver can only be accomplished at the expense of much loss of vitreous. The corneoscleral sutures should then be tightened as quickly as possible, the iris pillars reposited, and judicious prayer indulged in.

D. Difficulties with section

Care should be taken immediately preceding section that the superior rectus suture has not been placed improperly and has not slipped.

With the assistant fixing the globe, it is quite rare that a suture is cut with a Graefe knife. If one or both sutures are inadvertently cut, the sutures are simply reinserted before the lens is delivered.

If the knife is tilted improperly, or if it has a defective blade which prevents it from cutting smoothly, aqueous may be lost before the counterpuncture is made and the point may become entangled with iris, back of cornea, or even lens. In this event, the knife should be removed, the chamber filled with air, and the section started over again. The same remedy should apply if a Graefe knife is carelessly inserted backward.

The anterior chamber may collapse after the counterpuncture but before the section is completed, with prolapse of iris in front of the knife (1) if the surgeon tilts the knife improperly and allows aqueous to escape too soon, or (2) if there is excessive orbital "pressure."

In the former instance, the iris can either be milked back over the edge of the knife or the chamber can be filled with saline or air with the knife in place. The section can then be completed without cutting the iris.

In the latter instance, a stream of saline directed along the knife may keep the iris out of the way or it may be necessary to remove the knife and complete the section with scissors. Stevens' scissors, inserted with the curve *downward,* are preferable for completing or enlarging a section. It is never necessary to go ahead and cut the iris with the knife.

E. Expulsive hemorrhage

An explusive hemorrhage during operation almost always results in loss of vision, with such disorganization of the globe that it should be enucleated as soon as permission can be obtained. Only extremely rarely can an eye be saved by immediately tying the corneoscleral sutures and evacuating the choroidal hemorrhage through a posterior sclerotomy several days later.

F. Partial dislocation of lens before it is grasped

Very occasionally the lens will partially dislocate at the time of the section, before the forceps are applied. This may be accompanied by spontaneous prolapse of vitreous into the anterior chamber. In this case it is best to perform a complete iridectomy and remove the lens with an erisophake and/or loop.

G. Complete posterior dislocation of lens

With extreme rarity an intact lens may dislocate completely and sink into the back of an eye. This occurs only if the vitreous is fluid. Such an eye is best closed without attempting to remove the lens. The lens can be removed later if the eye remains irritated. If removal is necessary, it may be possible to trap the lens in the anterior chamber, or it may be necessary to remove it by means of irrigation and a loop or a hook, or even by opening the eye and then turning the patient face downward while extracting the lens. If the lens capsule is ruptured, a posteriorly dislocated lens should be removed immediately.

H. Bleeding into the anterior chamber

Bleeding into the anterior chamber during operation generally occurs before delivery of the lens. The blood comes either from the incision or from a small iridodialysis. In either event, the bleeding should be allowed to stop completely and the blood removed from the anterior chamber before the

lens is delivered. Hemorrhage is rarely a result of inadvertently grasping iris with the intracapsular forceps and tearing the iris root, or from too forcible use of a spatula for reposition of the iris.

I. Incarceration of iris in incision

If the corneoscleral sutures are tightened before the iris is reposited, strands of iris are likely to be drawn into one or more of the suture tracts. The iris should be smoothed back into place before the sutures are actually tied. Care should be taken to free the iris strands with a spatula; otherwise the pupil will subsequently be "peaked."

J. Distribution of iris pigment

If considerable iris pigment is dislodged during an otherwise uneventful extraction, the anterior chamber should be irrigated gently.

Postoperative management

Eserine (¼-percent solution) is instilled once or twice, and a monocular dressing with shield is applied. If there has been rupture of the lens capsule, or if the patient has any chronic injection of conjunctiva or lid margins, an antibiotic is administered systemically as a prophylactic measure for several days. He is allowed out of bed the day of operation. Atropine (1-percent solution) is instilled the day following operation and the pupil is kept about medium size thereafter until the aqueous ray is negative.

The corneoscleral sutures are removed not earlier than the 11th postoperative day. After thoroughly anesthetizing the eye with instillations of 4-percent cocaine solution, the knot of each suture is cut with the sharp tip of iris scissors, with the scissors pointed upward, before the suture is grasped with forceps. If the patient has a tendency to squeeze the eye, removal of the sutures is delayed a week or longer. Induction of akinesia by means of an O'Brien block is occasionally advisable.

If vision in the other eye is very poor, a temporary lens is prescribed within two weeks after operation.

Postoperative complications

A. Infection, uveitis, lens sensitivity

These three complications are grouped together because a clear-cut distinction between them is not always possible.

A purulent infection will rarely develop around a corneoscleral suture. It is manifested by infiltration around the suture and is an indication for immediate removal of the suture, plus antibiotics. Failure to remove the suture promptly may lead to purulent endophthalmitis.

Purulent endophthalmitis may occur without relation to sutures, apparently from introduction of bacteria into the eye at the time of operation. Only a few years ago almost all eyes with postoperative purulent endophthalmitis were lost. The majority are now saved by the use of antibiotics.

The terms postoperative "uveitis" or "iritis" indicate merely a nonpurulent intraocular inflammation. Such inflammation may result either from undue traumatism, imperfect healing, or a very low-grade infection. Antibiotics are rarely beneficial for these nonpurulent inflammations, but foreign-protein therapy often appears to help.

Lens sensitivity may develop if there is retained lens cortex. There is considerable evidence that the development of sensitivity is dependent on a low-grade infection, but this is not altogether clear. Lens sensitivity does not develop until at least six days after operation. It is manifested by marked inflammation of the anterior segment, with gradual formation of a cyclitic membrane. The patient usually shows a positive skin reaction to 0.1 cc. of 2-percent lens protein injected intracutaneously. Such a skin test should be read 48 hours after injection.

If development of lens sensitivity is recognized early, the eye should be opened and the retained lens material removed as completely as possible with forceps, regardless of vitreous loss. In any event, the patient should

be desensitized. For this purpose, injections of 0.1 cc. of 2-percent lens protein plus staphylococcus toxin are given twice a week. The concentration of staphylococcus toxin employed depends on the patient's reactivity to test doses; a 1:100 dilution is most frequently used. Desensitization is carried out for at least six weeks prior to extracting a cataract from the other eye, as prophylaxis in case its capsule ruptures.

B. Glaucoma

Glaucoma following cataract extraction may result from postoperative uveitis or from extensive anterior synechias. Such synechias may result if the anterior chamber remains flat for a few days during the healing period. Collapse of the chamber is uncommon with the use of two corneoscleral sutures, but it very occasionally does occur, usually with an associated combined detachment, at any stage before the sutures are removed and especially at the time they are removed. If it remains collapsed for as long as three days, it should be reformed with air.

If postoperative glaucoma cannot be controlled with drugs, the operation of choice should usually be a cyclodialysis.

C. Anterior-chamber hemorrhage

A postoperative anterior-chamber hemorrhage usually results from rupture of newly formed capillaries in the healing incision. It may occur at any time within 2 or 3 weeks after operation, usually in 4 to 6 days. Such hemorrhages almost always clear completely, but some blood usually seeps into the vitreous and absorbs rather slowly. Blood should be evacuated from the anterior chamber only if it fills the chamber, has definitely clotted, and shows no appreciable absorption after 3 or 4 days.

D. Detachment of retina

A simple detachment of the retina is considerably more common in an aphakic than in a phakic eye. Hughes and Owens found it occurred 10 times as often after marked loss of vitreous as after no vitreous loss, but no more often following intracapsular extractions than following extracapsular extractions. The prognosis for reattachment of the retina in an aphakic eye is not as poor as is widely believed. Almost 30 percent of such retinas can be reattached with one diathermy operation, and almost 30 percent of those reoperated can be reattached with a second operation.[8]

E. Prolapse of iris

Iris prolapse is extremely rare if two properly placed corneo-scleral sutures are used. It is no more frequent with merely a peripheral iridotomy than with a full iridotomy. If an iris prolapse is small and is completely covered with conjunctiva, it need not be repaired. If it is large or not covered with conjunctiva, it should be excised as soon as it occurs and an additional corneoscleral suture inserted.

F. Capsular remains, occlusion of pupil, displacement of pupil

If the lens ruptures and there is retained capsule, the capsular remains may be dense enough to require a discission or capsulectomy as soon as absorption of lens cortex is obviously complete. Even more frequently, a retained posterior capsule which is initially transparent may in later years develop Elschnig bodies and require a discission.

Postoperative uveitis may result in an occluded or displaced pupil, or incarceration of iris or vitreous in the incision may cause the pupil to be grossly displaced. In such instances, a central pupillary opening may have to be made with a discission knife or with scissors.

G. Rupture of anterior hyaloid membrane

Over 50 percent of patients who have round-pupil intracapsular extractions develop a break in the anterior hyaloid membrane some months after operation. The incidence is lessened if the pupil is kept me-

dium-sized and mobile, instead of widely dilated, during convalescence. Usually the rupture causes no symptoms, but occasionally it produces transient signs of mild iritis and vitreous opacities. In such a case, the pupil should be kept dilated for a few weeks.

H. Miscellaneous

Gaping of the incision and/or filtering bleb is so rare with two corneoscleral sutures as to be of no real significance. We have never seen epithelization of the anterior chamber following an extraction with even one corneoscleral suture.

Striate keratitis rarely persists more than a few days after operation, but persistent striate keratitis and/or epithelial edema occasionally results if there was preëxisting endothelial dystrophy of the cornea, undue traumatism to the posterior surface of the cornea, or loss of vitreous. Epithelial edema may sometimes be partially alleviated by the use of a 5-percent sodium-chloride ointment.

Development of drug sensitivity, especially to atropine, is annoying but seldom of real importance; local use of one of the antihistamine compounds, such as 2-percent pyribenzamine ointment, is of value in controlling the reaction. Excessive astigmatism can result from improper coaptation of the incision. Sympathetic ophthalmia is extremely rare.

CENTRAL CONTROL OF INTRAOCULAR PRESSURE BY ACTIVE PRINCIPLES*

ERNST SCHMERL, M.D.,† AND BERNHARD STEINBERG, M.D.
Toledo, Ohio

In a previous publication[1] we submitted experimental evidence to indicate the presence of a diencephalic center or centers which exercise a regulating control of intraocular pressure. The nature of this regulation is the subject of the present paper.

It was noted in some of our preliminary investigations that spinal fluid appeared to exert a variable action upon intraocular pressure. Exposure of the animal either to light or to darkness was one of the environmental factors which determined the change. A cyclic variation of tension in man during day and night has been observed by Thiel,[2] Schoenberg,[3] and others. The tension was found to fall during the day and to rise at night. Duke-Elder[4] suggested as possible causes the effect of extraocular muscles, the pumping action of the ciliary muscle on the scleral spur, redistribution of blood, and change in its osmotic value.

Exposure of eyes to light has been shown to result in a fall of tension, whereas, darkness induced an increase. The mechanism for this effect has been ascribed to constriction and dilatation of capillaries.[4] On the basis of these, as well as our, observations, we decided to investigate the relationship of light and dark exposure to changes in intraocular pressure and to diencephalic centers.

MATERIALS AND METHODS

Rabbits and ducks were the subjects used in these experiments. The intraocular pressure was determined tonometrically. Two of the rabbits had congenital hydrophthalmus. All the other animals were normal and varied from 14 months to 2 years of age. The animals were exposed for 4 hours to bright daylight in addition to a 300-watt bulb placed 50 cm. from the cage. In producing dark adaptation, the animals were kept for 12 to 15 hours in total darkness. Volumes of 0.5 to 0.7 ml. of spinal fluid from rabbits and 3 to 6 ml. from people with light and dark adaptation were injected intravenously into rabbits. Intraocular pressure was determined at 10-minute intervals for 1 hour. In a small number of experiments, aqueous humor from rabbits' eyes was injected intravenously, and crude water extracts of the anterior and posterior lobes of rabbit pituitary gland was administered subcutaneously. These rabbits were exposed either to light or to darkness.

In order to determine the variations of tension to light and to darkness, 10 normal rabbits were placed in total darkness and then exposed to light on 26 occasions. The intraocular pressure was determined under similar conditions in two normal ducks and in two hydrophthalmic rabbits.

RESULTS

The intraocular pressure was increased in normal rabbits transferred from total darkness to bright light. In most instances, the increase consisted of 3 or more millimeters of mercury, which was considered a significant change.[5]

In normal ducks, the intraocular pressure decreased upon exposure to light from darkness. The decrease was of 3 or more millimeters mercury. The ducks reacted in a manner similar to man. A reverse reaction had taken place in rabbits (Table 1).

In rabbits with congenital hydrophthalmus, there were no significant changes in tension upon exposure to light. The tension became increased in 3 out of 16 experiments.

When spinal fluid was obtained from rab-

TABLE 1

CHANGES IN INTRAOCULAR PRESSURE DUE TO LIGHT ADAPTATION*

Type of Animal Tested	Number of Animals	Number of Experiments	Range Tension in Darkness in mm. Hg	Range Tension in Light in mm. Hg	Difference in Tension between Dark and Light	
					Number of Experiments	Tension
Normal rabbits	10	52	10 to 28	19 to 31	41 11	+3 to 8 0 to +2
Hydrophthalmic rabbits	2	16	11 to 25	11 to 23	7 6 2 1	0 − 3 +10 + 3
Normal ducks	2	15	15 to 23	11 to 17	1 5 9	− 2 − 3 −4 to −7

* Conclusion: In adapting itself from darkness to light, the intraocular pressure rises in normal rabbits, is unaffected to some extent in rabbits with congenital hydrophthalmus, and is decreased in normal ducks

bits exposed to bright light and the fluid was injected intravenously into other rabbits, the tension became elevated 3 or more millimeters of mercury in most of the animals. On the other hand, spinal fluid obtained from rabbits kept in total darkness produced a reduction of tension.

Spinal fluid from people exposed to bright

TABLE 2

EFFECT OF INTRAVENOUS INJECTION OF SPINAL FLUID UPON INTRAOCULAR PRESSURE OF RABBITS*

Nature and Source of Spinal Fluid	Number of Experiments	Range of Tension in mm. Hg Before Injection	Range of Tension After Injection of Spinal Fluid	Difference in Tension Before and After Injection of Spinal Fluid	
				Number of Experiments	Tension
From rabbits exposed to light	14	15 to 25	15 to 29	9 3 2	+3 to 7 +1 to 2 0
From people exposed to light	6	21 to 31	16 to 25	1 4 1	−3 −6 −8
From people exposed to darkness	14	15 to 24	19 to 29	1 2 6 3 2	+7 +5 +4 +3 +2
From rabbits exposed to darkness	22	18 to 29	16 to 24	2 9 7 2 2	−5 −4 −3 −2 0

* Conclusion: Spinal fluid contains active principles which increase or lower intraocular pressure. Exposure to light or darkness is a factor which determines an excess of one or the other of the active principles. Spinal fluid from people has a reverse effect to that from rabbits.

light reduced the intraocular pressure in rabbits. Fluid obtained from people kept in darkness induced an elevation of tension in rabbits (Table 2).

Crude water extracts of the anterior lobe of the pituitary gland were injected into rabbits subcutaneously. The anterior-lobe extract of animals kept either in darkness or exposed to light showed an increase in tension in most of the experiments. There was no selective action. On the other hand, extracts of the posterior lobe of rabbits exposed to light increased the tension while extract of animals kept in darkness decreased it (Table 3).

The aqueous humor was removed from a number of rabbits kept either in darkness or in bright light. The humor was injected intravenously into other rabbits. No significant changes in tension took place.

Discussion

The experiments outlined in this paper indicate that there is a secretion of two active principles, probably by the posterior lobe of the pituitary body. One of the principles serves to raise and the other to lower intraocular pressure. The principles are secreted into the spinal fluid, apparently in in such quantities as to produce a balanced action upon tension. The experiments also indicate the influence of light and darkness in inducing greater secretion of one or the other of the active principles.

TABLE 3

EFFECT UPON THE INTRAOCULAR PRESSURE OF CRUDE EXTRACTS OF ANTERIOR AND POSTERIOR LOBES OF THE PITUITARY BODY REMOVED FROM RABBITS EXPOSED EITHER TO LIGHT OR TO DARKNESS*

Nature of Crude Extract of Pituitary Body	Number of Experiments	Range in mm. Hg of Intraocular Pressure Before Subcutaneous Injection of Crude Extract	Range in mm. Hg of Intraocular Pressure After Injection of Crude Extract	Difference in Tension Before and After Injection	
				Number of Experiments	Tension
Anterior lobe of rabbits exposed to light	10	15 to 24	20 to 26	1 3 1 4 1	+7 +5 +4 +3 +1
Anterior lobe of rabbits exposed to darkness	8	18 to 27	22 to 29	1 3 2 2	+10 +5 +3 −2 to −4
Posterior lobe of rabbits exposed to light	12	17 to 25	20 to 28	1 1 4 3 1 1 1	+7 +6 +5 +3 +2 +1 0
Posterior lobe of rabbits exposed to darkness	14	18 to 27	15 to 25	1 2 3 3 3 2	−6 −5 −4 −3 −2 −1

* Conclusion: These experiments with crude extracts suggest that the posterior lobe of the pituitary body secretes active principles which alter intraocular pressure in response to exposure to light or darkness.

Based in part on experiments reported previously,[1] as well as on the work in this paper, and partly on investigations still to be published, the mechanism of action of the active principles upon intraocular pressure has been formulated.

The mechanism consists of secretion of active principles, probably by the posterior lobe of the pituitary body. It is not unlikely that other areas in the region of the posterior lobe may be concerned with production of these principles. The active principles are thrown into the spinal fluid of the third ventricle and affect the autonomic diencephalic centers. The stimuli travel in the diencephalon and along the autonomic fibers to the eyes,[1] inducing among other effects either a dilatation or constriction of capillaries depending on the predominance of the type of active principle. Other investigators had demonstrated repeatedly[6-8] that a rise in intraocular pressure is associated with dilatation of capillaries and dark adaptation, whereas, a fall in tension follows capillary constriction and light adaptation. Feigenbaum[9] and others showed that changes of intraocular pressure in response to exposure to dark or light are not related to pupillary motility. Others workers failed to find any relationship to accommodation.

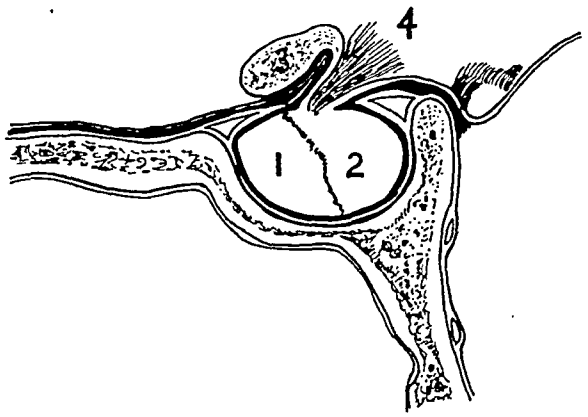

Fig. 1 (Schmerl and Steinberg). Anatomic relationship of the optic chiasma to the pituitary gland. (1) Anterior lobe of hypophysis. (2) Posterior lobe of hypophysis. (3) Optic chiasma. (4) Infundibulum. (After Gray's *Anatomy*, Philadelphia, Lea and Febiger.)

The mechanism of conduction of light and dark impulses from the retina to the posterior lobe may be explained on the basis of anatomic contiguity between the optic apparatus and the posterior lobe of the pituitary body (fig. 1) which, together with the tuber cinereum and the mammillary bodies, compose the hypothalamus.

Summary

Spinal fluid contains active principles, one of which increases and the other reduces intraocular pressure. Exposure of eyes to light or darkness is one of the factors which determines the quantitative secretion of one or the other of the active principles. On the basis of suggestive experiments, it is postulated that the active principles are secreted by the posterior lobe of the pituitary gland. These experiments indicate the probability that some forms of glaucoma may be induced by a disorder of the secretory mechanism of the active principles.

THE USE OF PLACENTAL EXTRACT IN THE TREATMENT OF HERPETIC KERATITIS AND SUPERFICIAL PUNCTATE KERATITIS*

BERNARD KRONENBERG, M.D.
New York

In therapeutics, the use of a homologous substance is rare. Most medications are plant extracts, minerals, or tissues of heterologous origin, rather than human tissue. An easily obtainable homologous tissue, one which contains a great number of important factors, is the human placenta. The placenta contains hormones, vitamins, enzymes, and antibodies in addition to many other factors. A tissue extract made from many pooled placentas contains a great variety of all these substances.

FILATOV'S WORK

Filatov[1] and his co-workers have reported the use of various types of tissues and tissue extracts. His work based on his theory that:

Tissues, which have been stored and treated under certain conditions, showed impaired viability, but these tissues became rich in substances which stimulate biochemical processes and regeneration. These substances have been called biogenic stimulators. The exact nature of these stimulators is unknown to us so far. These substances, when introduced into a diseased organism stimulate the regenerative processes of the organism and the pathologic processes diminish or disappear.

Filatov has reported the use of such extracts in a great variety of conditions. He has stated that they are especially valuable in such ocular diseases as retinitis pigmentosa, keratoconus, and optic atrophy.

The purpose of this paper is to make a preliminary report on the production and clinical uses of placental extracts. The work on which this paper is based has already occupied a year and a half, but it can be regarded only as ground work. Much remains to be done. To date we have been concerned with the following problems:

1. To break down the tissue extract into its component factors.
2. To determine, if possible, the nature of the biogenic stimulator.
3. To corroborate the work of Filatov.
4. To determine the effects of the use of tissue extracts on conditions not previously treated by this method.

PART I: PREPARATION OF PLACENTAL EXTRACTS

The technical method of the preparation of aqueous placental extract used in this investigation is essentially based on the method proposed by Filatov for the extraction of biogenic stimulators from homologous tissue. The biochemical work of making the various extracts was done by Dr. Edgar L. Milford of the Lederle Laboratories. An attempt was made to obtain uniform extracts in order better to evaluate the clinical results. The placental extract was first broken down into four factors:

* From the Eye Clinic of the New York Eye and Ear Infirmary. Read at the New York Society for Clinical Ophthalmology, May 5, 1947.

1. Aqueous extracts—containing water-soluble vitamins and hormones and most likely the biogenic stimulator.

2. Lipoid extract—containing cholesterin and lecithin.

3. Immune-gamma globulin—containing many antibodies found in human blood, and because of its pooled nature containing a greater variety.

4. Tissue coagulant—containing a factor which lowers the blood-clotting time.

Preparation of aqueous placental extract

Normal full-term placentas are transferred immediately after expulsion under aseptic precaution to sterile containers and placed in a freezer at 2°C. to 4°C. Only placentas from women with negative tests for syphilis and free from toxemia of pregnancy or any other disease transmissible by blood are used. The placentas are kept at 2°C. to 4°C. for two weeks prior to processing. After removal of blood clots and umbilical cord, the placentas are coarsely ground. The ground tissue is mixed with sterile distilled water in the proportion of 500 cc. per 450 gm. of placental mass. The mixture is stirred for one-half hour and then heated to 37°C., and the heat is maintained at that point for one hour. The mass is stirred constantly during the heating process. With the use of a hydraulic press at 70-tons pressure, the liquid portion is separated from the finely ground placental pulp and from coagulin formed during heating. The partly clarified extract is then sterilized by filtration through a 10-pound Mandel filter. This method of sterilization was judged less likely to effect the active principle than tyndallization in the event that the principle was thermolabile.

The stability of the extract being unknown, it was thought best to store the extract under conditions which have proved effective in minimizing the potency loss of other unstable biologic products. It was, therefore, concentrated into a dry powder, which was stored at 4°C. and used as the standard source of all therapeutic preparations in the investigation.

The aqueous extract found most satisfactory for clinical use was prepared by using 1 gm. of powder for 100 cc. buffered saline. The mixture was shaken and then dialized under aseptic precautions against three changes of saline. The protein content after sterile filtration was 4.9 percent. The extract was preserved by the addition of small quantities of phenol, which on comparative clinical studies was shown to have no effect on its potency. The clinical results obtained and reported in this paper are based on this dialized preparation.

It is interesting to note that the apparent effects of the extracts are consistently much greater when the placentas are first solidly frozen and stored for two to three weeks prior to processing than when the placentas are processed immediately after delivery. This seems to be in accord with Filatov's findings as to the importance of so-called unfavorable but not fatal conditions, such as storage at low temperature, in the development of biogenic stimulators.

The extract was also tested for its titers of immune antiviral and antitoxic bodies, before and after drying and heating. The overall diphtheria antiviral antibodies and influenza-A and B strains were less in the heated and vacuum-desiccated extract than in the original. Comparative fractional precipitation tests with ammonium sulfate showed that heating under the conditions described removed practically all the low beta globulins; whereas, gamma globulins and albumin were not affected.

It is also of interest to note that, despite prolonged dialysis against buffered saline, no appreciable loss of effect was found. This indicates that the active principle is probably in a colloidal condition or bound to a colloidal carrier.

Further attempts will be made to fractionate this standard extract with the view of recovering the active principle in some one fraction, which will be submitted to chemical

studies. The results obtained will be published at some later date.

Preparation of the lipoid extract

The lipoid extract was prepared in two fractions—ether and acetone soluble and acetone insoluble. The ether-acetone soluble fraction, which probably contains cholesterin, Factor A, was suspended in almond oil in 25-percent strength. This mixture was sterilized by passing it through a Sietz filter. The ether-acetone soluble fraction, found to contain mostly lecithin, was not used clinically because of the severe reactions it caused when injected intramuscularly in rabbits.

Preparation of immune globulin

This process will be described in detail in a paper to be published in the Journal.

To summarize briefly. Gamma globulins comprise about 11 percent of the plasma proteins and are found primarily in Fraction II, to a smaller extent in Fraction III.

Clinical interest in gamma globulin lies not in its physical constants, but in the fact that many of the antibodies elaborated by the defense mechanisms of the body are concentrated in this fraction.

Preparation of placental-tissue coagulant

The placental tissue coagulant is prepared essentially according to the method published by McKhann[2] in the *Journal of Pediatrics* for the treatment of hemophylia.

After placental tissues have been subjected to exhaustive saline extraction to obtain the immune globulin, the residue is extracted with cold phenolized saline at a temperature of 10°C. The pH of the mixture is adjusted to 9 with N/1NaOH, put through a homogenizer and allowed to stand in a cold room at 10°C. for 12 hours. The coarse placental tissue is separated from the extract with the use of a hydraulic press. The effluent is clarified by centrifugation through a Sharpless centrifuge. The clarified extract is precipitated at its isoelectric point (pH 5) by addition of N/5 hydrochloric acid, drop by drop, under constant mechanical stirring. The precipitate formed is allowed to settle in the cold room. It is suspended twice in acidified cold distilled water (pH 5.2). When the supernatant is colorless, the final precipitate is collected by centrifugation, then dissolved in weak sodium-hydroxide solution containing 0.5-percent NaCl The pH of the coagulant solution is adjusted to 7.5. This solution is centrifuged and sterilized by being passed through a medium Berkefeld filter.

The final coagulant solution in 1-cc. quantity will clot 1 cc. of reclarified horse plasma, with a control time of 10 minutes, in one minute. This test is used for determining the potency of the coagulant. The protein content of the final extract is about one percent.

Part II: Clinical report

This report presents the results of the work done with the various placental extracts in the treatment of a variety of ocular diseases. Twenty-four patients were treated at various times with some one or several of the extracts described in Part I of this paper. The results obtained indicate that the aqueous extract may be of value in the treatment of virus diseases of the cornea. Indications also exist that immune globulin may prove of value in the treatment of uveitis.

Aqueous placental extract in superficial punctate keratitis

Gratifying results were obtained with the use of aqueous extract in both superficial punctate keratitis and in herpetic corneal lesions. Six cases were treated in this group. It would seem to me most valid to assume that the presence of the biogenic stimulator in the aqueous extract gave impetus to the regenerative processes of the cornea. The assumption that the results were obtained because of the presence of antibodies in the placental extract seems to me untenable. The use of the concentrated gamma globulin failed to produce any improvement.

Four patients with superficial punctate

keratitis were treated with the aqueous placental extract described in Part I. The patients responded very favorably. Of the patients in this group, three had a permanent recovery after the injection of 3 to 5 full doses of the aqueous extract. They showed no recurrences upon subsequent examinations over a period of a year. These patients had previously failed to respond to local therapy, foreign-protein therapy, or administration of vitamins—all of which had been used over a period of one month. The third patient required more extended therapy but is now symptom free for as long as four months at a time.

The dosage of the aqueous extract depends upon the concentration. As of this writing, 2 cc. of concentrated solution is given intramuscularly.

Case reports

Case 1. Mrs. C. G., aged 45 years, consulted me first on April 25, 1946, complaining of recurrent attacks of pain of the right eye following an injury three months previously. A diagnosis of superficial punctate keratitis was made. The patient was treated locally until June 10, 1946, with some improvement but with frequent recurrences. She then received three full doses of the aqueous extract and by the 24th of June, the cornea no longer stained. Subsequent examinations did not show any staining nor reveal any recurrence.

Case 2. Mr. R. M., aged 42 years, consulted me on June 1, 1946, giving a history of recurrent attacks of pain, photophobia, and blurring of the vision of the left eye, of several months' duration. A diagnosis of superficial punctate keratitis was made. The patient received local therapy until June 17, 1946, without any improvement. Aqueous placental extract therapy was then instituted, and he received four full doses. By July 8, 1946, his lesions had healed and subsequent examinations revealed no other lesions.

Case 3. Miss R. B., aged 16 years, was referred from the service of Dr. Raymond E. Meek of the New York Eye and Ear Infirmary. The patient had first consulted clinic on April 26, 1946, giving a history of lesions of one year's duration. A diagnosis of bilateral superficial punctate keratitis was made. Prior to the injection of placental extract, she had received every local therapy known or suggested—foreign proteins, vitamins, iontophoresis, and thyroid extract because of her low basal metabolism. Her lesions disappeared for the first time after the injection of three full doses of the aqueous placental extract. The recovery in this case has not been permanent, but the patient has been symptom free for as long as four months. When she does have a recurrence, she receives one or two injections of extract and again remains symptom free for several months.

Case 4. Miss M. M., aged 30 years, consulted me first on October 1, 1947, with a history of recurrent attacks of redness of both eyes lasting from 4 to 5 days and occurring 3 to 4 times a month. She had received various types of local therapy including a series of desensitization injections by another ophthalmologist for a period of one year. Two injections of 1 cc. of the aqueous placental extract healed the condition within 48 hours. Since this case is rather recent no definite conclusions can be drawn so far, but it does suggest that this therapy is effective in producing rapid healing of corneal lesions.

Aqueous placental extract in herpetic keratitis

In both of the cases treated for herpetic corneal lesions, the lesions were completely healed after several full doses of the concentrated extract. These patients had previously failed to respond to any local therapy including the use of ether. One of these cases was referred by another ophthalmologist specifically for treatment with this extract. The patient had failed to respond to a course of treatments which extended over a period of six months and included iodine applications to the cornea and repeated curettage.

Case reports

Case 1. Mr. S. R., aged 70 years, consulted me on November 18, 1946, giving a history of local treatment for herpetic keratitis for 5 to 6 months. The treatment had been unsuccessful and he had had many recurrences. The first injection was given on November 14, 1946. On November 25, 1946, there was no longer any staining, and since then there has been no recurrence.

Case 2. Mr. M. A., aged 54 years, consulted me on March 23, 1946. A diagnosis of herpetic keratitis was made. Local treatment was given until September with constant recurrences. He was then given a series of placental-extract injections and, on September 24th, there were no staining areas. Two months later, this patient had a recurrence which was again treated with the extract. This cleared up shortly and to date there has been no further recurrences of the condition.

Other experiments with placental extracts

Aqueous placental extract was used in the treatment of retinitis pigmentosa. It cannot be said that the results obtained in this disease were as good as those reported by Filatov and his co-workers. They are, nevertheless, worth reviewing here.

Retinitis pigmentosa

Six cases of retinitis pigmentosa were treated over a period of one year. All received intramuscular injections of the aqueous placental extract and the lipoid extract.

Careful visual fields were done, and the visual acuity was recorded for each of the six patients prior to the use of these extracts. These examinations were repeated at frequent intervals during the course of the treatments. Whereas, Filatov reported increased visual acuity and enlargement of the visual fields as a result of his treatments, not one of the patients treated by me showed either one of these improvements at any time. What they did seem to show after injections of the extract was an apparent arrest of the deterioration. Although this is no criterion, since many patients continue for years without change, it has some significance. Two of the patients reported here had been under my care for at least a year prior to treatment with placental extracts and had shown exceedingly rapid deterioration of both visual fields and visual acuity. Examination showed an arrest of the disease upon treatment. These two patients, whose subjective evaluations are trustworthy, report also some improvement in night vision.

An attempt was made to treat all these patients with lipoid extract. The use of this extract was based on Filatov's findings that cod-liver oil injections were as effective as aqueous placental extract. If this is correct, it would indicate that the active principle would be of a lipoid nature rather than of a protein nature. The lipoid extract was prepared to test this assumption. However, the local reactions upon injection were so severe, that the use of the lipoid extract had to be discontinued until it could be refined.

Other conditions treated

In the hope that the presence of the biogenic stimulator might be of some benefit, the placental extracts were tried on four types of eye conditions whose treatment is unsatisfactory. Placental-extract injections were given in cases of old corneal opacities, tuberculous episcleritis, diabetic retinopathy, and macular edema as a result of angiospasm of a branch of the central retinal artery. None of the patients treated for these conditions showed any improvement or change in their condition as a result of the injections.

An important question to be answered is whether the effects obtained with the placental-extracts injections can be ascribed to the foreign protein in the extracts. The evidence would seem to contradict this possibility. Each of the patients who showed improvement upon injections of placental ex-

tracts, had previously received foreign-protein therapy without any improvement. It might be noted that the aqueous extract contains only 4.9-percent protein; whereas, foreign proteins are usually used in much higher concentrations. It is most likely, therefore, that the results obtained are due to some other factor, which is probably the biogenic stimulator.

Use of placental-tissue coagulant

One more placental extract at least warrants mention at this point—placental tissue coagulant, which lowers the blood clotting time. Its use has been demonstrated by McKhann in the treatment of hemophylia. Since hemorrhage is a well-known complication in surgery on diabetics, it was my theory that such an extract should be useful in this connection. I have used it prior to surgery, in two cases, with good results. The clotting time was lowered from 4½ to 1½ minutes in one case and from 3½ to 1½ minutes in the other. Both operations, a cyclodialysis and a cataract operation, were performed with a minimal amount of hemorrhage. Further use of placental-tissue coagulant has been temporarily suspended, however, until the side effects can be examined and studied in greater detail.

Summary

The preparation of aqueous placental extract, lipoid extract, and placental-tissue coagulant is described. A preliminary report on the use of aqueous placental extract in the treatment of herpetic keratitis and superficial punctate keratitis is given. The favorable results obtained in the treatment of these diseases indicate the need for further clinical investigation with a larger group of cases.

The favorable treatment of retinitis pigmentosa with placental extract, as reported by Filatov, was not corroborated by the results obtained.

Old corneal opacities, tuberculous episcleritis, diabetic retinopathy, and vascular changes in the retina, did not respond to treatment with placental extract.

Placental-tissue coagulant was used preoperatively to lower the blood-clotting time in diabetics.

END RESULTS IN RETINAL DETACHMENT

LEO J. CROLL, M.D., AND MAURICE CROLL, M.D.
Detroit, Michigan

The retina as a whole is not involved in retinal detachment, but a cleavage occurs between the two primitive retinal layers, with the pigment epithelium remaining in position attached to Bruch's membrane, while the inner retinal layers become separated from it.

The retinal pigment epithelium originates from the outer neurodermal layer of the embryonic optic cup. The remaining layers of the retina arise from the embryonic inner neurodermal layer. Thus, in retinal separation, the inner layer becomes displaced from the outer layer, allowing the potential space to become an actual space.

CLASSIFICATION OF DETACHMENTS

All retinal detachments may be classified as secondary and the cases of idiopathic detachment are probably caused by inflammatory or degenerative changes. Terry,[1] in examining microscopic sections of eyes, classified separated retina into four general types: (1) Retinal separation with typical hole in retina, arising from trauma. It may be associated with mild uveitis. (2) Retinal separation that arises from exudation under the retina. (3) Retinal separation with uveal melanomas. (4) Retinal separation with myopia.

INJURIES CAUSING DETACHMENT

The types of injuries causing retinal detachments are: (1) Direct injuries to the eye, including perforating wounds, intraocular foreign bodies, and contusions. (2) Indirect injuries to the eye, such as blows and contusions on the head.

Duke-Elder[2] states that the choroid is more easily ruptured than the healthy retina, and the normal eye can stand the most severe trauma involving even rupture of the sclera and the loss of vitreous without the occurrence of a detachment. We have seen a great many more tears of the choroid in war injuries than tears of the retina.

Severe inflammatory lesions have been recognized as etiologic factors in retinal detachment for a long time. It is only comparatively recently that a mild equatorial and anterior choroiditis has been considered as a precipitating factor in retinal detachment. In these cases, the detachment is due either to the formation of exudative subretinal fluid, to traction by fibrous tissue, or to shrinkage of the globe. In war injuries, we have seen severe vitreous hemorrhages which, by contracting fibrous bands, produce detachments as a late sequela.

INCIDENCE OF RETINAL HOLES

Gonin,[3] in his latest papers, obtained an 87-percent incidence of holes in retinal detachment, and it was his opinion that retinal holes were almost invariably found in retinal detachments, if sufficient time were spent in looking for them. Duke-Elder, in summing up the significance of retinal holes, states that the hole iself is not sufficient to cause the detachment. Other factors —disease, degeneration, and severe trauma —play a part in retinal detachment. The consensus of opinion today is that a retinal hole exists in nearly every case of retinal detachment except those caused by intraocular tumor. Retinal tears or holes may be single or multiple and of varied form and size.

TYPES OF RETINAL HOLES

The types of retinal holes usually seen in retinal detachment are:

1. Crescentic, horseshoe-shaped tears, the convexity is always turned toward the optic nerve and usually occurs in the upper half of the globe.

2. Round holes, occurring either singly or

in groups, are generally in the temporal half of the globe, usually in the supratemporal quadrant.

3. Irregular slits and fine sievelike perforations are usually seen near or at the periphery.

4. Dialysis or disinsertion at the ora serrata almost always occurs at the lower part of the globe—most frequently in the inferior and inferior temporal quadrants. Subsequent detachment spreads slowly backward and upward with delayed involvement of the macula and visual disturbance.

In war injuries, when the patient suffers severe, violent trauma, more than one hole is often found in retinal detachment. In several cases that we observed the retina was lacy, ripply, shrivelled, and sievelike, with many holes.

Retinal holes have been known to heal spontaneously by glial proliferation, as reported by Samuels.[4] However, the general tendency is for the hole to become larger and the retinal detachment to become progressive.

Mechanism of detachments

The mechanism of some of the detachments is fairly clear. This is true principally of those detachments due to a tumor pushing the retina inward; organization of fibrous tissue pulling the retina inward; tearing of the retina by sudden traumatic distension; wrinkling up of the retina in a shrunken globe.

Two other groups in which the mechanism is more or less clear are: (1) Exudative detachments which are not typically associated with a retinal hole, and (2) serous detachments in which a hole is characteristically present.

In spontaneous retinal detachments, the essential factor is the preceding inflammation or degeneration of the retina, vitreous, or choroid. In some of our traumatic cases, the retinal separation was secondary to gross ocular disorganization and was an incident in severe progressive ocular disease.

Clinical symptoms

The significant clinical symptoms of retinal detachment are:

1. The complaint of seeing "spots in the eyes," with the appearance of muscae volitantes, suggestive of degenerative changes in vitreous or peripheral choroiditis.

2. The symptom most commonly looked for is photopsia, the sensation of flashes of light, indicative of slight movements of the retina. The flashes of light are more significant when they are constantly projected from a single region of the retina.

3. If the detachment is large or central, vision will become blurred or completely lost. However, if the detachment is shallow and localized away from the macula, it may give rise to no symptoms and vision may be good. Usually the patient complains of a cloud or a curtain appearing in front of the eye.

4. An area of visual-field defect corresponding to the area of detachment is present. The red reflex is altered and appears gray over the detached area. As the eye is examined with an ophthalmoscope, it is noted that there is a change in the normal color of the fundus as the area of detachment is approached and that this area is out of focus with the rest of the fundus. The detached retina appears as a gray or bluish-gray veil with few or many folds; or it may assume the proportions of a large balloon and obscure the disc. The vessels seen rising angularly over into the area of detachment lose their normal light streak and appear as dark, almost black, tortuous cords.

All authorities agree that a retinal hole or tear is the rule. The tears, holes, or rents are characterized by their sharp borders and the visible red choroid. If no retinal hole is found, it may be because the hole is located too far peripherally or is hidden by a fold. Retinal holes usually do not occur in cases of choroidal tumor. Gifford,[5] however, in 1936, reported a case of choroidal tumor with a hole.

TABLE 1

SUMMARY OF 15 CASES OF RETINAL DETACHMENT

Patient (Name and Age)	Age of Detachment	Previous Surgery	Etiology	Holes	Vision Before Surgery	Vision After Surgery	Visual Fields
G.J. 19 yrs.	3 months	none	inflammatory	none	20/100 J-5	20/100 J-5	improved

LOCALIZING POSITION OF TEARS

The position of a retinal tear may be localized ophthalmoscopically by estimating the number of disc diameters 1.5 mm. from the tear to the disc or ora serrata. This is a gross approximate method and easily done. Each disc diameter is 1.5 mm. and the ora serrata is considered to be 8 mm. from the limbus of a globe measuring 24 mm. on its anteroposterior axis.

Drawing of the fundus with details and localizing the retinal hole in relation to retinal blood vessels is another helpful method.

Stine's method,[6] with tables for retinal localization, is a more accurate method. The patient uses a Schweigger perimeter at 19 cm. and looks at his own eye in a mirror, or uses a finger (propioceptive) if the macula is damaged. He looks at the tear by means of a giant scope and draws until he is beyond the range of the arc. The arc is rotated until it intercepts the ophthalmoscopic beam, the reading on the perimeter arm is noted, to-

gether with the angle through which it is turned. Tables for localization of retinal tear on the globe are then consulted.

Case reports

All of the patients with retinal detachments herein reported were operated on by different members of the eye staff of the Eye Center, Crile General Hospital.

The operative procedure consisted of making a large conjunctival flap, with good exposure of sclera. The area of detachment was outlined with methylene blue, and the scleral area so outlined was treated by means of a single-point, insulated-tip electrode which produced micropunctures. In many places the punctures were enlarged to insure adequate drainage of the subretinal fluid.

Drainage holes stay open longer, and the retina is more likely to fall back into position, when a special diathermy current (coagulation and cutting) is used. Partial drainage is thus established early in the operative procedure, and the retina is more easily caught by the adhesive choroiditis. Multiple diathermy punctures give adequate drainage; whereas, surface coagulation with two or three diathermy punctures may give inadequate subretinal-fluid drainage. In war injuries, where the retina often is shrivelled and has multiple holes, the entire affected area should be treated, in an effort to close all the retinal tears and cause adhesions of the retina around the holes.

Case 1

History. G. J., aged 19 years, was inducted into the Army on September 18, 1943. Each eye had normal vision, and there was no history of eye injury or disease. On March 15, 1945, the right eye became blurred. He was hospitalized on March 24, 1945, overseas. He was given bed rest and binocular bandadges were applied for three weeks. He was evacuated to Crile General Hospital on May 20, 1945.

Findings. Detachment of retina (inflammatory type), right eye, inferior temporal quadrant, with inactive chorioretinitis in the same area. No tear or disinsertion was found. In spite of conservative therapy, the detachment persisted. Vision was: O.D., 20/100, J5; O.S., 20/15, J1.

Operation. On July 20, 1945, a barrage was done between the 6- and 10-o'clock positions, and surface coagulation was applied between the 8- and 10-o'clock positions.

Result. October 20, 1945. The retina was flat. Vision was: O.D., 20/80, J5; and there was definite visual-field improvement.

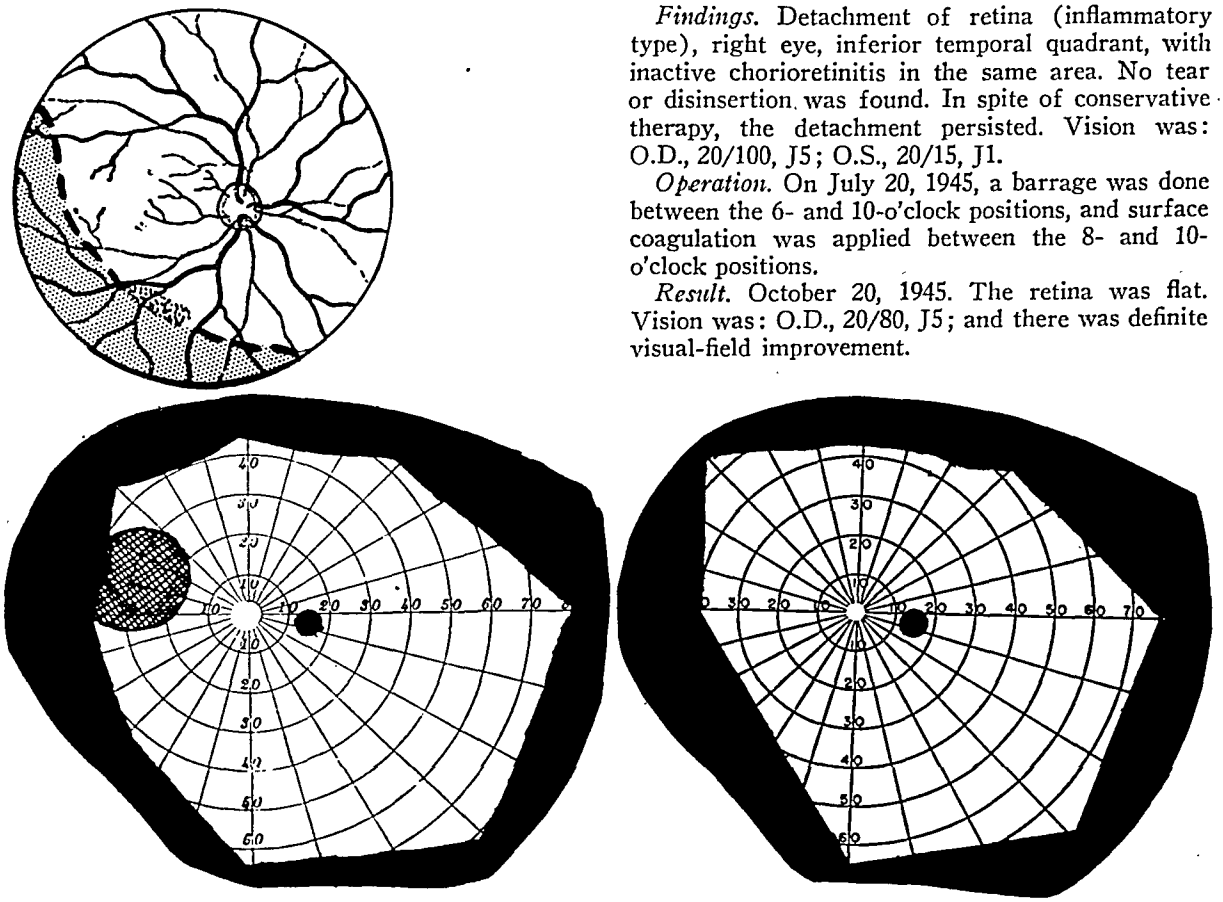

Fig. 1 (Croll and Croll). *Case 1.* Detachment of the retina (above), inferior temporal quadrant, right eye. Before surgery (left) vision was 20/100; fields for 3-mm. and 1-mm. white. After surgery (right) field for 3-mm. white; vision, 20/80.

CASE 2

History. R. B., aged 23 years, was rejected, in April, 1942, by the Navy for defective vision. He was inducted into the Army in September, 1942. In April, 1944, he tried to fire a carbine, sighting with the right eye, but he couldn't see with the right eye. He neglected to report this ocular condition until November, 1944. He returned from Iran on January 20, 1945.

Findings. There was a massive detachment in the right eye, with disinsertion of retina, involving the inferior temporal and nasal quadrant, right. Striae retinae were present above the macula. There was atrophy of the retina of the left eye in the inferior nasal quadrant, corresponding to the area of detachment in the right eye. Vision was: O.D., hand movements; O.S., 20/20, J1.

Operation. On March 20, 1945, an extensive barrage was done with a Liebel-Flarsheim single-insulated diathermy tip, from the 4- to the 9-o'clock positions. The power setting was 19.

Result. On July 17, 1945, the retinal disinsertion was still visible, but the retina adjacent to this was flat and adhered to the choroid. Vision was: O.D., 20/100 (marked improvement); definite visual-field improvement.

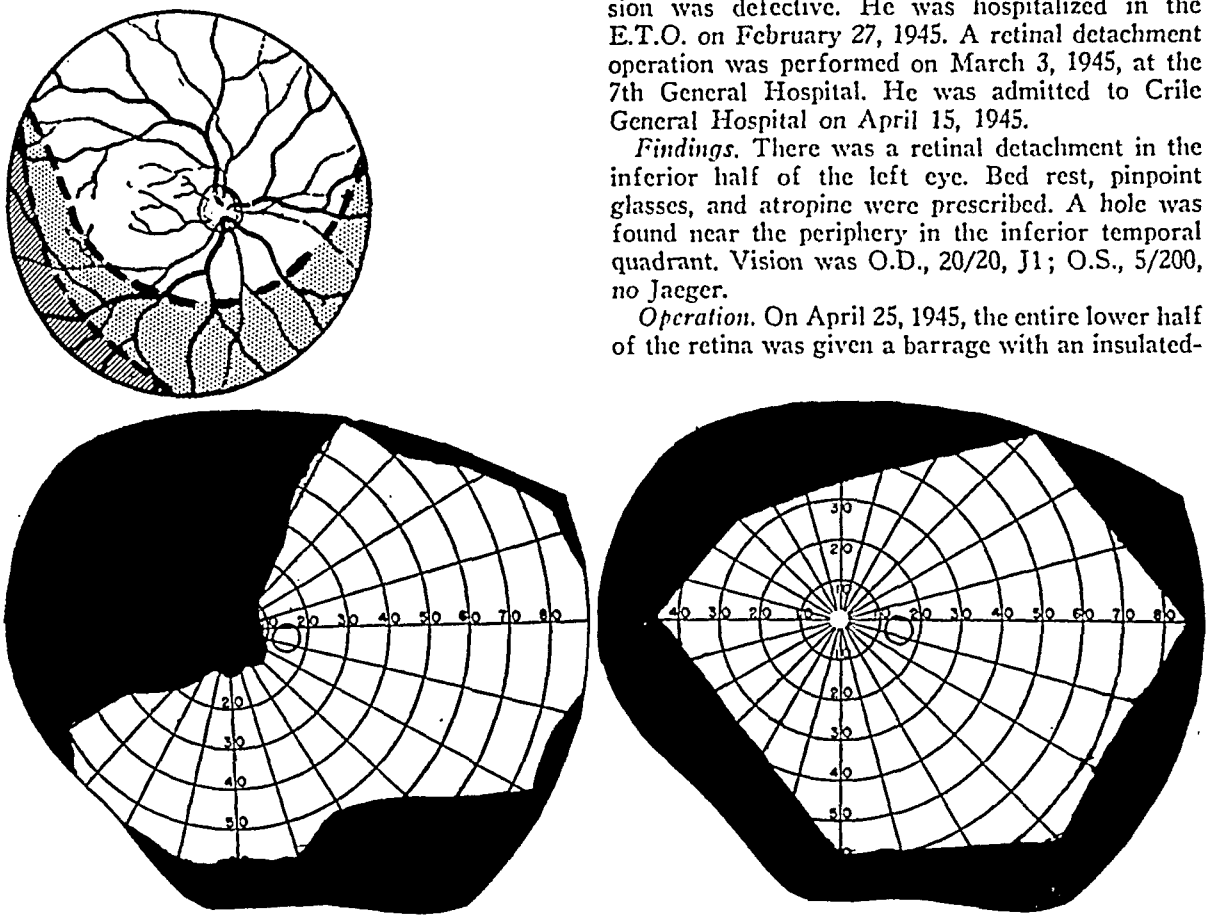

Fig. 2 (Croll and Croll). *Case 2.* Massive detachment (above) in the right eye, with disinsertion of the retina. Before surgery (left) vision was counting fingers at 2½ feet. After surgery (right) vision was 20/100 with correction. Visual field for 3-mm. white.

CASE 3

History. M. J., aged 35 years, during September, 1944, received a blow to the left eye from a fist. In December, 1944, the patient complained of flickering and jumping lights before the left eye. Vision was defective. He was hospitalized in the E.T.O. on February 27, 1945. A retinal detachment operation was performed on March 3, 1945, at the 7th General Hospital. He was admitted to Crile General Hospital on April 15, 1945.

Findings. There was a retinal detachment in the inferior half of the left eye. Bed rest, pinpoint glasses, and atropine were prescribed. A hole was found near the periphery in the inferior temporal quadrant. Vision was O.D., 20/20, J1; O.S., 5/200, no Jaeger.

Operation. On April 25, 1945, the entire lower half of the retina was given a barrage with an insulated-tip electrode. The retinal hole was sealed.

Result. On July 17, 1945, the retina was flat, and the adhesive choroiditis was holding well. Vision was: O.S., 10/200; with correction, 15/200. Visual fields showed definite improvement.

CASE 4

History. B. J., aged 23 years, had normal vision when he enlisted in September, 1940. There was no history of trauma. In November, 1944, the right eye became blurred and vision was only light perception. He arrived at Crile General Hospital on March 31, 1945, from the E.T.O.

Findings. There was detachment of the retina, right eye, with iridocyclitis and secondary glaucoma. No tear or disinsertion was found. There was increased intraocular pressure. A choroidal

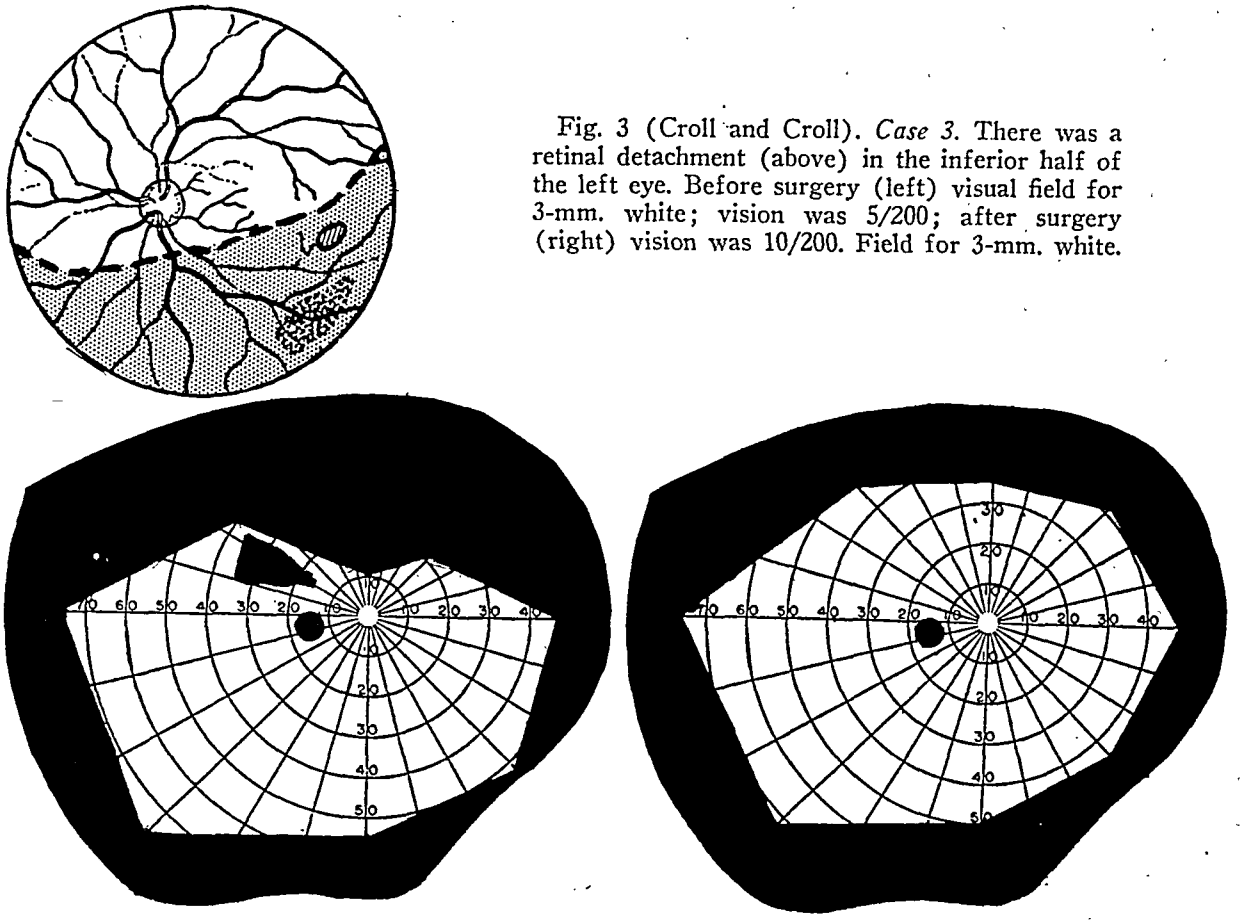

Fig. 3 (Croll and Croll). *Case 3.* There was a retinal detachment (above) in the inferior half of the left eye. Before surgery (left) visual field for 3-mm. white; vision was 5/200; after surgery (right) vision was 10/200. Field for 3-mm. white.

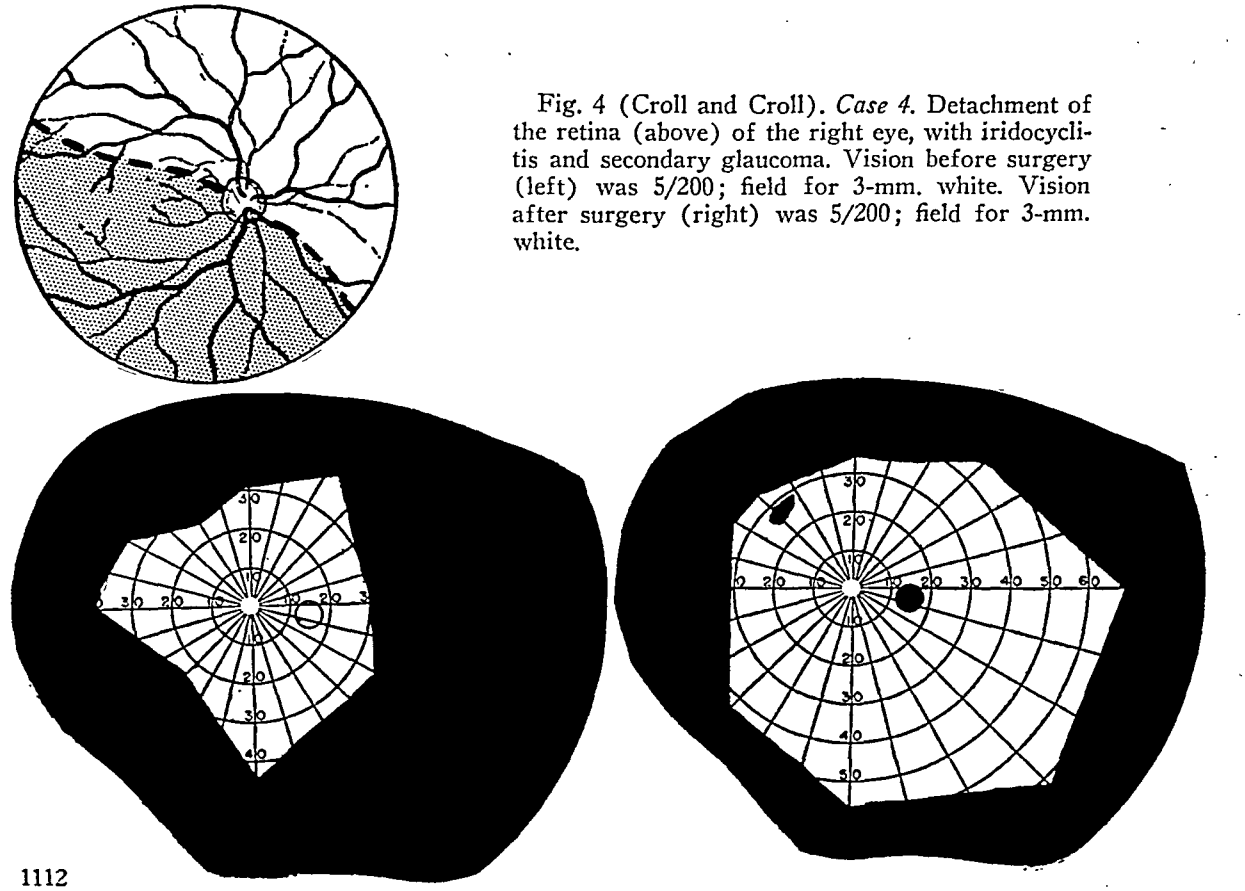

Fig. 4 (Croll and Croll). *Case 4.* Detachment of the retina (above) of the right eye, with iridocyclitis and secondary glaucoma. Vision before surgery (left) was 5/200; field for 3-mm. white. Vision after surgery (right) was 5/200; field for 3-mm. white.

tumor was considered. After treatment—paracentesis, atropine, foreign protein—a good red reflex was obtained by transillumination. Vision was: O.D., 5/200; O.S., 20/15, J1.

Operation. On April 27, 1945, an extensive barrage was done inferiorly between 3- and 9-o'clock positions with a Liebel-Flarsheim single, insulated diathermy tip. Power setting was 20, using a special retinal detachment current.

Result. On July 17, 1945, the retina was flat and the progressive detachment was cured. The eyeball was preserved. Vision was: O.D., 5/200, no Jaeger. There was marked improvement in the visual fields.

CASE 5

History. H. A., aged 32 years, was injured by fragments from mortar shell in France on February 2, 1945. On February 3, 1945, a multiple cautery procedure was done at an evacuation hospital. He was an ambulatory patient, then in bed for four days only, and again ambulatory. He was evacuated to Crile General Hospital, March 31, 1945.

Findings. In the right eye was a bullous, nearly complete retinal detachment, with retinal disinsertion between the 7- and 9-o'clock positions. There was a choroidal rupture through the macula. Vision was: O.D., 20/400, with head tilted to left; O.S., 20/15, J1.

Operation. On April 4, 1945, a large triangular laceration of the sclera was found at the 6-o'clock position, in front of the insertion of the inferior rectus muscle. It was sutured before diathermy punctures were applied over the sclera between the 5- and 10-o'clock positions.

Result. On July 15, 1945, the retina was flat and the progressive detachment was cured. The eyeball was preserved. Vision was: O.D., 20/200, with head tilted to left. There was marked improvement in the visual fields.

CASE 6

History. R. Z., aged 23 years, was wounded in action on October 18, 1944, in Italy. Mortar fragments penetrated his right eye. He had noted floating spots in right eye since injury. On July 27, 1945, a curtain came down over field of vision, from the temporal side of the right eye. He was admitted to the 17th General Hospital and was placed in bed for one month. Pinhole spectacles were prescribed. He was evacuated to the United States and arrived at Crile General Hospital on August 29, 1945.

Findings. An extensive retinal detachment was present in the lower half of the right eye. There was edema of the macula and a disinsertion from the 6:30- to the 8-o'clock positions. An intraocular foreign body less than 0.25 mm. in size was present in the inferior temporal anterior vitreous. It showed no motion with magnet application. There was slight

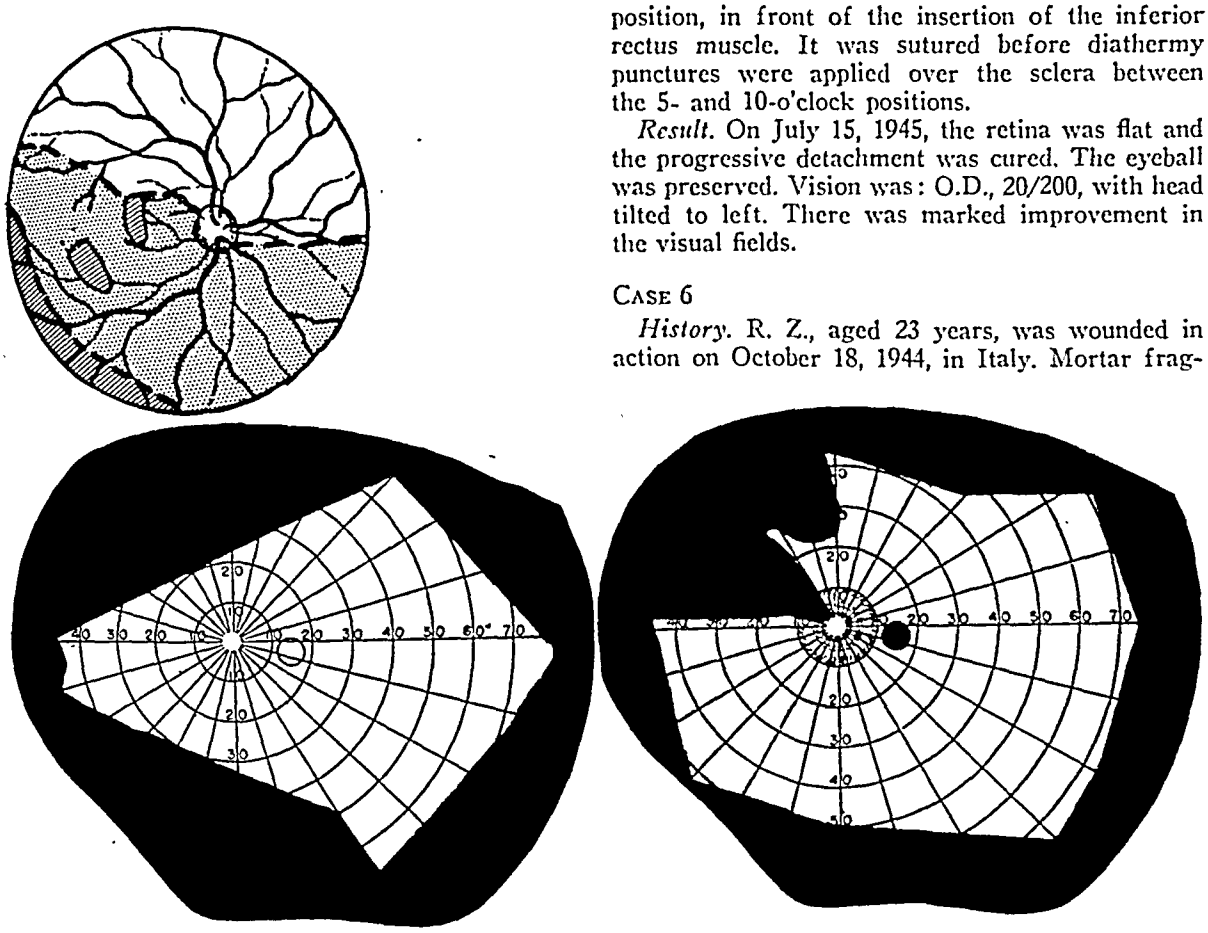

Fig. 5 (Croll and Croll). *Case 5.* In the right eye was a bullous, nearly complete retinal detachment. Before surgery (left) the target was an ophthalmoscope light and vision was light perception only. After surgery (right) vision was 20/200+ with correction. Target, 3-mm. white.

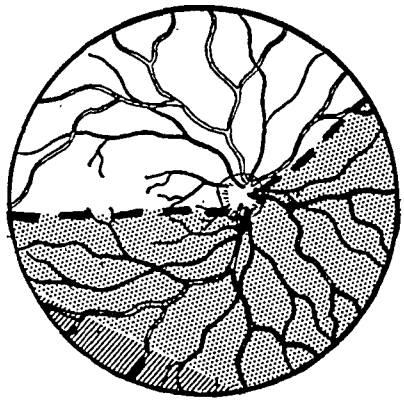

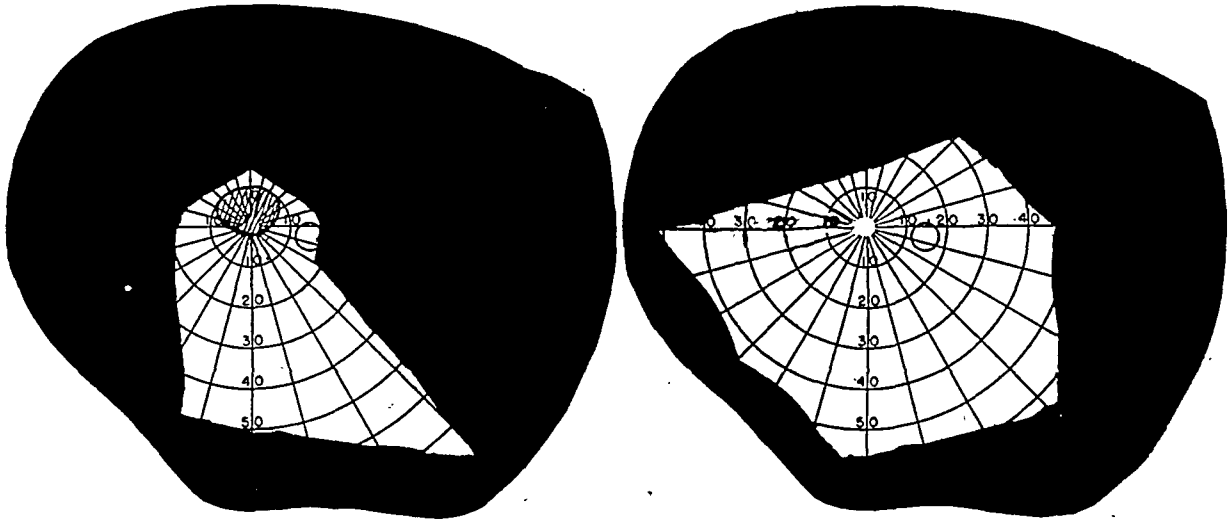

Fig. 6 (Croll and Croll). *Case 6.* An extensive retinal detachment (above) was present in the lower half of the right eye. Before surgery (left) visual field for 6-mm. white; vision was light perception. After surgery (right) field for 6-mm. white; vision was light perception.

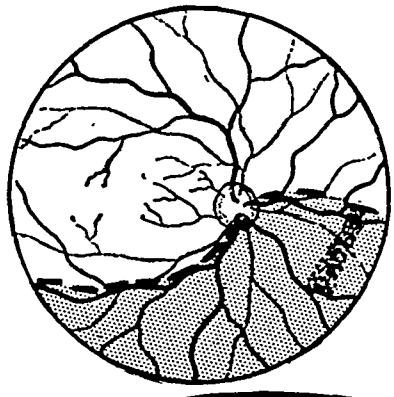

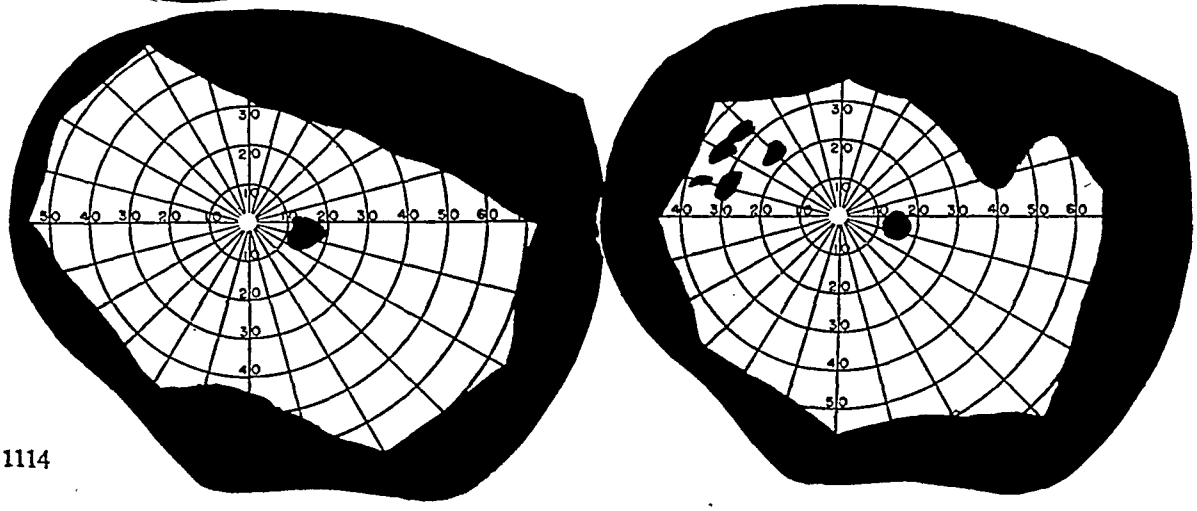

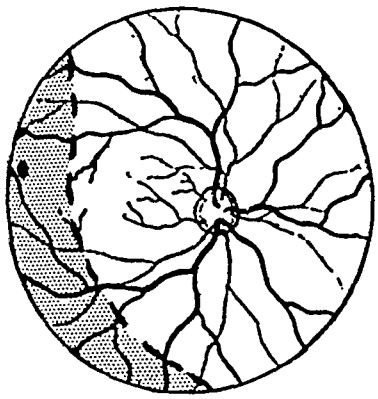

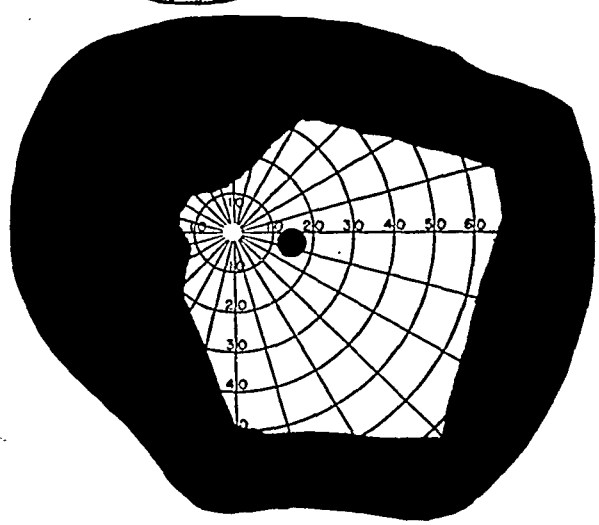

Fig. 7. (Croll and Croll). *Case 7.* The retina (above) was in position everywhere except at the extreme inferior nasal quadrant, right eye. Before surgery (left) vision was 20/100, correctible to 20/20; target for field was 3-mm. white. After surgery (right) vision was 20/100 correctible to 20/15. Field for 3-mm. white.

siderosis of the iris and lens capsule. Vision was: O.D., light perception; O.S., 20/20, J1.

Operation. One September 12, 1945, an unsuccessful attempt was made to remove the foreign body. An extensive barrage was done on the area of detachment, the inferior half nasally up to the 2-o'clock position.

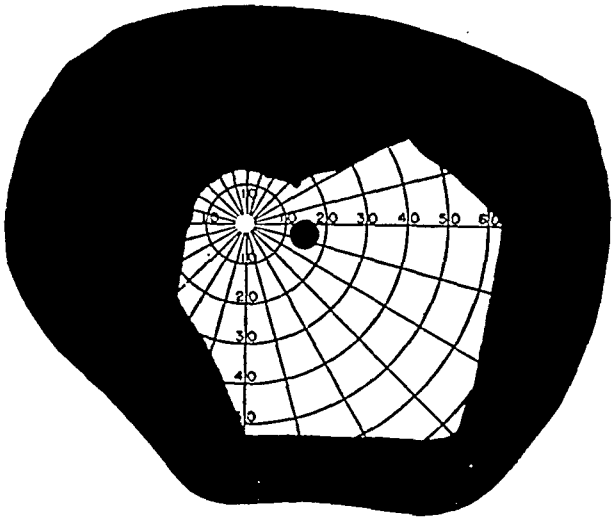

Fig. 8 (Croll and Croll). *Case 8.* While the patient was in bed, the retina, right eye (above), would flatten and the fields would become normal. When he was up for short periods, retinal detachment would recur. Before the second operation (left) vision was 20/80, correctible to 20/60. Target—3-mm. white. After surgery (right), vision was 20/80, correctible to 20/70+3. Target—3-mm. white.

Result. The retina was in good position, the extensive detachment cured and the eyeball preserved. Vision was light perception. The visual field showed improvement. The intraocular foreign body (nonmagnetic) was still retained.

CASE 7

History. F. R., was 24 years of age. While on Omaha Beach, one of our own demolitions exploded 20 yards from the patient. The blast was sufficient to throw patient over, even though he was lying down. On December 10, 1944, six months later, he first noticed a dark spot over the upper right eye. He was operated on March 1, 1945, at the 67th General Hospital and arrived at Crile General Hospital on April 4, 1945.

Findings. The retina was in position everywhere except at the extreme inferior nasal quadrant. No tear or disinsertion was seen. On April 24, 1945, the patient complained of flashes of light. There was definite deterioration of the field. The fundus showed a progressive detachment. Vision was O.D., 20/100, corrected to 20/20; O.S., 20/20.

Operation. On April 25, 1945, with a Liebel-Flarsheim single insulated diathermy tip, an extensive barrage was done from the 4:30- to the 9-o'clock positions. Power setting was 20.

Result. On July 18, 1945, the retina was flat, the progressive detachment cured, and a complete reattachment had been obtained. Vision remained 20/20. The visual fields were slightly improved.

CASE 8

History. R. H., aged 21 years, had normal vision in each eye in May, 1944. In August, 1944, the right eye became blurred, and he saw spots and flashes. There was no history of ocular injury. He was hospitalized in the E.T.O., and given bed rest, atropine, and pinpoint glasses for two weeks.

Findings. While the patient was in bed, the retina would flatten and the fields would become normal. When he was up for short periods, a retinal detachment of the right eye would recur. He was observed for several months. Before the first operation, no hole could be found, but after the first operation, a hole was found. Vision was: O.D., 20/80, corrected to 20/60; O.S., 20/20, J1.

Operation. On July 2, 1945, a surface coagulation of the sclera, from the 11- to 6-o'clock positions, was done. The sclera was light brown on completion. The detachment increased because there was insufficient drainage from two diathermy punctures, and only one half of the retinal hole was treated. On

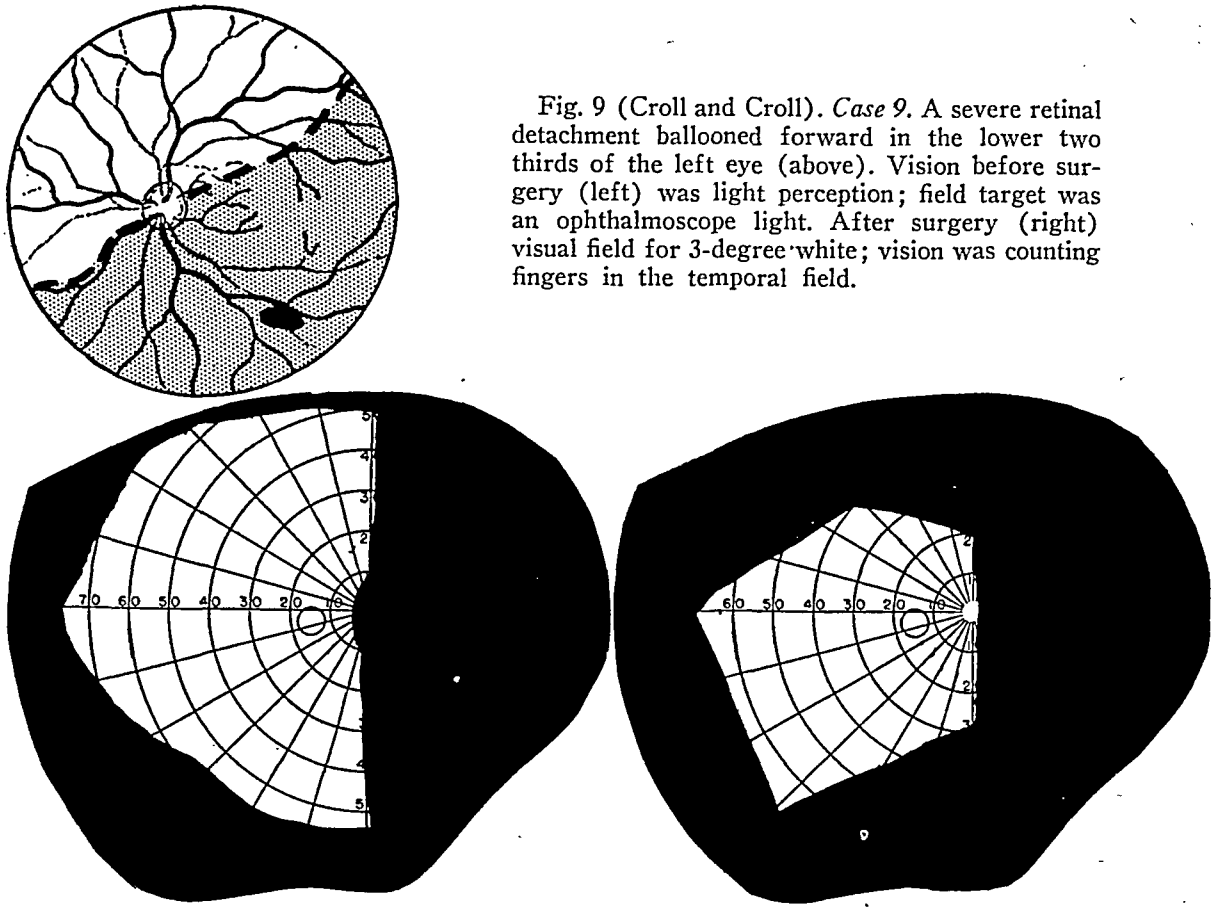

Fig. 9 (Croll and Croll). *Case 9.* A severe retinal detachment ballooned forward in the lower two thirds of the left eye (above). Vision before surgery (left) was light perception; field target was an ophthalmoscope light. After surgery (right) visual field for 3-degree white; vision was counting fingers in the temporal field.

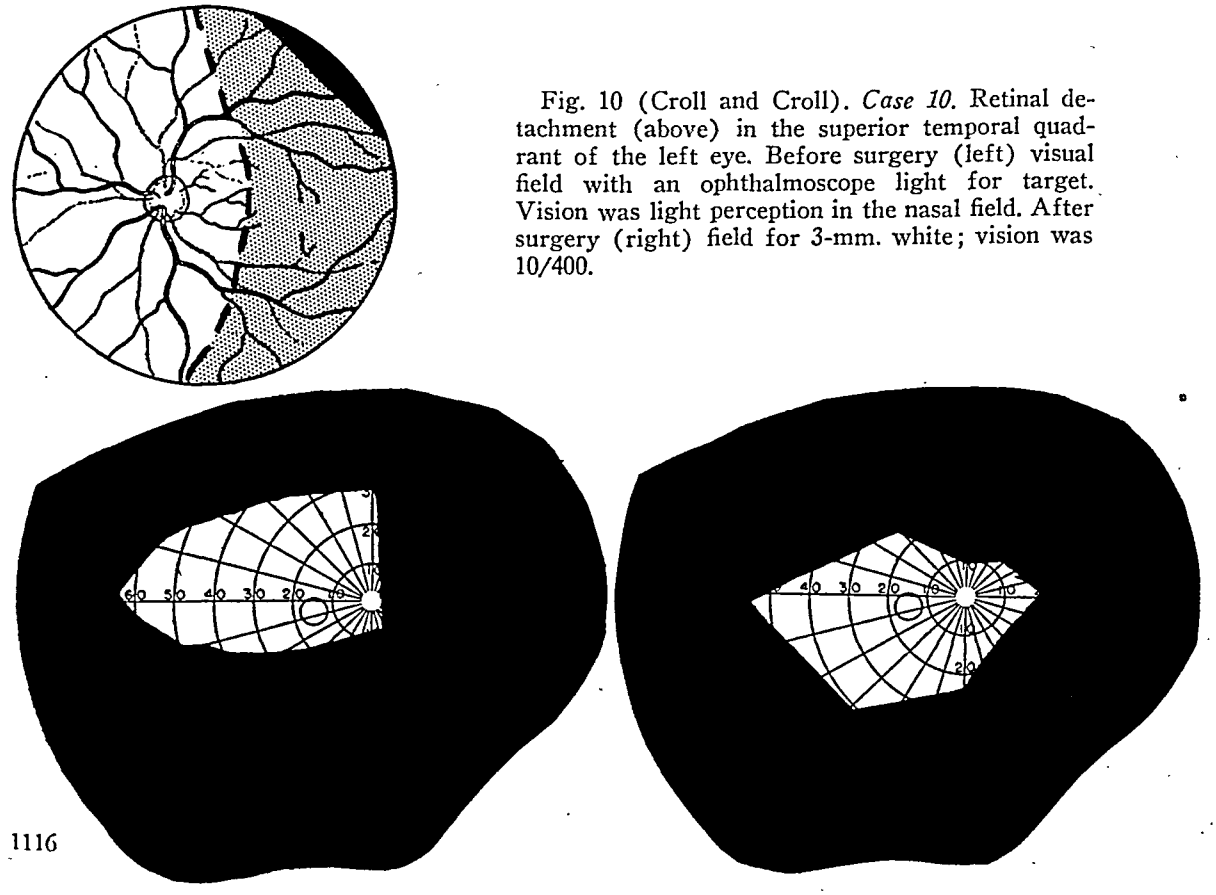

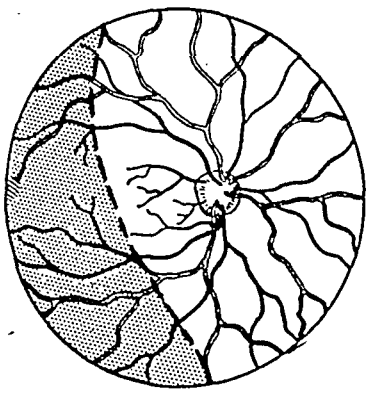

Fig. 10 (Croll and Croll). *Case 10.* Retinal detachment (above) in the superior temporal quadrant of the left eye. Before surgery (left) visual field with an ophthalmoscope light for target. Vision was light perception in the nasal field. After surgery (right) field for 3-mm. white; vision was 10/400.

July 25, 1945, the operation was repeated, an extensive barrage being used. The retinal hole was sealed.

Result. On September 20, 1945, the retina was in good position and completely reattached. Vision was: O.D., 20/80, corrected to 20/70+3. There was a slight contraction of the visual fields.

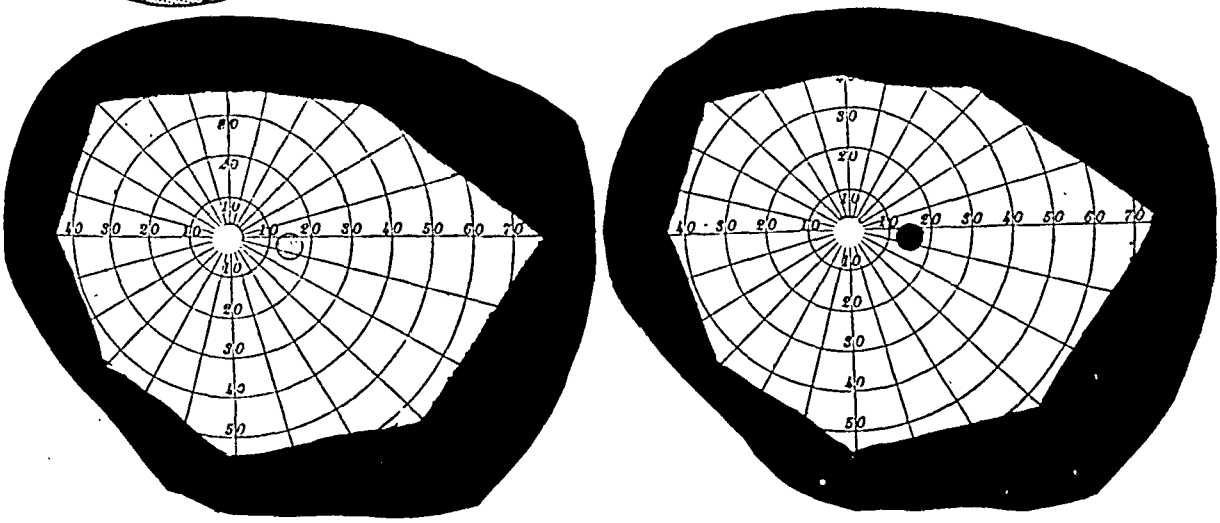

Fig. 11 (Croll and Croll). *Case 11.* Retinal detachment (above) of the right eye. Before surgery (left) vision was 20/30; field for 3-mm. white. After surgery (right) vision was 20/30; field for 3-mm. white.

CASE 9

History. F. L., was 19 years of age. On April 23, 1945, his left eye was injured by a fist in Germany. He was given bed rest for three weeks. When he was allowed up, the detachment of the retina recurred. On May 25, 1945, an operation for retinal detachment was done at the 15th General Hospital, Belgium, and the patient said that vision was poor following surgery.

Findings. A severe retinal detachment ballooned forward in the lower two thirds of the left eye. A retinal tear was present, inferiorly, at the 5-o'clock meridan, near the periphery. Vision was: O.D., 20/15, J1; O.S., light perception.

Operation. On July 5, 1945, a barrage of diathermy punctures was made from the 9- to the 3-o'clock positions. The area between the 4:30- and 6:30-o'clock positions was also treated with surface coagulation.

Result. On September 20, 1945, the retina was flat and completely reattached. The eyeball was preserved. Vision was: O.S., counted fingers in the temporal field. There was a slight contraction of the visual field.

CASE 10

History. C. O., aged 26 years, was wounded in action when a mortar shell exploded close to him on July 23, 1944.

Findings. There was a retinal detachment in the superior temporal quadrant of the left eye, with disinsertion from the 1- to the 3-o'clock positions. The macula was destroyed. Vision was O.S. poor light perception in the nasal field; O.D., 20/20, J1.

Operation. On January 10, 1945, a surface coagulation was done, but the detachment recurred. On April 9, 1945, an extensive diathermy barrage was done over the area of detachment.

Result. The retina was flat and completely reattached, and the eyeball preserved. Vision was: O.S., 10/400, with a slight improvement in the visual field.

CASE 11

History. P. P., aged 24 years, was wounded, March 8, 1945, in action in Germany by a fragment from a booby trap. A fragment was removed from the right eye at the Battalion Aid Station, and the sclera was closed with two silk sutures. At the 187th General Hospital, a diagnosis of retinal detachment was made. He arrived at Crile General Hospital on August 6, 1945.

Findings. A retinal detachment of the right eye was found in the extreme temporal quadrant, and there were vertical folds from the 7- to 11:30-

o'clock positions. Macular edema was present. A retinal tear was found at the 9-o'clock position in the far periphery. The vitreous contained about five small foreign bodies, which showed no movement on magnet application. X-ray films were negative for foreign bodies. Vision was: O.D., 20/30, J1; O.S., 20/20, J1.

Findings. There was a retinal detachment in the inferior nasal temporal area of the right eye, with a disinsertion between the 3- and 7-o'clock positions. An observer looking at the inferior aspect of the retina could see a shrunken retina with massive vitreous hemorrhage. Vision was: O.D., poor light perception in the nasal field only; O.S., 20/20, J.I.

Operation. On June 9, 1945, a resection was made of a crescent-shaped piece of sclera, 19-mm. long and 3-mm. wide, extending from the 3- to the 8-o'clock positions, clockwise, beginning 11.5 mm. behind the limbus. A diathermy barrage was done around the operative site, thereby shrinking the scleral shell to fit the shrunken retina.

Result. On August 20, 1945, the retina was in a better position, although details were still obscured by the absorbing vitreous hemorrhage. Vision was: clear light perception nasally and slight light perception, temporally. The visual fields were improved.

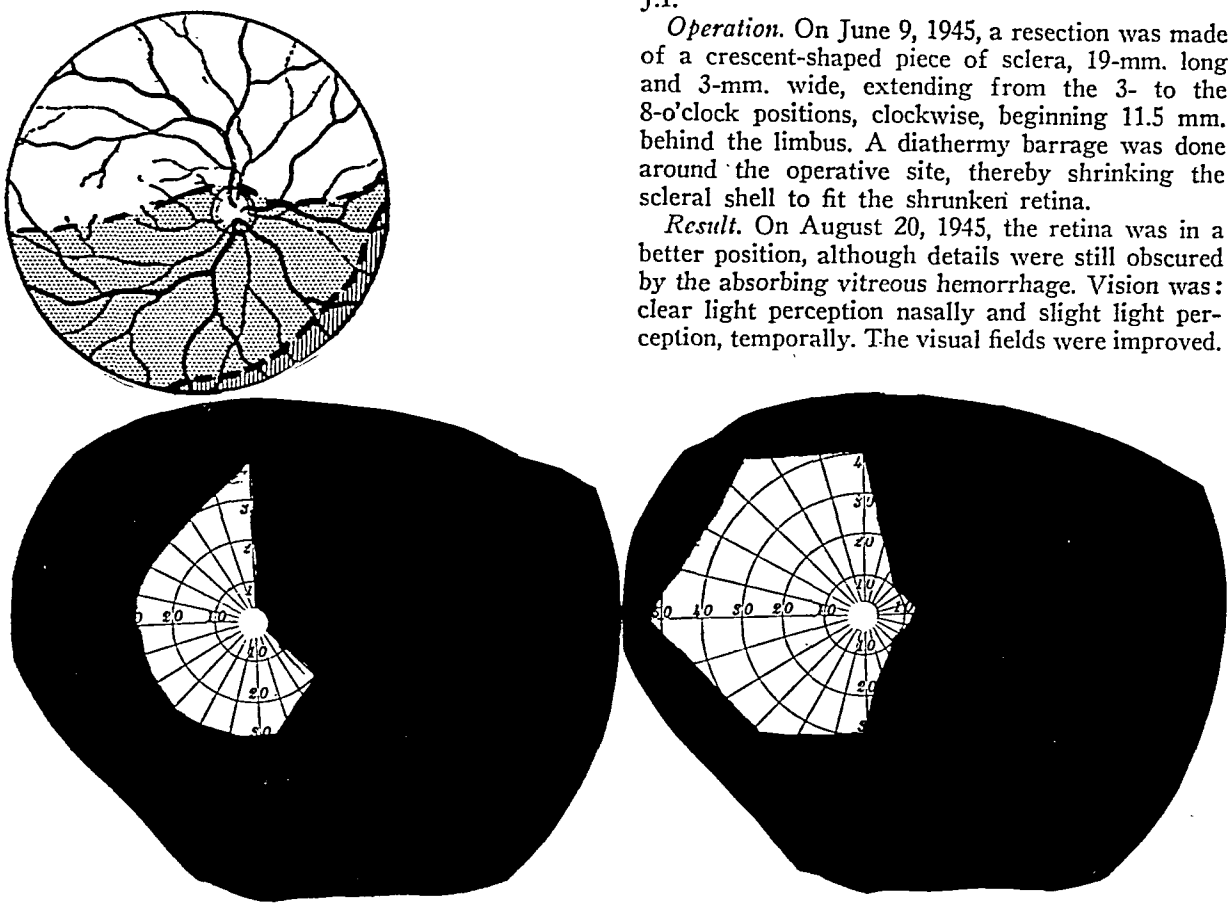

Fig. 12 (Croll and Croll). *Case 12.* Retinal detachment (above) in the inferior nasal-temporal area of the right eye. Before surgery (left) vision was light perception in the nasal field: target, ophthalmoscope light. After surgery (right) vision was clear light perception in the nasal field and slight light perception in the temporal field; target, ophthalmoscope light.

Operation. On August 14, 1945, a barrage was done from the 6:30- to 11:30-o'clock positions and the area from the 8:30- to 11-o'clock positions was treated by surface cautery, with a ball electrode over the area of the retinal tear.

Result. The retina was in good position and completely reattached. Vision was: O.D., 20/30, J1. The visual fields were unchanged. The nonmagnetic foreign bodies were still retained.

CASE 12

History. S. R., was 29 years of age. On April 4, 1945, in England, a grenade exploded close to him. He immediately lost nearly all vision in the right eye. Bed rest, pinhole glasses, and eye drops were prescribed.

On August 27, 1945, muscle surgery was performed for divergent strabismus, and anterior and posterior uveitis developed. On September 13, 1945, the right eye was enucleated to avoid possible sympathetic ophthalmia. It was feared that the scleral resection area had broken open, but on removal of eye, the area was found to be well healed.

CASE 13

History. J. E. was 24 years of age. On April 16, 1943, a bullet fragment ricocheted into his right eye. He was hospitalized at Walter Reed Hospital where an unsuccessful attempt was made to remove an intraocular foreign body. On April 1, 1945, while in Germany, he noted defective vision in the right eye. On May 1, 1945, he was operated on for retinal

detachment at the 52nd General Hospital, and another unsuccessful attempt to remove the foreign body was made.

Findings. A retinal detachment was present in the right eye. There were two large bullous areas above with a larger bullous area, lateral, and disinsertion from the 6- to the 10-o'clock positions. The retina was shrunken. Vision was: O.D., light perception only; O.S., 20/60, J1, correctible to 20/20, J1.

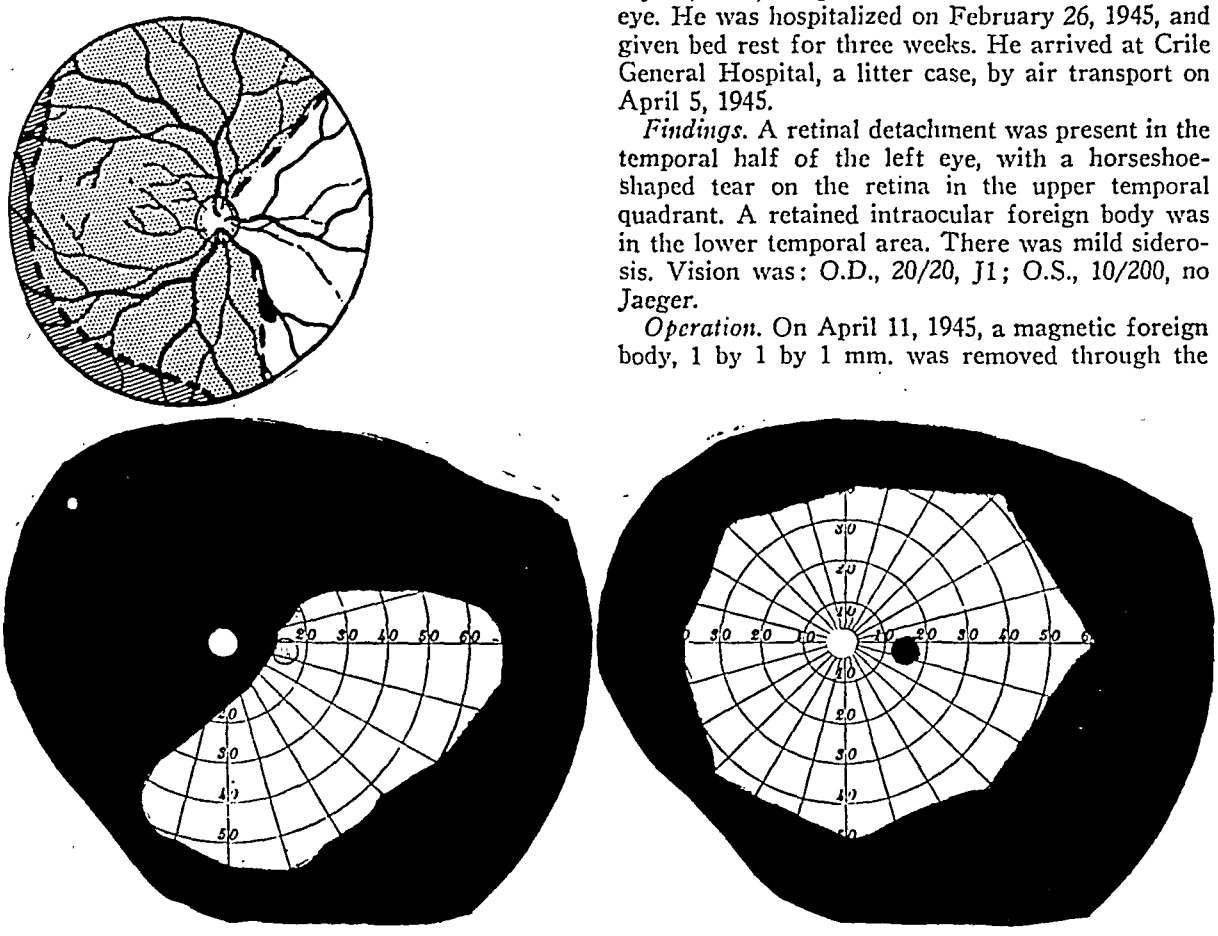

Fig. 13 (Croll and Croll). *Case 13.* Retinal detachment (above) of the right eye. Before surgery (left) vision was light perception; the target, ophthalmoscope light. After surgery (right) vision was 20/100; target, 3-mm. white.

Operation. On June 28, 1945, an eyeball shortening procedure of Müller[7] was done, with excision of a crescent-shaped piece of sclera, 20-mm. long and 2.5-mm. wide, extending from the 5- to the 10:30-o'clock positions, beginning 11.5 mm. behind the limbus. A diathermy barrage was done around the operative site. A fundus examination, immediately after surgery, showed the retina to be flat.

Result. On October 20, 1945, the retina was flat and completely reattached. The progressive detachment was cured. Vision was O.D., 20/100. There was definite visual-field improvement. The patient still had a retained foreign body, probably from the lead bullet (non-magnetic?).

CASE 14

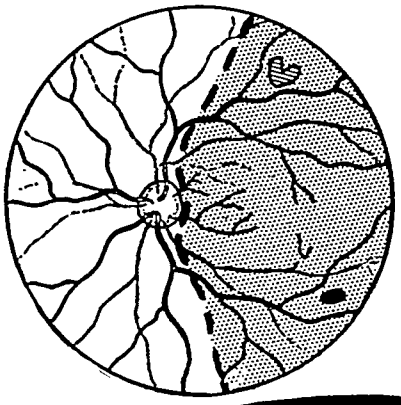
History. W. M., aged 25 years, in September, 1944, was fixing a tire in Finchaven, New Guinea, when something struck his left eye. About February 25, 1945, the patient noticed a veil over his left eye. He was hospitalized on February 26, 1945, and given bed rest for three weeks. He arrived at Crile General Hospital, a litter case, by air transport on April 5, 1945.

Findings. A retinal detachment was present in the temporal half of the left eye, with a horseshoe-shaped tear on the retina in the upper temporal quadrant. A retained intraocular foreign body was in the lower temporal area. There was mild siderosis. Vision was: O.D., 20/20, J1; O.S., 10/200, no Jaeger.

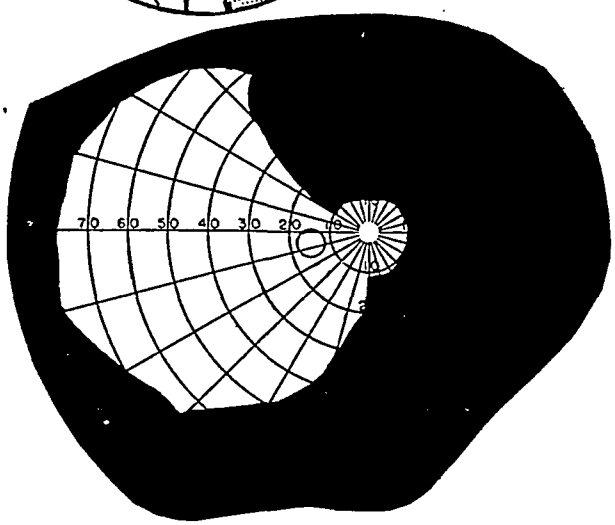
Operation. On April 11, 1945, a magnetic foreign body, 1 by 1 by 1 mm. was removed through the pars-plana approach; then an extensive barrage was done with a single, insulated diathermy tip from the 6-to 12-o'clock positions.

Result. Plastic cyclitis developed, with posterior synechias. The anterior chamber was loaded with cells; fundus details were obscured. The patient did not respond to typhoid, penicillin, or atropine therapy. On May 8, 1945, the left eye was enucleated. There was no sympathogenic involvement of the right eye. Microscopic slides of left eye showed cyclitis with a cyclitic membrane, and detachment and gliosis of retina.

CASE 15



History. E. J., aged 23 years, was injured by a detonator-cap explosion in Germany on April 24, 1945. On April 30, 1945, he was operated on at the 203rd General Hospital and a foreign body was



removed. He arrived at Crile General Hospital on May 25, 1945.

Findings. There was poor light reflex and a massive vitreous hemorrhage of the left eye. Two intraocular foreign bodies were removed by the pars-plana approach, one temporal and one nasal, on June 11, 1945. The vitreous cleared. On August 23, 1945, the patient helped to lift a piano and a curtain closed over his left eye. Field and fundus examinations the next morning showed an almost total retinal detachment. Vision was: O.S., light perception only; O.D., 20/20, J1.

Operation. On August 29, 1945, after five days' rest in bed, an extensive barrage was done over the temporal half of the retina.

Result. The eye did poorly, and was enucleated on October 2, 1945.

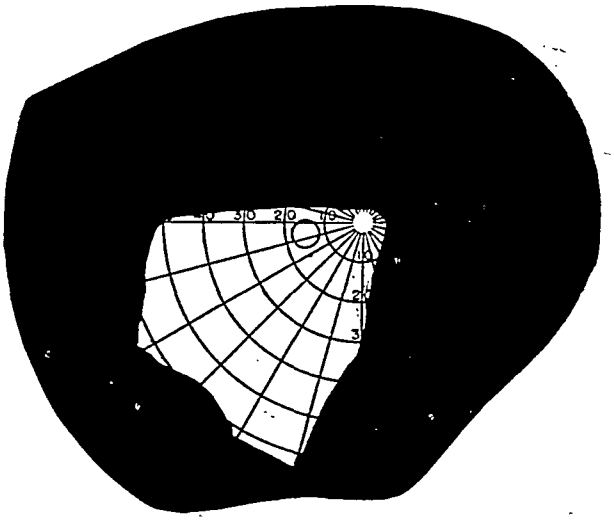


Fig. 14 (Croll and Croll). *Case 14.* A retinal detachment (above) was present in the temporal half of the left eye, with a horseshoe-shaped tear on the retina. Before surgery (left) field for 5-mm. white; vision, 10/200, not correctible. After surgery (right) field for 6-mm. white; vision, light perception only.

COMMENT

Areas of dialysis were present in six cases and peripheral holes in five, and no hole was seen in four cases. Extensive barrage was done over the affected area because of the severity of the injuries. The use of a combination of coagulation and cutting current, rather than coagulation current, is preferred to obtain delayed healing of micropunctures, thus resulting in adequate drainage and reattachment of the retina. In cases of spontaneously reattached retinas in young and active patients, recurrent detachments resulted when the patients became ambulatory, necessitating surgery. Scleral resection was done in two cases of severe retinal detachment, with good results.

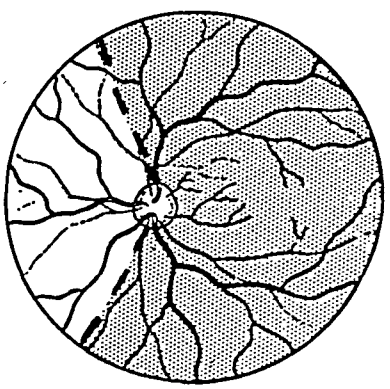

Fig. 15 (Croll and Croll). *Case 15.* Poor light reflex and massive vitreous hemorrhage of the left eye.

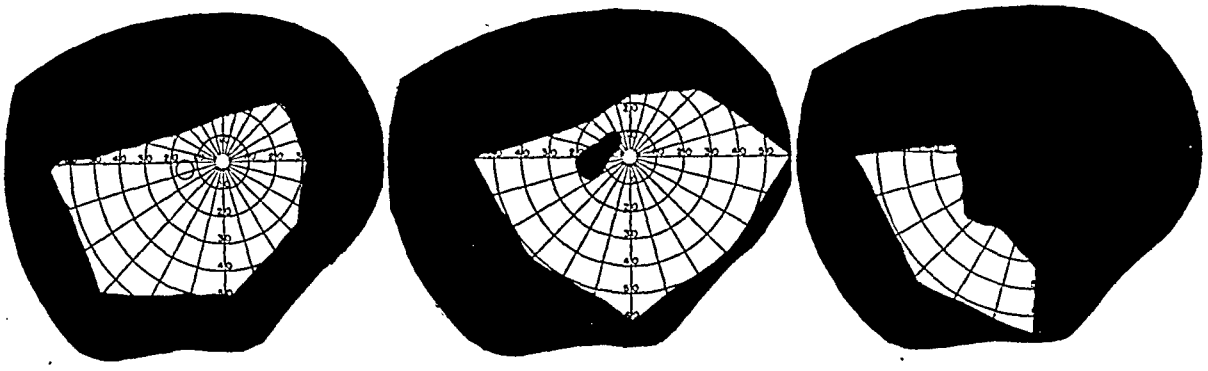

Fig. 16 (Croll and Croll). *Case 15.* Before surgery (left) visual-field target was ophthalmoscope light. (Center) Field for 3-mm. white after removal of two intraocular foreign bodies; vision, 20/400. (Right) Sudden and almost complete detachment after lifting piano. Target used was 18-mm.

Acknowledgement is made to Lieut. Col. G. C. Struble, Maj. H. G. Scheie, Maj. J. D. Sleight, and Captain Hoyt for allowing us to present these cases and to Sgt. Helen Hellebo who performed the visual-field studies and prepared the enclosed field records.

THE FUNCTIONAL ORGANIZATION OF THE THIRD-NERVE NUCLEUS IN THE CAT*

PIERRE C. DANIS, M.D.†
Brussels, Belgium

In 1942, Szentagothai showed by means of a modified Horsley-Clarke stereotaxic instrument, and a technique of direct stimulation of the oculomotor nerve nucleus that the representation of the striated ocular muscles within this nucleus for the cat and the dog is rather different from the one usually admitted.

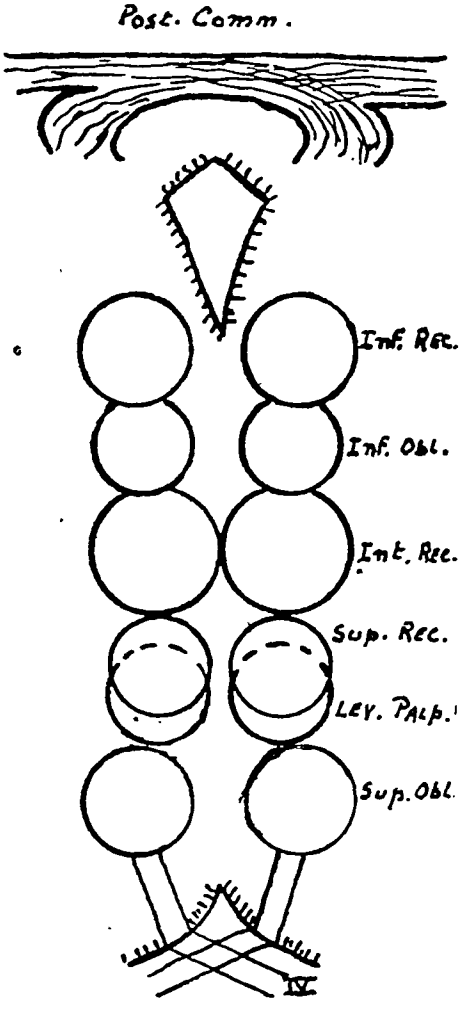

Fig. 1 (Danis). Functional organization of the third-nerve nucleus of the cat and the dog according to Szentagothai.

In 1943, Bender and Weinstein repeated this type of experiment on the monkey (Macaca Mulatta). Their conclusions were similar with those of Szentagothai.

According to these authors, the distribution of the radicular cells corresponding to the different eye muscles would be on the following pattern: going from the rostral to the caudal end of the third-nerve nucleus one would have the radicular cells for the inferior rectus, the inferior oblique, the internal rectus, and the superior rectus. The cells connected with the levator palpebrae would be grouped at the posterior end of the third-nerve nucleus against the fourth-nerve nucleus (fig. 1).

Szentagothai was unable to find any functional organization of the nucleus in a dorso-ventral direction. Bender and Weinstein believe that the different cell groups have more or less the shape of commas whose tails come under the head of the next anterior group. This arrangement would explain the fact that stimulation at different depths on the same dorsoventral axis gave different ocular movements.

None of these authors was able to show an organization of the nucleus in the transverse plane.

This type of experiment does not allow one to determine with certainty whether the innervation of the ocular muscles is crossed, direct, or mixed; it shows, however, that the majority of cells innervates the ipsilateral muscles.

These researches give a scheme of the functional organization of the third-nerve nucleus that is very different from those commonly published in ophthalmic and neurologic textbooks. The scheme more often

† Fellow of the Belgian American Educational Foundation.

reproduced for man is the one of Brouwer. This scheme is partly the extension to man of the experiments of Bernheimer on the monkey.

Bernheimer and all the other authors who have studied the localization of the eye muscles within the third-nerve nucleus have used the technique of retrograde degeneration (rabbit: van Biervliet, Bernheimer, Bach, Schwabe; cat: Abd-el-Malek Shafik, Latumeten). Szentagothai has also extirpated isolated eye muscles. The distribution of the retrograde degeneration in the third-nerve nucleus confirmed his results obtained by localized electrical stimulation.

The technique of retrograde degeneration is not in this case very reliable because the tigrolysis is sometimes very difficult to distinguish from normal variations, and has by itself given results as divergent as those obtained by Bernheimer and by Bach.

As the investigations of Szentagothai and of Bender and Weinstein are the only two mentioned in the literature which have used this precise technique of localized stimulation of the third-nerve nucleus, we thought it would be interesting to repeat these experiments. For technical reasons we chose the cat.

Further research will have to be done to show that our results, in broad lines in agreement with those of Szentagothai and of Bender and Weinstein, can be extended to man and other species.

Technique

Under barbiturate anesthesia, the head of the cat is held in the Horsley-Clarke apparatus illustrated in the paper of Talbot and Marshall. The posterior and lateral parts of the calvarium are chipped off to the junction with the tentorium cerebelli behind, and to the frontal bone rostrally. After incision of the meninges, the two occipital lobes are progressively drawn apart exposing the superior colliculi whose posterior aspects are covered by the anterior and medial end of the tentorium cerebelli. This bony nib is resected to give a clear approach to the superior colliculi. Bleeding is sometimes important when one approaches the brain stem; this can be greatly reduced by ligating the sinus longitudinalis superior and the vein of Galen. No animals died during the experiments.

When the anatomic landmarks of the superior colliculus are clearly visible, the stimulating apparatus is put in place. We have used a unipolar electrode formed by a sharpened steel needle. The needle is electrically insulated with varnish except at the extreme tip.*

The electrode is driven in vertically (that is to say in a plane perpendicular to the plane: external auditory canal-infra-orbital margin) at various distances from the midline and going from the posterior limit of the superior colliculus forward over about 4 mm. If the distance from the midline exceeds 1 mm. the needle going downward does not meet the nucleus. When the needle is presumed to be in the region of the third-nerve nucleus, which, as an average, is 6 to 7 mm. below the level of the sulcus between the superior colliculi, the electrical stimulus is applied at different depths and the eyes are observed.

As stimulus we have applied threshold (7 volts) and suprathreshold potentials of spike form at 60 per second, cathodally.

To locate exactly the points stimulated, we have used a technique consisting of passing through the electrode as anode a direct current of 10 to 20 microamperes during 10 seconds. The exposed tip of the electrode deposits in the nervous tissue some iron that can readily be shown later (fig. 2) as a spot about 0.2 mm. in diameter.

We find that in this type of experiment, recording very slight movements of the eye elicited by threshold stimulus, it is better to take out the orbital hooks of the Horsley-Clarke apparatus. These hooks strongly compress the inferior eyelid and conjunc-

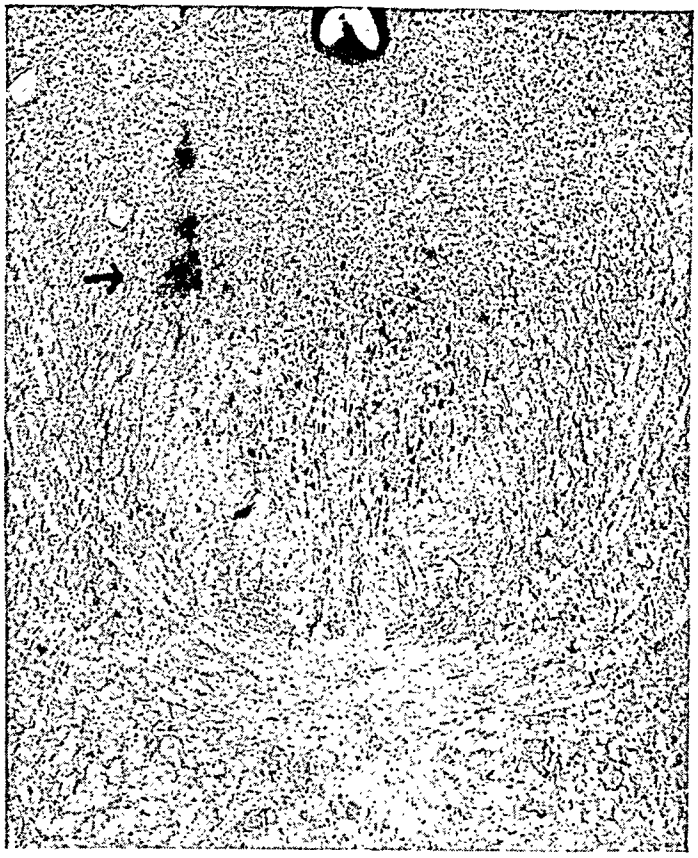

Fig. 2 (Danis). Frontal section at the anterior end of the third-nerve nucleus of the cat. (Gallocyanin stain, ×20.) The arrow indicates the iron blue mark. The dark line above this mark corresponds to the needle track. On the section it appears brownish.

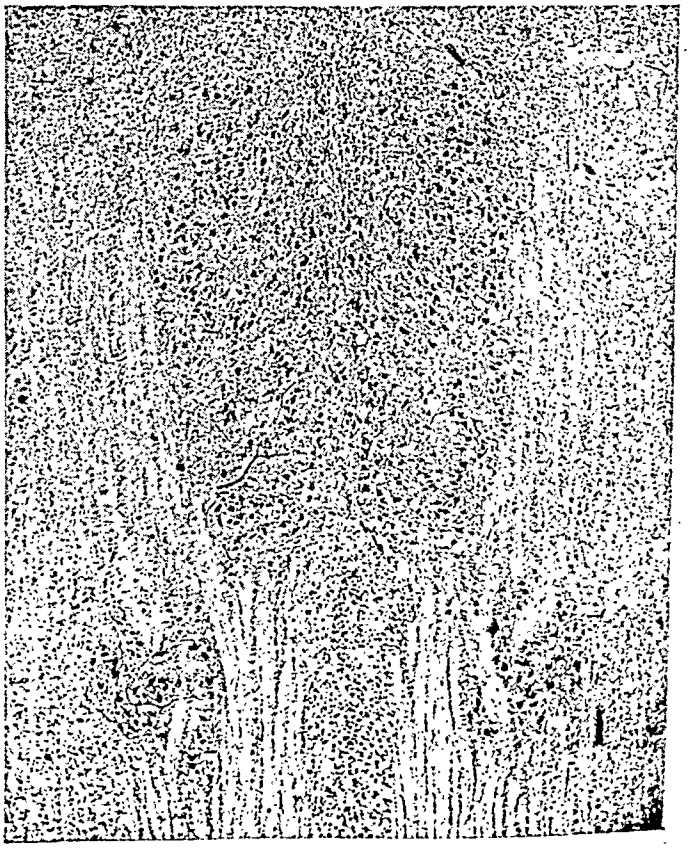

Fig. 3 (Danis). Horizontal section of the third-nerve nucleus of the cat. The section is parallel to the floor of the aqueduct of Sylvius. (Gallocyanin stain.) One can see the two lateral columns more or less fused on the midline. On the midline in the anterior part, the nucleus of Edinger-Westphal. Posteriorly and a little more laterally than the third-nerve nucleus, the two fourth-nerve nuclei. (× 24.)

tiva against the orbital rim and may, therefore, hinder completely free motion of the eyes. Before putting the stimulating apparatus in place, we replaced the orbital hooks by a frontal band which pressed the head down against the maxillary pieces to obtain a firm fixation.

At the end of the experiment the animal was killed and fixed by perfusion.

The brainstem is sectioned frontally in a plane approximately parallel to that followed by the electrode. Serial sections are made at 50 microns with the technique of Marshall, then submitted to a Prussian-blue test and stained with gallocyanine.

Anatomy

We will not give a detailed description of the oculomotor-nerve nucleus in the cat. This can be found in the papers of Abd-el-Malek Shafik, Bach, Beauvieux, Benjamin, Crouch, Latumeten, LeGros Clark, Levinsohn, Monakow, Panegrossi, Spitska, and Winkler.

The general structure is best seen on a horizontal section parallel to the floor of the aqueduct of Sylvius (fig. 3). The nucleus is formed by two columns of large multipolar cells, in anteroposterior direction under the floor of the aqueduct of Sylvius lying on the dorsal aspect of the posterior longitudinal bundle. In their anterior portion the two columns are clearly separated by a space containing the small-cell nucleus of Edinger-Westphal. In agreement with Bach, Benjamin, Brouwer, Latumeten, Levinsohn, Spitzka, and Winkler, and contrary to Beauvieux and Panegrossi, this nucleus was always seen to be present and well developed in the cat. In their posterior portion, the two masses get thicker laterally and dorsoventrally, and the central space is occupied by cells similar to those of the lateral columns; at this level there is no clear anatomic limit between the right and the left nucleus (LeGros Clark). At the posterior end, the two nuclei are once more clearly separated from each other. Like the other authors, we have not the impression that these medial cells are organized in a group anatomically distinct from the lateral nuclei, equivalent to the nucleus of Perlia.

Like Bach and MacLean, we have not found with enough constancy a subdivision of the lateral column in a dorsal and a ventral part, on different slides of the same or different animals, to justify a subdivision into two groups, ventral and dorsal, contrary to Abd-el-Malek Shafik, Monakow, Panegrossi, Spitzka, and Winkler.

On frontal sections the two columns have a V shape, opening upward. In the anterior part, the branches of the V are separated from each other; as one goes toward the posterior end the two branches tend to meet in their medial and inferior part as if by filling the space with cells similar to those of the lateral nucleus. These cells constitute the central group described on the horizontal sections.

Results

I. Points of stimulation

In a given animal, going on any transverse line from the right to the left, we have never seen any modification of the type of ocular response. If at a given level one obtained an elevation of the eye, at all other points of positive stimulation on the same transverse line and the same depth, the response was an elevation. The same applies to adduction of the eye or depression.

If one takes care to use a minimal stimulus, one will obtain a unilateral response—except when the needle is on the medial plane or so near that it is difficult to exclude a bilateral stimulation.

As far as the possibility of a contralateral innervation is concerned, our experiments do not allow us to exclude definitely this possibility, but it is certainly of little importance. In the large majority of cases the ocular response is ipsilateral, and the few cases where a contralateral response was obtained corresponded to stimulation on the midline. Because the needle is so near

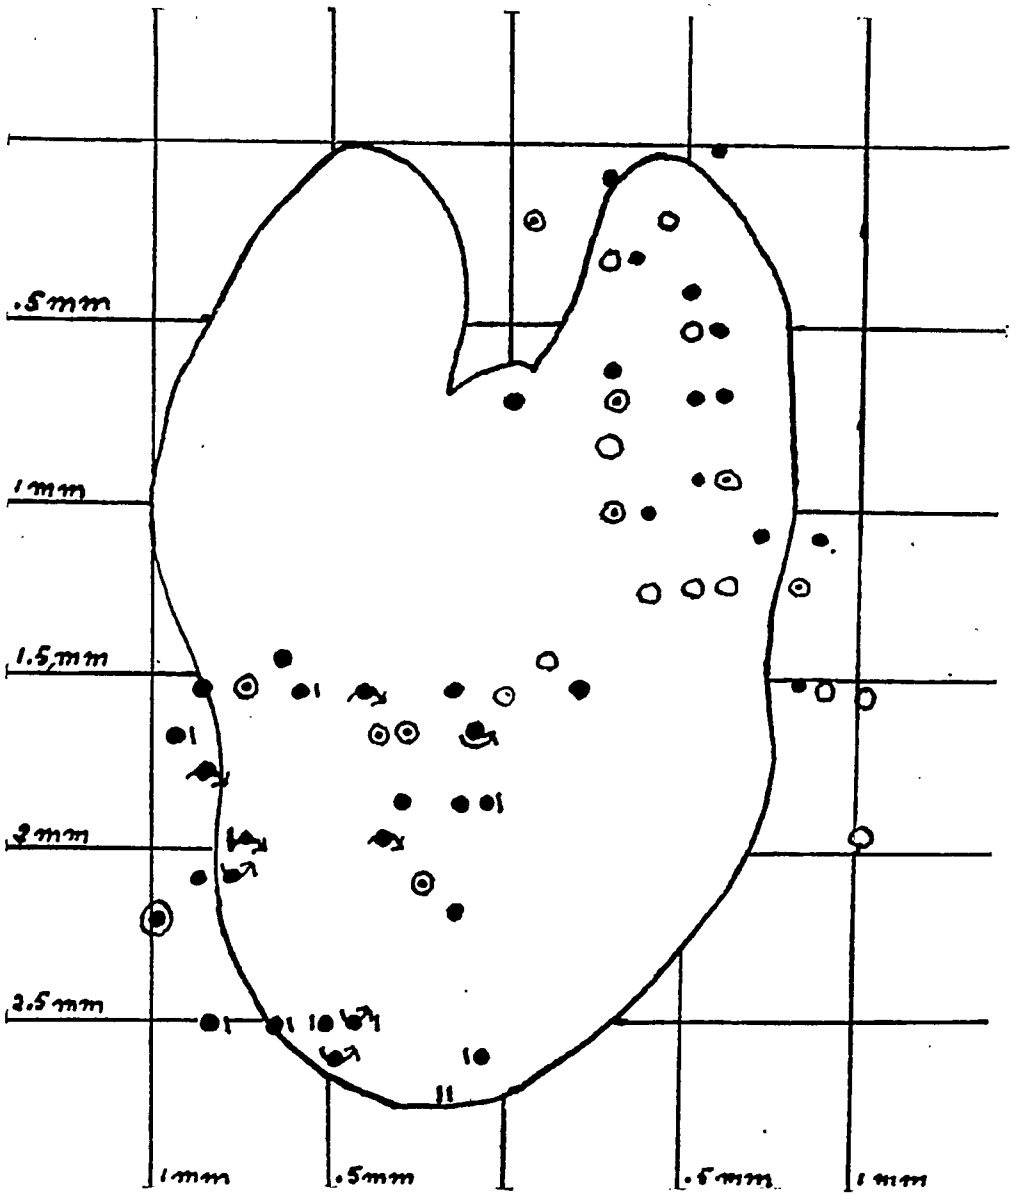

Fig. 4 (Danis). Horizontal projection at the depth of the nucleus (above the fibers level) of responses obtained in different cats (8):

• Represents an elevation of eye if on the left part of the drawing, a depression if on the right side (the point on the midline corresponds to a depression.

○ Represents a movement of pure adduction of the eye.

⊙ Represents a mixed movement of the eye, adduction with elevation if on the left part of the drawing, adduction with depression if on the right side.

\ Indicates an elevation of the upper eyelid.

Indicates if the elevation was associated with an intorsion.

Indicates if the elevation was associated with an extorsion.

This drawing gives the location of the points of stimulation in the antero posterior and the transverse plane.

the midline, the experimental conditions do not permit a discrimination between a contra- or bilateral innervation or a stimulation of the contralateral cells.

This agrees with the descriptions of Abd-el-Malek Shafik and Beauvieux. For these authors there are more direct than crossed fibers, the crossed fibers being located the nearest to the midline.

In Figure 4 the location of the different points of stimulation is given on a horizontal section. The fact that on the same anteroposterior level two different responses are sometimes seen is due to the

fact that it is a composite drawing of the points of stimulation recorded in eight cats and reduced to the same scale.

II. Types of response

As far as an organization in a dorsoventral direction is concerned, which was defended by Latumeten for the cat and Le Gros Clark for all the species as a general rule, we have been unable to find any definite proof.

We shall in connection with the work of Bender and Weinstein mention here a special point of technique. In their paper Bender and Weinstein describe the ocular responses obtained in the anterior part of the nucleus by stimulating points in dorsoventral direction: first depression of the eye, underneath adduction, still deeper elevation of the ipsilateral eye; between these three regions they obtained mixed responses: depression and adduction between the two first ones, elevation and adduction between the two deeper.

We have obtained the same type of responses in the anterior part of the cat's nucleus, but each time we have seen that the two inferior marks were in the efferent fibers of the third nerve while the point for depression of the eye was within the nucleus. The anteroposterior organization of the nucleus and the disposition of the radicular fibers must be kept in mind. The axones of the cells go downward, forward, and slightly outward to emerge at the inferoventral aspect of the peduncle. Thus the fibers pass under the cells anterior to those from which they are originated. This tends to be more marked on the Horsley-Clarke apparatus. The electrode being perpendicular to the orbitoaural plane forms with the longitudinal axis of the brainstem an angle of about 110° toward the rear. This explains furthermore that in front of the nucleus, the electrode can stimulate fibers without going through the nucleus. This can simulate a nuclear response if a careful location of the point of stimulation is not done (fig. 5).

This interpretation of some of the results of Bender and Weinstein, as applied to the cat, seems to be confirmed by the fact that in the anterior part of the nucleus, three different ocular movements could be obtained on the same dorsoventral axis and in always the same sequence—depression, adduction, elevation; in the middle part two responses only could be obtained—adduction and elevation; and in the posterior part only one—elevation.

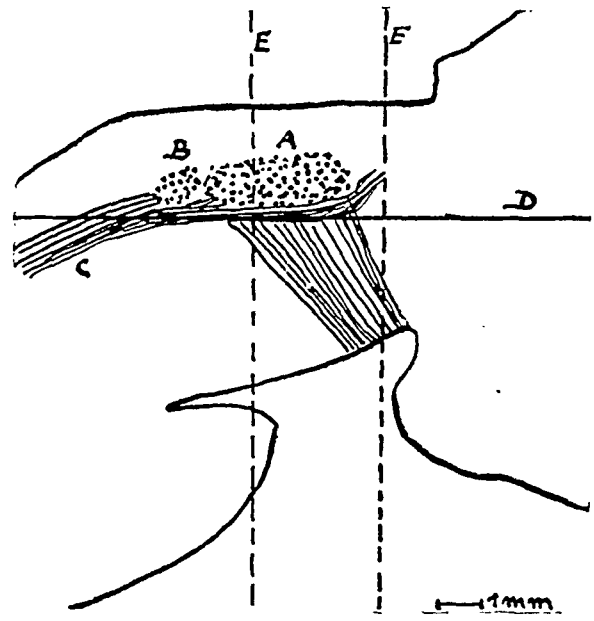

Fig. 5 (Danis). Sagittal section of the brainstem. The roof of the aqueduct of Sylvius is not represented. Composite drawing to show on the same plane the disposition of the third-nerve nucleus and the direction of the nerve fibers: (A) third-nerve nucleus; (B) fourth-nerve nucleus; (C) posterior longitudinal bundle; (D) horizontal plane of the Horsley-Clarke apparatus corresponding to the orbitoaural plane in the animal; (E) direction of the electrode.

In no instance, basing ourselves only on landmarking by the technique mentioned above, have we been able to obtain two points located on top of each other and still within the nucleus that would give different ocular responses. In some instances one could obtain at one point a sort of mixed response that could be attributed to the combined stimulation of two different muscles; but this always happened in zones that were at the common limit of two zones, disposed

anteroposteriorly, where one obtained a pure response of one or the other type.

III. Analysis of results

If in the interpretation and the mapping of the results, one remembers the features that we have mentioned, so as to retain only the points of stimulation located in the nucleus and not under it, a very definite organization of the third-nerve nucleus appears in the anteroposterior direction. Going from the rostral to the caudal end, one has successive points giving depression of the eye (isolated or sometimes with extorsion), then pure and extreme adduction of the eye, then elevation of the eye. The elevation of the eye when the stimulation is carried into the posterior part of the nucleus is accompanied by an elevation of the upper lid. An isolated elevation of the upper lid is only seen when the extreme posterior part of the nucleus is stimulated.

We have already mentioned that in certain cases a mixed response was obtained, depression of the eye with adduction or elevation with adduction. Plotting at the same scale the results obtained on different cats, one sees that these mixed responses fall at the margin of the zones where simple responses of one or the other type were obtained (figs. 4 and 6). It seems, therefore, that one can attribute these responses to a double stimulation due to the fact that the electrode is at the junction of two territories with different functions. Our technique shows no well-cut limit between two territories functionally different.

In their principal lines these results confirm those of Szentagothai and of Bender and Weinstein.

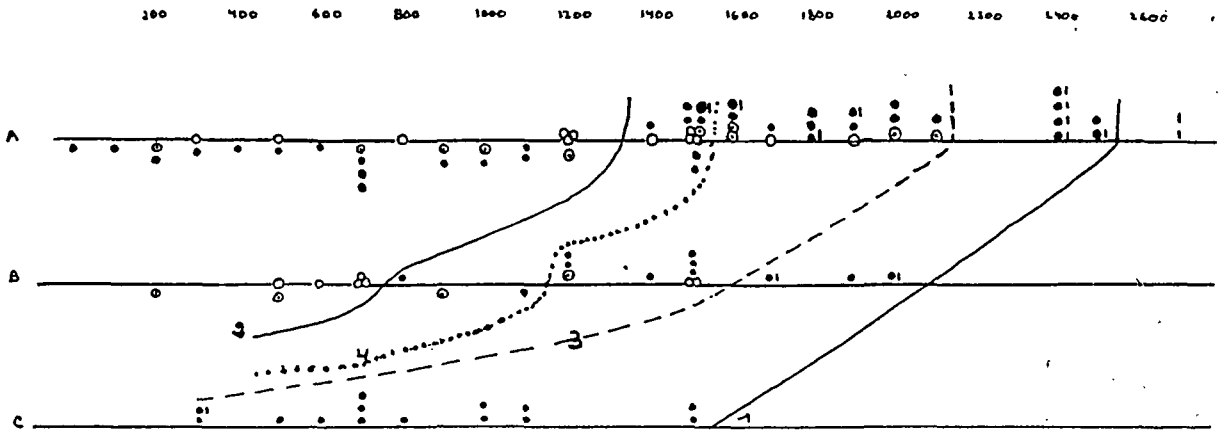

Fig. 6 (Danis). Anteroposterior projection of the point of stimulation observed in eight cats (only the points shown on Figure 4 are recorded) and reduced to the same scale. The numbers on the upper line indicate in microns from the anterior pole of the nucleus the level of the stimulation in the anteroposterior direction. The three horizontal lines correspond to three different levels in depth, the upper one corresponding to the intranuclear stimulations. In this projection the position of the stimulation in regard to the midline is not taken in account. All the points on the same horizontal line correspond to stimulation at the same depth in different animals. The number of points at a given level on a horizontal line corresponds to the number of different points of stimulation. All the points on the same vertical line correspond to the same situation of the electrode, and the horizontal line indicates their respective level in depth and the response obtained. For every point on (C) and (B) there is point on (A).

● Indicates an elevation of the eye or a depression, if it is above or under the horizontal line respectively.

○ Indicates a pure movement of adduction.

⊙ Indicates a mixed movement of adduction with elevation if above the horizontal line, or depression if under the horizontal line.

\ Indicates an elevation of the upper lid.

1 and 2 indicate the posterior and anterior limit of the zone where an elevation of the eye is obtained; 3 indicates the posterior limit of the zone where an adduction could be obtained; 4 indicates the posterior limit of the zone where a depression could be obtained.

We have, however, obtained rather different results as far as the localization of the inferior oblique is concerned. Bender and Weinstein localized with some doubt the radicular cells of this muscle in the anterior part of the nucleus between the ones for the inferior rectus and the ones for the internal rectus. They base this opinion on the fact that, at this point, stimulation gives an isolated extorsion of the ipsilateral eye (in 4 monkeys out of 24 experimented on). Szentagothai gives the same localization for the territory in front of the one for the internal rectus, but this was nearly always accompanied by a slight depression of the eye. In no cats have we obtained elevation of the eye by stimulation of points between the territories for the internal rectus and the inferior rectus. In all cats the same sequence of movements was obtained, going from the caudal to the rostral end of the nucleus—elevation, adduction, depression.

We believe that the inferior oblique must be localized behind the internal rectus in the

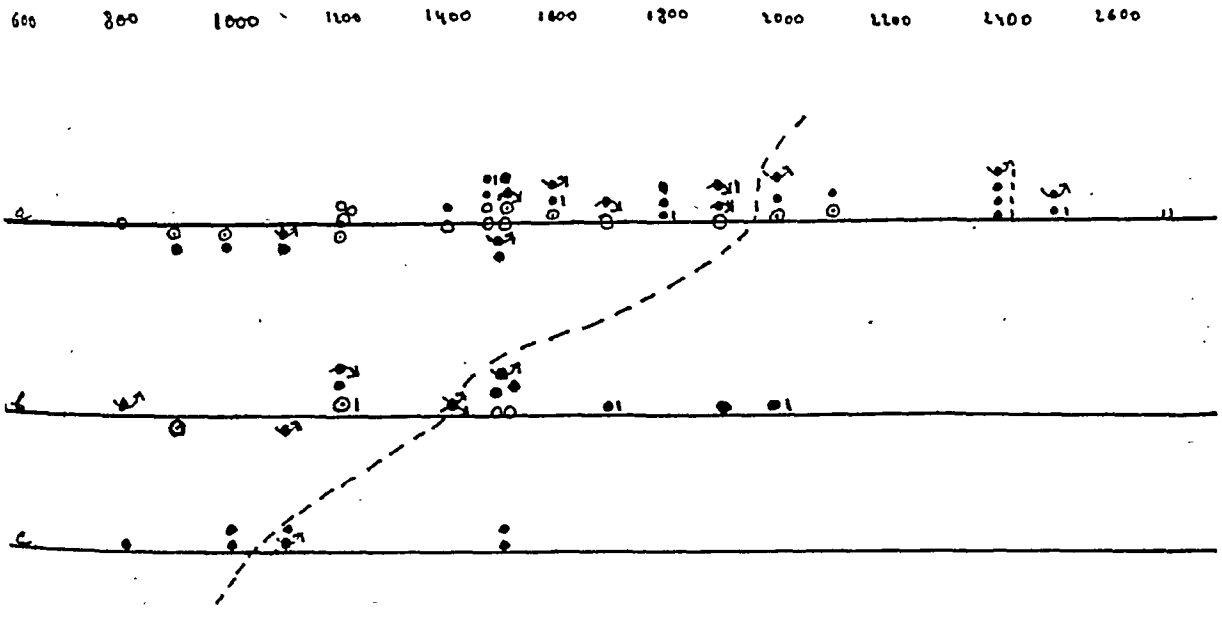

Fig. 7 (Danis). Same projection as Figure 6 to show the distribution of the movement of elevation with intorsion and of elevation with extorsion.
↷ Elevation with intorsion (superior rectus).
↷ Elevation with extorsion (inferior oblique).

inferior oblique (fig. 1) in the cat, basing his opinion on the same criteria, isolated extorsion of the eye.

This argument does not seem decisive because at this level we are at the posterior limit of the zone for the inferior rectus, a muscle which also gives an element of extorsion in the depression of the eye (this was also found by Bender and Weinstein). It seems, therefore, doubtful to use the extorsion of the eye as only criterion to differentiate the action of the inferior oblique from the inferior rectus.

We too have obtained extorsion in the vicinity of the superior rectus and levator palpebrae because, in this zone, we could obtain three types of elevation—elevation with intorsion (superior rectus), pure elevation (it was impossible to see any torsional component in this movement), and elevation with extorsion (inferior oblique). We may analyze a representation (fig. 7) which superimposes the results obtained at similar anteroposterior levels in three different cats. Of the seven points for the inferior oblique (elevation with extorsion) five are well posterior to the average locus for the superior rectus (elevation with intorsion). These

few data show the center for the inferior oblique is even behind that for the superior rectus.

Conclusions

In general our results on the cat are in agreement with those of Szentagothai and of Bender and Weinstein done respectively on the cat and dog and on the monkey. However instead of localizing the inferior oblique in the anterior part of the nucleus between the inferior rectus and the internal rectus, we locate it behind the internal rectus in the vicinity of the superior rectus and probably between the superior rectus and the levator palpebrae, near its antagonist the superior oblique.

1. With the technique used there is no functional organization of the third-nerve nucleus in the transverse nor in the dorsoventral direction. The latter we regard as a confusion of nuclear and fiber organization.

2. The majority of cells send fibers to the ipsilateral muscles. A contralateral innervation was not seen, but the hypothesis of a weak crossed innervation is impossible to deny by this method.

3. The functional organization of the third-nerve nucleus follows the following plan, going from the caudal to the rostral end: inferior rectus, internal rectus, superior rectus, inferior oblique, levator palpebrae. This does not correspond to a discrete anatomic organization, for the experiments with stimulation show that these zones merge into each other.

These experiments give a functional organization of the third-nerve nucleus in the cat that differs from those proposed on the basis of retrograde degeneration, by Abd-el-Malek Shafik and Latumeten, for the cat, and by Brouwer for man. This scheme in its broad lines resembles the one demonstrated by Szentagothai for the cat and by Bender and Weinstein for the monkey.

Of the other experimenters using the technique of retrograde degeneration, Monakow, Bach, and van Biervliet proposed a roughly similar arrangement of the third-nerve nucleus with the depressor muscles in the rostral part and the elevator muscles in the posterior part. All three authors also put the inferior oblique behind the internal rectus in the vicinity of the superior rectus, but only van Biervliet localized, in the rabbit as we do in the cat, the inferior oblique behind the superior rectus.

The author wishes to acknowledge his indebtedness to Dr. Samuel A. Talbot, whose help, interest, and criticisms have permitted the realization of this work.

ESSENTIAL PROGRESSIVE ATROPHY OF THE IRIS*

MORTIMER A. LASKY, M.D.
Brooklyn, New York

Essential progressive atrophy of the iris is a relatively uncommon disease. Duke-Elder[1] characterizes it as a unilateral disease of unknown etiology that is marked by a slowly progressive atrophic change in the tissues of the iris, which leads to the complete disappearance of large portions of the iris and ultimately ends in blindness from absolute glaucoma.

Since Sugar[2] reported his case in 1945, Arruga[3] and Cyukrasz[4] have each added a new one, the latter author reporting a bilateral case in which cyclodialysis successfully relieved the glaucoma. This paper brings the total cases reported in the literature to 51. Undoubtedly more cases have existed and it is hoped that some of these will be reported. The writer has had the opportunity to follow a case of this disease for over 10 years and the case history is being submitted as an addition to the current literature.

The iris atrophy and the glaucoma are both the outstanding clinical observations in this entity.

CASE REPORT

History. Miss N. S., aged 22 years, was first seen by me on June 5, 1934, with the complaint that the pupil in her right eye had "dropped down." There was no history of trauma or disease. Her vision had not been affected. Examination disclosed a pear-shaped pupil, which was eccentrically displaced down, giving the impression of a congenital coloboma of the iris. Uncorrected vision was 20/50 in the right eye, and 20/200 in the left eye. She had a myopic error and correction improved vision in the right eye to 20/30; the left eye to 20/20.

Examination on June 14th and 19th of the same year revealed no change; the media were clear and the fundi were normal but there were deep physiologic cups in the discs. The patient was advised to return at frequent intervals. In October, 1934, she had a bilateral salpingo-oophorectomy, the pathologic records of which could not be obtained.

Course: She failed to return for observation until March 14, 1939, five years later. On that day she stated that one week previously she noticed that there were two pupils in her right eye. Examination showed the displaced pupil below and a large gap in the superior iris. The gap had many strands of iris tissue in it. The nasal portion of the iris was gray, while the normal iris tissue was dark brown. The true pupil reacted to light, especially in its upper portion.

Vision was: O.D., 20/100, correctible to 20/40 with a −1.50D. sph.; O.S., 20/100,

* From the Long Island College of Medicine and the Brooklyn Eye and Ear Hospital. Presented before the Brooklyn Ophthalmological Society, October 23, 1947.

correctible to 20/20—1 with a —1.25D. sph. The peripheral fields were normal at this time. Tension was; O.D., 23 mm. Hg; O.S., 15 mm. Hg (new Schiøtz). Wassermann test was negative; nose and throat examinations were essentially negative; but a positive Mantoux reaction was obtained.

On April 18th, the iris atrophy had extended farther nasally and the gap had increased in size (fig. 1). The lower margin of the true pupil was adherent and immobile. The patient was warned to expect

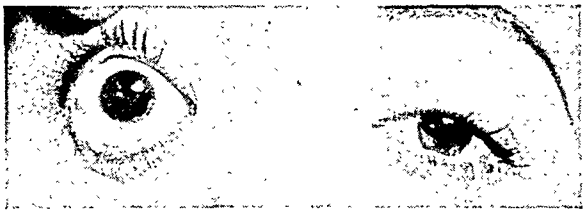

Fig. 1 (Lasky). *April 18, 1939.* The iris atrophy had extended farther nasally and the gap had increased in size.

trouble and to report at the first sign of pain or inflammation in the eye.

We next saw her on September 7, 1939, (fig. 2). By then she had developed more visual loss and had some redness of the eye with a vague feeling of disturbance. The tension was found to be: O.D., 35 mm. Hg; O.S., 20 mm. (new Schiøtz), and the peripheral field of the right eye showed a moderate general contraction with an angular defect in the inferior nasal quadrant. The blind-spots were normal. Pilocarpine solution (1 percent) was prescribed for use every four hours in the right eye.

Surgery. On September 16th, she returned complaining of a heavy dull pain in the right eye. Tension proved to be: O.D., 56 mm. Hg; O.S. 18 mm. Operation was advised and the patient consented. In view of the deterioration of vision and poor prognosis in this ailment, it was decided to do a Lagrange sclerectomy with as large an opening as possible. The procedure was accomplished without any difficulties on September 21st, and a large dark bleb resulted. Tension became: O.D., 23 mm. Hg; O.S. remained at 18 mm. No changes were noted in the iris or pupil of the right eye. The eye gradually became white, and a good bleb, partially filled with black pigment, was present. The fundus was clearly seen but the view was distorted due to a large astigmatic error, which appeared following the operation.

Fig. 2 (Lasky). *September 7, 1939.* By now the patient had developed more visual loss and had some redness of the eye with a vague feeling of disturbance.

There was occasional pain in the right eye despite normal tension. The bleb became progressively darker and more prominent. Iris atrophy continued to progress and there was a grossly evident anterior synechia formation at the 6- to 7-o'clock region of the limbus. On February 17, 1940, almost five months after the Lagrange sclerectomy, the tension of the right eye rose to 48 mm. Hg, (new Schiøtz), so an Elliot trephining operation (2 mm.) was performed temporally to the previous opening. However, this proved adequate for only six months A second Elliot trephination (2 mm.) was done at the 3-o'clock limbus position. After this procedure, the tension remained at 35 mm. Hg (new Schiøtz).

Because of the failure of these various operations, it was decided to abandon the anterior-segment procedures and to do a

posterior sclerectomy. On November 8, 1940, a 2-mm. button of sclera was removed from the infero-temporal quadrant of the globe in the region of the equator. This procedure was accompanied by the loss of a small amount of vitreous. A large bulbous area appeared beneath the conjunctival flap. It remained boggy for about two months and gradually became reduced in size. The tension did not return to normal limits until the operative area had become well healed with a flat well-formed bleb. On January 18, 1941, tension was: O.D., 13 mm. Hg (Schiøtz).

Outcome. The patient was not seen again by me until November 5, 1941. At this time the vision was: O.D., 1/200; O.S., 20/50; correctible to O.D., 20/30 with a −1.0D. sph. ⊂ −8.0D. cyl. ax. 70°; O.S., 20/20 with a −1.0D. sph. Tension was: O.D., 25 mm. Hg (Schiøtz). The original pupil was displaced to the 7-o'clock limbal area. The Lagrange filtration was marked by a large irregular black bleb. The two Elliot trephinations could hardly be discerned. The site of the posterior sclerectomy was flat but thickened. The lens and vitreous were clear allowing a view of a normal fundus, although it was a greatly distorted picture due to the large astigmatic error.

The situation was relatively unchanged on March 8, 1942. Vision in the right eye was still 20/30 with correction, and tension was 20 to 25 mm. Hg (Schiøtz).

On April 15, 1947, the patient presented herself again for an examination and the following findings were elicited. Vision was: O.D., 15/400, unimprovable; O.S., 20/30, improved to 20/20 by −0.75D. sph. Tension was: O.D., 27 mm. Hg; O.S., 15 mm. Hg (Schiøtz). (She stated that tension in the right eye had been 25 to 27 mm. Hg (Schiøtz) at all times since 1942.) The left eye was normal in all respects. The right globe (fig. 3) showed very little evidence of the posterior sclerectomy, just some conjunctival thickening. At the site of the Lagrange sclerectomy, there was a large irregular bleb that was tense and well filled with black-stained material. The Elliot trephination on the nasal side was flat and sealed. The iris was adherent anteriorly from the 6- to 7-o'clock position at the limbus; the entire upper portion was missing except for a few long strands that tapered from the iris below to the anterior lens surface above; the

Fig. 3 (Lasky). *April 15, 1947.* The iris was adherent anteriorly from the 6- to 7-o'clock position at the limbus; the entire upper portion was missing except for a few long strands that tapered from the iris below to the anterior lens surface above.

remnant of iris had a serrated edge and hung like a hammock from the 8- to 3-o'clock position. The pupil was somewhat triangular with the base above; this base still reacted to light. There were no deposits on the posterior surface of the cornea. The aqueous was clear.

The lens was studded on its anterior and posterior surfaces by numerous pigment particles ("bird-in-flight" type) that were especially dense near the nasal equator. A posterior cortical lens opacity was present below. Beneath the site of the nasal Elliot trephination a notch in the lens edge was clearly visible. The vitreous seemed clear and the fundus appeared to be normal except for a pale disc.

Comment

The general consensus of opinion at present is that the glaucoma is secondary to the

formation of peripheral anterior synechias, Lloyd.[5] However, various other theories have been advanced; such as Feingold's[6] conception of irritating substances formed as a result of iris tissue destruction; Kreiker's[7] idea that iris tissue debris occluded the chamber angle; Licsko's[8] coupling of the latter with loss of iris surface for resorption of aqueous. Rochat and Mulder[9] first advanced the thought that the anterior synechias are the agents responsible for the glaucoma. Rones[10] points out that many instances occur in which large segments of iris are lost by operation or trauma and glaucoma does not necessarily supervene.

Iris atrophy has been a moot question. De Schweinitz[11] believed it to be due to a local abiotrophy. Feingold suggested that a congenital vascular disturbance of the smaller iris circle caused the atrophy; Sugar explained that a lack of involvement of the sphincter militates against this view. Kreiker believes that in adult life the cytolitic process that occurs in embryonic life, causing the resorption of the pupillary membrane, suddenly becomes newly active and attacks the normal iris tissue. However, I am inclined to concur with Rochat and Mulder in their belief that the iris tissue atrophy is secondary to the constant, progressive stretching of the iris as it is pulled to one side of the anterior chamber. As has been described in the present case, there has been formed a mass of anterior synechias not only in the chamber angle below but also recently above to the visible cornea; there is a constant inexorable traction force. The longer the eye survives, the more anterior synechias form and the greater is the iris tissue destruction.

The true cases of "essential" atrophy of the iris have all been notable for the absence of any posterior synechias, iris inflammation, or any signs of an inflammatory process other than the anterior synechias that are a constant feature. The answer to the problem appears to lie in the presently unknown factor which initiates the first localized anterior synechia. In this case the extensive migration of iris pigment to the posterior surface of the lens, as well as to the anterior surface, indicates the marked degree of mobilization of this substance in the "essential atrophy."

SENILE MACULAR LESIONS*

RALPH I. LLOYD, M.D.
Brooklyn, New York

ATROPHY OF THE CHOROID

The choriocapillaris and the pigment layer of the retina, with the lamina of Bruch between them, are referred to frequently as the tapetum. This is a convenience sanctioned by use and the fact that to the ophthalmoscopist they are a single tissue. The tapetum returns the light from the ophthalmoscope to the examiner's eye and hides the deep choroidal vessels.

In older persons the tapetum becomes depigmented and, as a rule, exposes the sclerosed choroidal vessels which finally become opaque. This atrophic process begins in the nasal periphery and may or may not involve the macula in the late stages.

In addition to exposure of the choroidal vessels, a sheen or watered-silk effect spreads over the macula, interfering somewhat in the examination of that part of the fundus. This sheen is due to changes in the internal limiting membrane. It is surprising how far atrophy of the tapetum may go with but moderate effect upon the vision other than contracted fields and enlarged blindspots. Perhaps this may be explained by the work of Cohen and Verhoeff disclosing normal caliber of the retinal and choroidal vessels despite advanced changes in their vessel walls. A more advanced stage of this atrophy is featured by a denser sheen over the macula, a meaty fundus background with undulating finer retinal vessels, indicating a wrinkling of the tissue beneath. The vision now is definitely lower and retinal changes can be seen with red-free light (fig. 1).

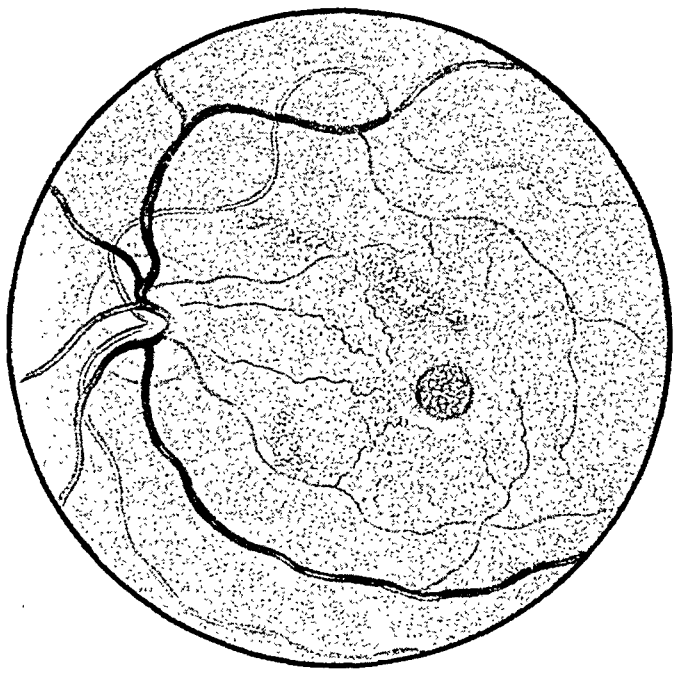

Fig. 1 (Lloyd). Early stage of choroidal atrophy in a woman, aged 61 years. There is a hole in the macula after a slight injury. Vision is 20/40.

*Read in part at the 82nd annual meeting of the American Ophthalmological Society, San Francisco, California, June, 1946.

The atrophic process may spread over the entire fundus exposing the deep sclerosed vessels everywhere except at the macula and, as long as this patch of choroid remains, vision is very good indeed in *good light.* If the patch beneath the macula disappears, the patient is blind. Some of these

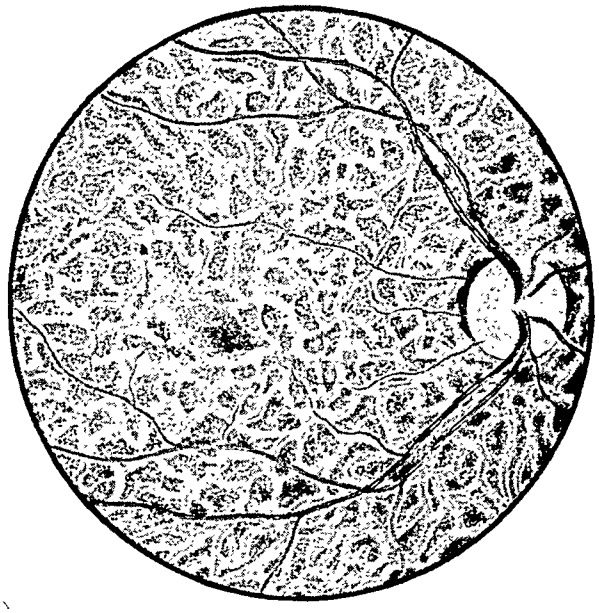

Fig. 2 (Lloyd). Advanced choroidal atrophy with surprisingly good vision in strong light (20/25 and 20/33). The patient, a woman, aged 64 years, showed night blindness and ring scotomas.

patients do not complain of night blindness, but some cannot see in poor light, and some also have ring scotomas (fig. 2). This unusual fundus picture may be referred to as progressive choroidal atrophy (fig. 3); or it may be designated by the term, choroideremia. None of these eyes have come to the laboratory as far as I can learn, and the cases are so few that essential details are lacking. No family incidence has been shown in this group, distinguishing these cases from those in which one or more members of a family have pigmentary retinitis or night blindness with fundus pigment and secondary posterior capsular cataract.

General choroidal atrophy may be contrasted with two more localized forms, peripapillary and central. The peripapillary atrophy is most frequently seen in high myopias which run through families. The central type is referred to as central areolar atrophy and may possibly develop without adequate explanation but is more often seen as the late stage of pseudotumor and angioid stripes. It follows occlusion of vessels in the nerve or retina after injections about the face, basal fractures, and without discovered etiology.

Hole in the macula

This is rarely seen except with choroidal atrophy and is at first limited to the tapetum with later serious effects upon vision. A rarer sequella of choroidal degeneration is pseudotumor of the macula caused by an accumulation of serum or blood beneath the pigment layer followed by characteristic changes.

Pseudotumors of the macula

These lesions, which require differentiation from tumor, are modest elevations of

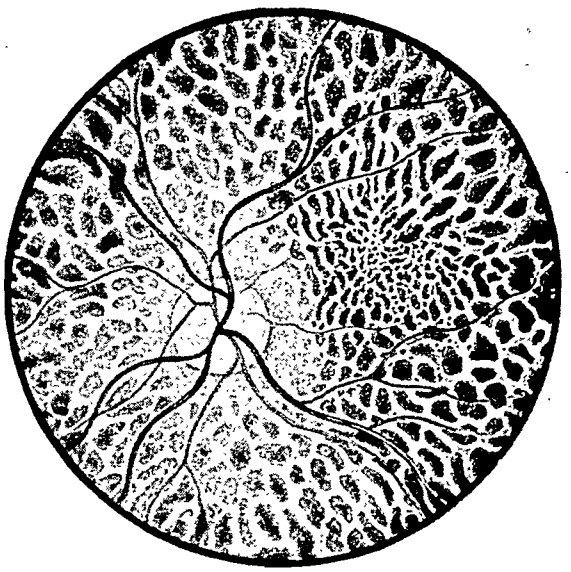

Fig. 3 (Lloyd). Late stage of progressive atrophy of the choroid. This man, aged 65 years, was blind but gave no history of difficulty in seeing at night.

3 to 6 diopters and of 6 to 8 disc diameters in width and height, somewhat lighter in color than the background and easily mistaken for a patch of choroiditis unless the

binocular scope is used. The first complaint, loss of vision, may precede objective evidence by a few weeks. The first visible change may be small hemorrhages, followed soon by the rounded mass in the macula (fig. 4). Two patients have recovered from this stage but neither had normal vision and one had a relapse within a year. The lesion may remain in the original state for some time but most of them undergo further changes within a few months. Cyst formation (fig. 5) is the most common type of lesion and is probably due to the clear exudate breaking through the pigment layer of the retina leaving no other covering than the retina. Less common is the organization of the exudate to form the woolly masses of Coats's disease (figs. 6 and 7). Better known is the sheet of organized tissue beneath the retina, the disciform degeneration of the macula (Kuhnt-Junius). Cysts are unstable and do not usually remain for any length of time (fig. 8). The clear exudate within may disappear along with the tapetum, leaving a bare spot in the macular area with sclerosed vessels and atrophic choroidal tissue as the background. Occasionally the sclera may be exposed. The fluid may spread laterally and raise the retina in folds, producing a flat detachment (fig. 9) of limited proportions. After a time, the involved tapetum atrophies and an extensive area of thinned pigmented tapetum remains. Occasionally there are streaks of "retinitis striata" beneath the retinal vessels (choroiditis proliferans, Fuchs).

The hand scope does not give satisfactory details of the cyst because the retinal image is never sharp but obscures the view of the deeper parts. The binocular scope shows the diaphanous retina in advance of the pigmented and hemorrhagic tapetum beneath. None of these spreading defects have been seen to pass over into a typical retinal detachment of average extent or elevation but I believe it does occur in elderly persons.

Judging from the appearance of the macular region after reattachment of the retina and the microscopic changes in the pigment layer in the late stages of pseudotumors, one should not expect too much improvement of vision because of damage to the pigment epithelium and the choriocapillaris.

Choroidal hemorrhages and the masses of "rice grains" (fig. 9a) about the macula usually referred to as retinitis circinata are common to every stage of these lesions. To the hand scope, the "star figure" of hypertensive disease, wreaths of retinitis circinata, and many hemorrhages seem to be in the retina but are actually in the tapetum.

A fulminating type of pseudotumor is due to the choroidal hemorrhage breaking through the lamina of Bruch, then through the pigment layer of the retina so it is seen with nothing but the retina over it. These lesions smother the light of the ophthalmoscope and look like the dark masses seen after cataract extraction which are recorded as subchoroidal hemorrhage or detachment of the choroid. The appearance of these is so alarming that the eye is usually enucleated at once.

One such case, reported by Dr. Verhoeff and Dr. Grossman, flattened down after six months; the macular region lost color; and microscopic examination showed the organized subretinal tissue characteristic of disciform degeneration. A case of the kind came to my care and, although the diagnosis was in doubt, because retroillumination at operation showed complete opacity of the area involved, the eye was removed about one week after total loss of central vision, known to have been 20/20 before the attack (fig. 10).

In none of the slides examined from cases of this type or illustrated in the literature, was the choroid stripped from the deeper tissues nor was blood found beneath the choriocapillaris. Excepting the stripping of the choroid by rupture of long ciliary vessels during operation for cataract or glaucoma, the term subchoroidal hemorrhage or detachment of the choroid is a misnomer.

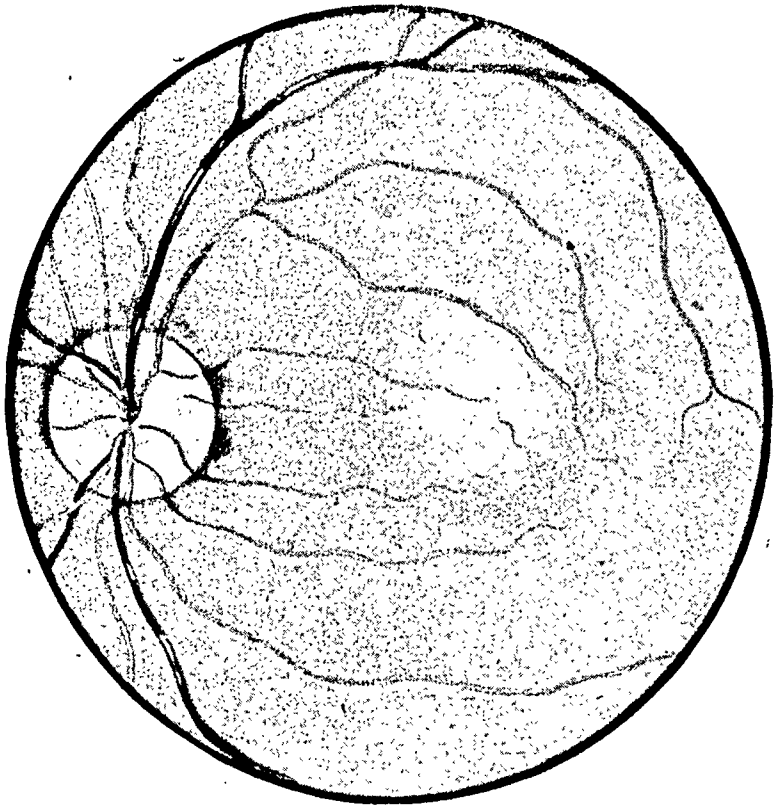

Fig. 4 (Lloyd). This illustrates the first stage in the development of pseudotumors of the macula. The patient, a man, aged 41 years, had recently been treated for syphilis. Small hemorrhages, followed soon by the rounded mass in the macula, were the first visible changes.

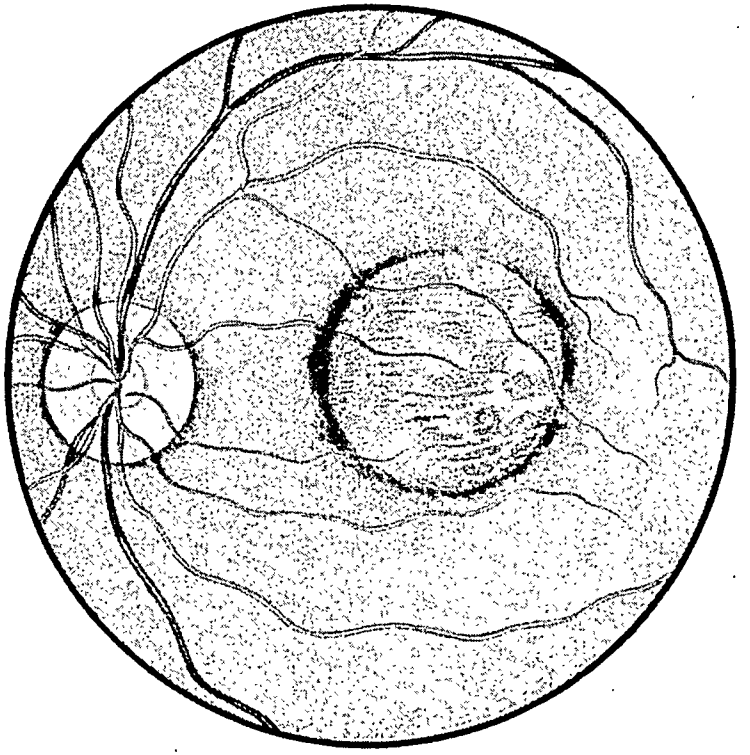

Fig. 5 (Lloyd). The same eye as shown in Figure 4. This drawing, made six months later than Figure 4, illustrates the change from a typical lesion to the cystic stage.

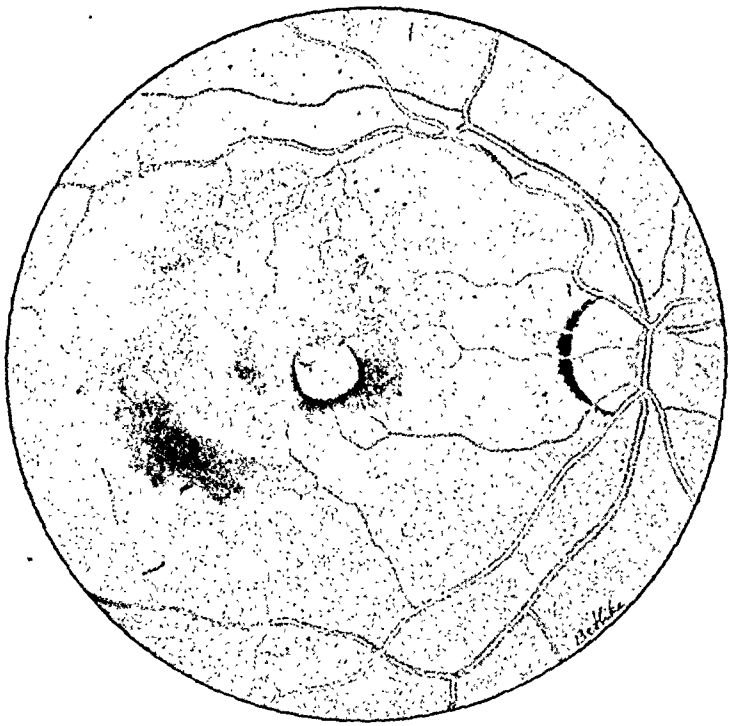

Fig. 6 (Lloyd). The patient, aged 54 years, showed as the first lesion, a hole in the macula, followed by hemorrhage and pseudotumor one year later.

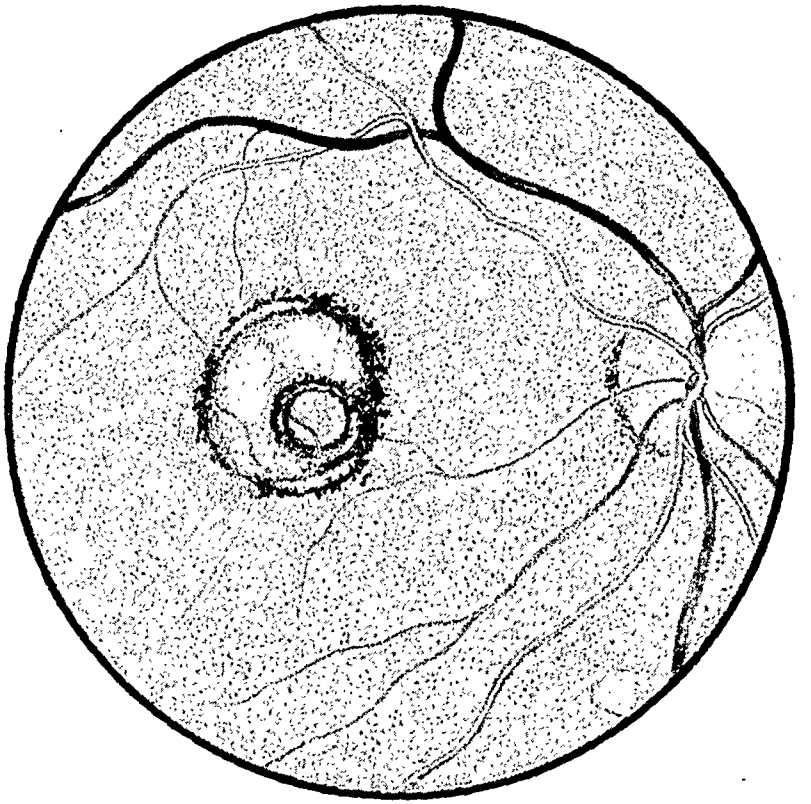

Fig. 7 (Lloyd). This drawing of the same eye as is shown in Figure 6 was made two years later. It illustrates the change into Coats's disease.

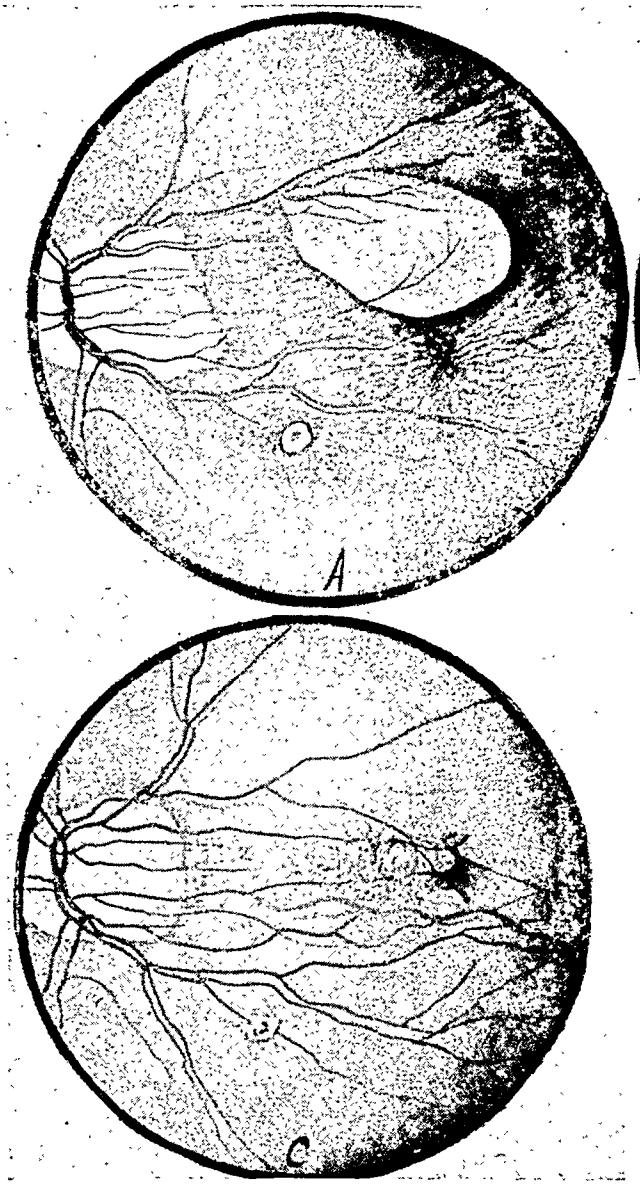

Fig. 8 (Lloyd). This illustrates the change from a cystic lesion (A) to a very small atrophic area in seven months. The patient, past fifty years of age, was highly myopic when the lesion appeared. (B) The lesion (—16D. sph. ⊂ —1.50D. cyl. ax. 165° = 20/50, 2 letters). Vision dropped to 1/200 three months later. (C) Five months later. Vision is 20/100. (Dr. Paul Chandler.)

The difference between the hemorrhagic type of pseudotumor, the usual pseudotumor, and the cyst which often follows is the presence of blood beneath the retina in the first instance; clear fluid beneath the pigment layer in the second; and clear fluid beneath the retina in the third. Judging from the appearance of the spreading lesion after cyst formation, it is fair to say that the difference in appearance between a cyst and a retinal detachment is due to the character of the retina at the macula and elsewhere.

The pseudotumor occurs most often in

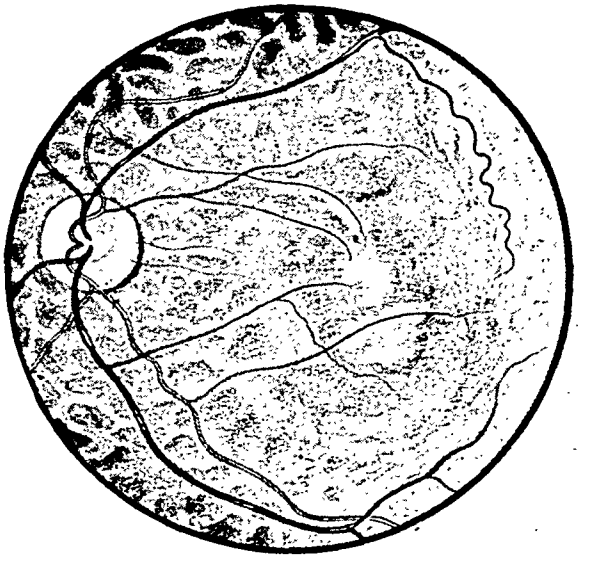

Fig. 9 (Lloyd). Illustrating the change from a cystic lesion to retinal detachment of limited area in six months.

older patients of the "healthy" arteriosclerotic type quite independent of the retinal lesions of the cardio-vascular-renal syndrome, although the two may go together. The lesions are often bilateral, with an interval of time elapsing between the attacks. The patient with pseudotumor may live for years after losing central vision, in contrast to those affected with high blood pressure. Quite young patients have been reported as having this condition, but the youngest in this group was aged 34 years. Most cases are found in the 50- to 60-years age group.

There is no explanation for the vulnerability of the macula that the location and frequency of the lesion implies. Atrophy of the peripheral tapetum with sclerosis of the choroidal vessels is a common antecedent and in three cases there were also holes in the macula. One patient had a definite history of syphilis.

Behr asserts that the lamina of Bruch controls the passage of nourishment and the return of waste products from the choriocapillaris to the external retinal layers. A highly albuminous fluid accumulates beneath the pigment layer, stripping it from the lamina. The pigment cells react to the exudate much as lens stroma reacts when exposed to aqueous. The epithelial layer proliferates and degenerates, making a sort of capsule beneath the retina with especially thick margins which throw back the light from the scope to form the image perceived by the examiner as retinitis circinata (Seefelder).

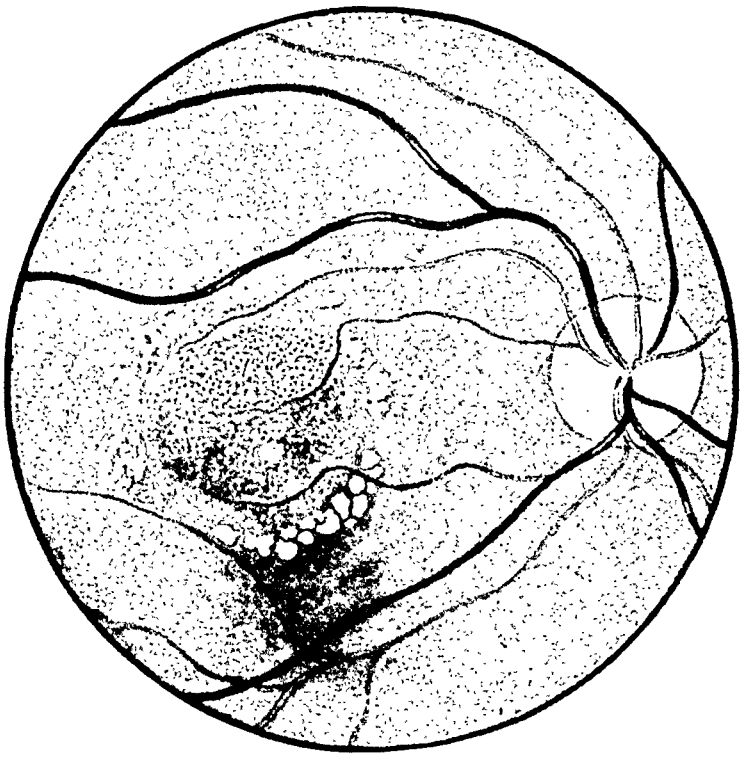

Fig. 9a (Lloyd). Bilateral lesions (see also Figure 9b) in a man, aged 65 years. "Retinitis circinata," here illustrated, is often seen in these cases.

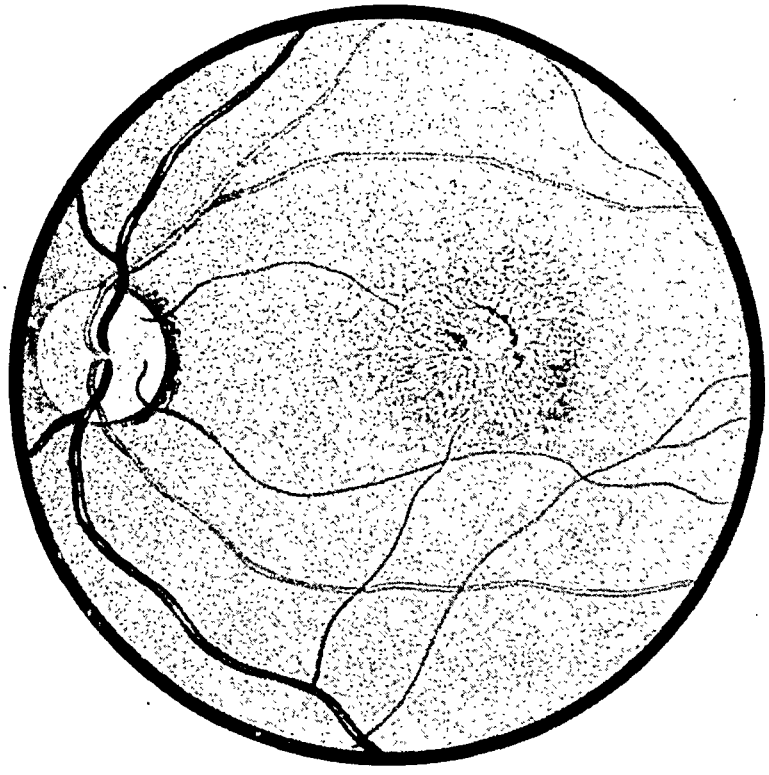

Fig. 9b (Lloyd). The soft spots in this eye are colloid masses in the lamina of Bruch.

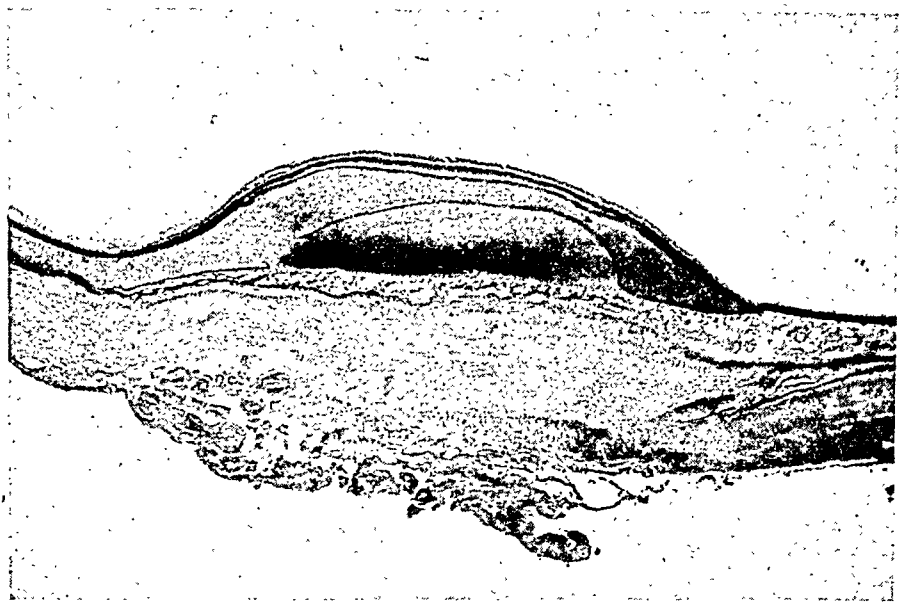

Fig. 10 (Lloyd). Sudden loss of vision with a dark mass in the macular area looking like "detachment of the choroid" after cataract extraction. The eye was removed one week after onset. The hemorrhage came from the choriocapillaris, lifted and broke the pigmentary layer. The break through the pigment layer is at the left.

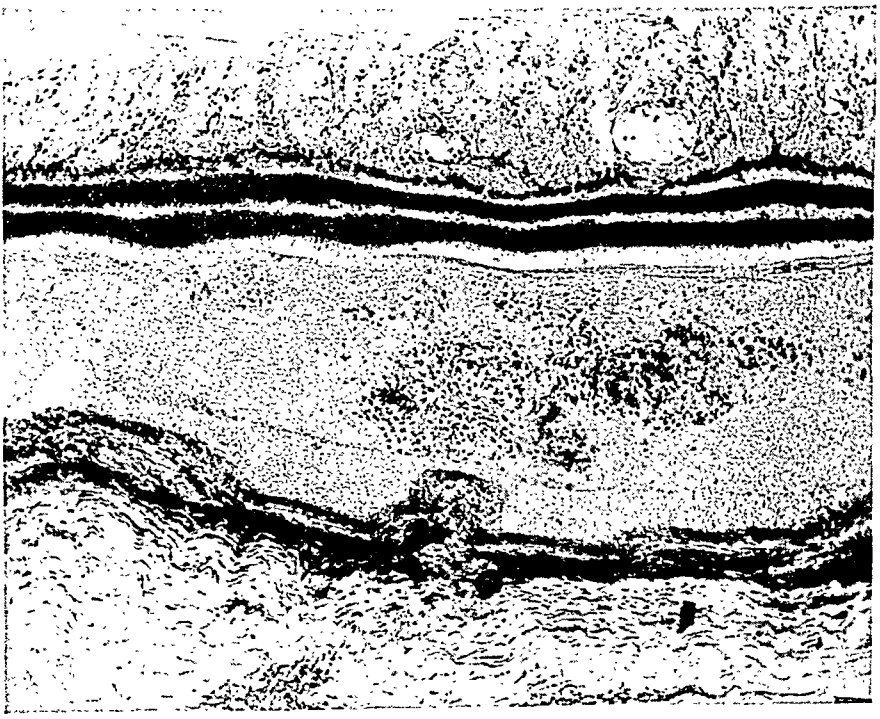

Fig. 11 (Lloyd). "Bud" from choriocapillaris passing through the lamina into the subretinal collection of blood in an acute case. From the same eye as shown in Figures 6 and 7.

Behr explains the connective tissue, bone, and cartilage found in the exudate beneath the retina in Coats's disease and disciform degeneration of the macula (fig. 11) as a metaplasia; but Axenfeld, Verhoeff, Vogt, Sandoz, and E. V. L. Brown* have demonstrated breaks in the lamina of Bruch (fig. 12) through which vessels passed into the organized subretinal tissue. This vascular intrusion also explains the recurring choroidal hemorrhages so often seen in these cases. Once vessels have entered the subretinal space, any form of connective tissue may develop. The diagnosis is confused by metastatic tumors of the choroid which look just like innocent lesions. This is probably due to the fact that the tumor mass in the choroid is small and concealed by an accumulation of subretinal fluid.

Every case should be examined carefully for sources of metastasis (fig. 13), the most frequent being the female breast and the prostate gland. Metastatic tumors at the macula are very rare and, in these older individuals, there is time enough to study the case until the diagnosis is certain. In younger patients, the ophthalmoscopic picture may be so strange and suggestive of tumor that we must fall back upon the well-established rule that an eye without possibility of useful vision should be sacrificed if there is serious doubt of the nature of the lesion.

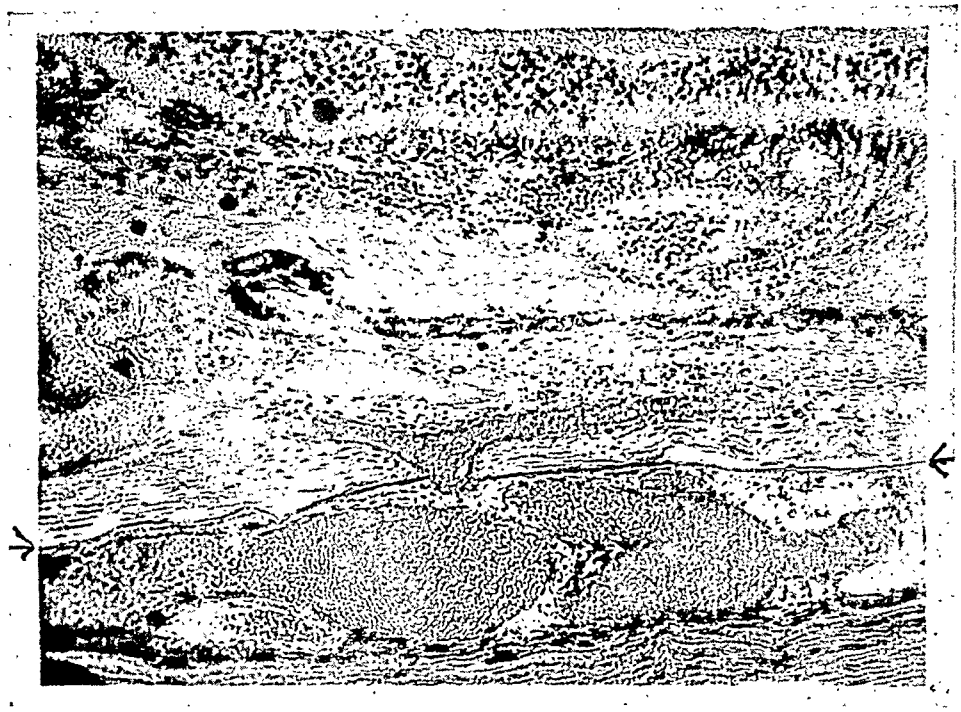

Fig. 12 (Lloyd). The black lines indicate the lamina of Bruch through which an arteriole is passing to the organized subretinal tissue. (From, Verhoeff and Grossman: Pathogenesis of disciform degeneration of the macula. Tr. Am. Ophth. Soc., 1937, p. 262.)

Chorioretinal tuberculosis presents a very similar picture but the vitreous is involved early and the course of the disease is more rapid. Scars of previous attacks and involvement of retinal vessels may assist in establishing the diagnosis. Positive reaction to tuberculin tests is also of diagnostic value.

*I am indebted for the privilege of examining slides from the three cases reported by Drs. Verhoeff and Grossman and also one from the case reported by Axenfeld in 1915. Drs. E. V. L. Brown, Beulah Cushman and Arnold Knapp have kindly given me slides from cases of this type reported by them.

Syphilis has rarely entered the picture because the fundus lesions it produces are results of vessel degeneration rather than gumma.

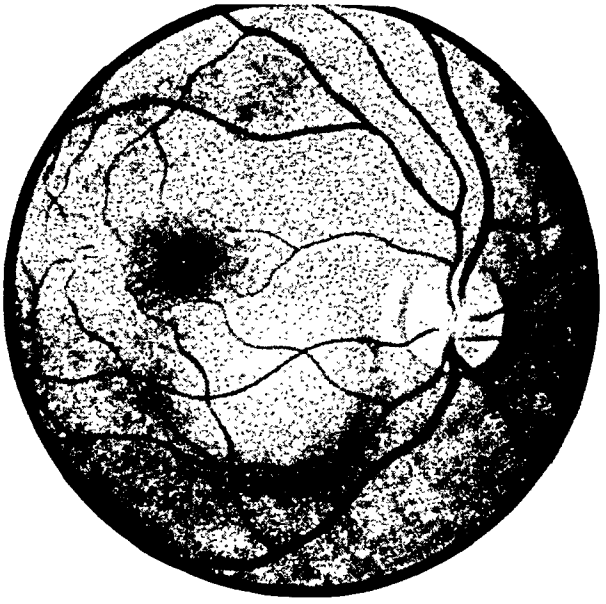

Fig. 13 (Lloyd). Metastasis from carcinoma of the breast in a patient about fifty years of age. The lesion was improved by X-ray therapy, but the other eye was involved in two years. (Dr. Walter Hipp.)

When these symptoms appear in children (fig. 14), the question of birth injury will arise. Lesions resulting from injury at birth are stationary, with threads of new tissue extending into the vitreous from the organized mass following hemorrhage. Blunt trauma may produce most confusing pictures but the damage is so severe that the eye is rarely retained. If it is retained, however, examination of the fundus is usually precluded by damage to the cornea or organization of tissue in the vitreous.

Two cases of congenital retinal folds (falciform ablation) required some study, but this condition is always connected with the disc and, although the fundus shows marked deviation from the normal, the clear vitreous permits satisfactory fundus examination.

A somewhat similar lesion is the so-called preretinal edema. A patient with this type of macular lesion had lived for many years in Africa and complained of poor vision in one eye after returning to this country. He improved under treatment, but I did not have the opportunity to follow the case to conclusion. The binocular scope located the pigment dots and the bubbles in the edematous retina but an exudate beneath the pigment layer caused the elevation. With the hand scope, the lesion looked as if the collection of fluid was preretinal, like the so-called preretinal hemorrhage, but both are really beneath the retina. Neither of these conditions has been examined under the microscope and, until this is done, there will be differences of opinion. I am sure

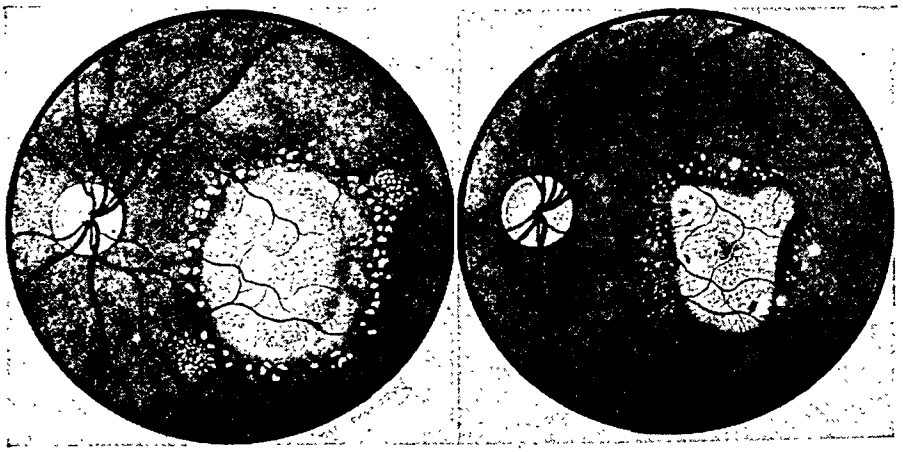

Fig. 14 (Lloyd). Lesion in a child aged 7½ years. The interval between the two drawings is two years. Tests were negative. The large spots about the lesion in the illustration at the left are crystals.

the so-called preretinal edema is not preretinal and would suggest use of the binocular scope in such cases to clear the doubt.

Angioid striping

This is a degenerative process occurring in eyes of older persons but with notable exceptions to age limits. The familial tendency is well known and, although this is considered an entity, the pathologic process is very similar to that of pseudotumors. It is not unusual to find typical cases in a family, as well as cases with similar fundus details excepting the stripes. The breaks in the lamina of Bruch are numerous but, because of brittleness, many are made when the section is cut.

The literature contains many case reports, but very few pathologic examinations have been made because only eyes removed after death have come to the laboratory. Hagedoorn, Böck, and Bertha Klien have each presented completed reports of cases studied with the ophthalmoscope and serially sectioned in the laboratory. Accumulation of fluid beneath the pigment layer, with organized subretinal tissue like that found in disciform degeneration, has been found but no mention is made of vascular intrusions.

An illustration (fig. 15) is presented showing angioid stripes in one eye while the other has a large atrophic area in the macular region with exposed sclerosed vessels of the deep choroid.

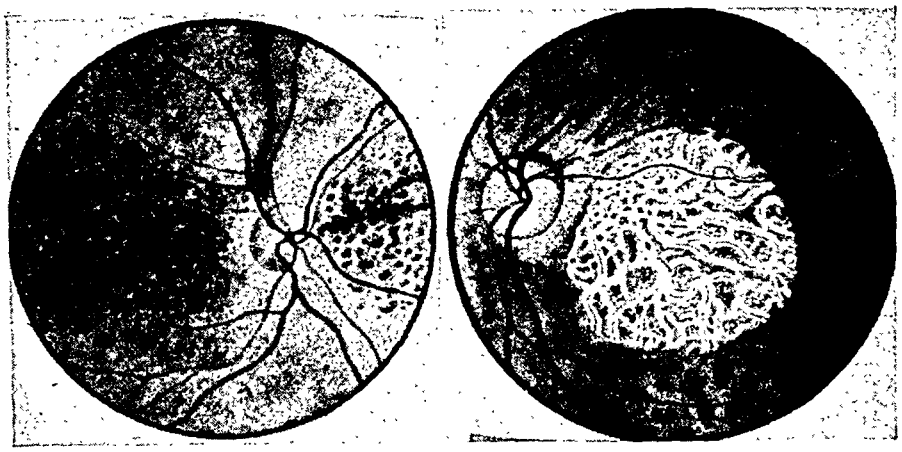

Fig. 15 (Lloyd). Angioid stripes in the right eye and central areolar choroidal atrophy in the left.

Summary

From this review it seems that a number of characteristic fundus lesions, considered to be entities, are really stages of a degenerative process affecting mainly the lamina of Bruch, the vessels of the choriocapillaris, and the pigment layer. This is to be expected, since Time takes its toll first of the elastic tissues, and its effects upon the vessel walls, skin, the sphincters and the detrusors are well known. The lamina is an elastic tissue and the choroidal vessels in the macular area seem especially vulnerable.

Although no detachment of the area or size seen in typical cases has occurred under observation, the similarity to flat detachments seen in young persons with myopia of moderate degree suggests the importance of routine serial sectioning of all posterior fundus lesions, with a systematic search for breaks in the lamina of Bruch and vascular intrusions.

Because of the reaction of the pigment layer to accumulations of fluid beneath it, one suspects that diathermy is effective because it inhibits the secretion and not because it closes a tear. Also, involvement of the macula in a detachment would seem to occlude much hope of good vision after reattachment.

These opinions should not lead one to think that I am opposed to operation for detachment. An ophthalmologist who has practiced when detachments were treated by prolonged rest in bed, subconjunctival salt injections, compress bandages, and tapping of the subretinal space—with a recovery rate of zero—can appreciate the benefits of the modern operation. The binocular microscope is essential to a satisfactory study of cases of this type and anyone who has used it can readily appreciate the advantages of observation with two eyes.

BARRIERS AND AIDS TO FUSION*

MARIANNE EYLES
Seattle, Washington

In attempting to discuss fusion, one is led from the study of the simple reflex to the elaboration of final percepts and concepts—from physiology to the realm of metaphysics. As objective investigators, we may not like the subjective aspects of psychology, but we should at least remember that the study of science must be synthetic as well as analytic. Thomas Young, the physicist and ophthalmologist, himself taught and followed that truism. Hence we shall not avoid mentioning such metaphysical concepts as consciousness, attention, and association, even though we translate them to forms of cerebral functioning.

SOME CONCEPTS OF FUSION ATTAINMENT

In considering the various theories of fusion in the visual cortex, the most easily understood are those which propound certain anatomic fusion centers, or a physiologic centering of fibers from corresponding retinal areas.

Unlike his well-known theory of conditioned reflexes, Pavlov's proposed thesis of cortical excitation and irradiation has not proved acceptable.

The replacement theory is summarized by stating that the cortical center selects parts from maximum capacity uniocular images, so that the final image is a mosaic derived from replacement rather than addition.

Chavasse suggests two possible theories. The first stipulates that fusion occurs by selection from two uniocular cerebral patterns, and the second that it occurs by reciprocal cerebral inhibition so that only one pair of corresponding areas can function at the same time. His refusal to consider the sensory aspects of fusion, however, and his insistence on regarding it simply as a motor reaction brought about by reflex activity leaves his reflexes like an army without a commander with no explanation of integration or synthesis.

The conclusions of Sherrington have led to the most complete concept of fusion. He proved that each uniocular image is developed and elaborated independently and that the union of the two images is the product of synthesis derived from interpretation with other already elaborated sensations.

We know that fusion is of late phylogenetic development and, as such, is easily liable to modification or perversion. For its natural and normal functioning it is necessary to have an overlap of the visual fields of the two eyes, a highly organized central nervous system, corresponding retinocerebral elements, and a correctly functioning extraocular muscle system so that the visual axes are correctly oriented.

The neural image arising in the retina is transmitted through nerve impulses to the lower visual reflex centers and the appropriate motor reaction for fusion is initiated by the higher visual reflex centers. We may note here the general acceptance of the conclusion that the semidecussation of the fibers at the chiasma has a motor significance rather than a sensory significance, since it provides a common efferent path. Thus there is no necessity for a common representation in the cortical field (Sherrington, Duke-Elder, and others).

BARRIERS TO FUSION

Barriers to fusion may be divided into two classes—those which prevent the development of fusion and those which cause its breakdown. Specifically they may be listed as follows:

* Presented at the sixth annual meeting of the American Association of Orthoptic Technicians, Chicago, October 12, 1947.

1. Dioptric. (a) Due to unequal uniocular images—for example, anisometropia over 4D, high astigmatism, aniseikonia. (b) Refractive—for example, hypermetropia or myopia may predispose to convergent or divergent strabismus respectively, the cause being a too tightly conditioned accommodation-convergence reflex. The uncorrected hypermetrope overaccommodates to see clearly and consequently overconverges. The resulting diplopia causes him to converge more to separate the images. Conversely the myope has no need to accommodate and, therefore, underconverges producing divergent strabismus. The initial treatment lies in correction with glasses, followed by an orthoptic loosening of the too tightly associated accommodation-convergence link.

2. Anomalous retinal correspondence. Although this is certainly a barrier to fusion, it should be considered as a biologic adaptation rather than a cause per se of the nondevelopment of fusion. The theory that anomalous retinal correspondence is a conditioned reflex—as Chavasse presumes—would be a most satisfactory explanation, if one is prepared to accept the principle of sensory conditioning. However, in spite of alleged synesthesia, no sensory conditioning has yet been demonstrated. The classical conditioned reflex refers to a motor or secretory response.

Duke-Elder regards anomalous retinal correspondence as secondary acquired correspondence which is a functional attribute. As an orthoptist, I can testify that it can be cured in 4 to 24 treatments in over 50 percent of cases (under 12 years of age) preoperatively. Another 15 to 25 percent will obtain true retinal correspondence in the first weeks after operation, provided preoperative, bimacular stimulation has been given. The cure may involve the extinction of a conditioned reflex, the reinforcement of an inhibited neural pathway, or the grounding of new neural connections.

If the anomalous retinal correspondence is not corrected before operation, any of the following situations may ensue:

a. The patient may develop a new anomalous correspondence adapted to the new position of the eyes.

b. He may turn the eye in again to the original angle in order to restore the old anomalous correspondence.

c. He may have persistent diplopia of the paradoxical or false type, or of the true type.

d. The possibility of obtaining fusion without training is remote and might occur only if there was a history of previous fusion, and if the eyes were straight after operation. Even then suppression would probably prevent the development of fusion.

3. Amblyopia. In this condition we need only consider amblyopia ex anopsia, which may be either the cause or the result of strabismus. When the child is conscious of diplopia, he turns one eye in further to separate the images and then suppresses the vision in that eye so that it becomes amblyopic from disuse. This is an active inhibition which is cerebral in character. Treatment consists in appropriate stimulation of the amblyopic eye and is usually successful. Unless fusion is stimulated and attained before operation while the amblyopia is in the process of being cured, there will be no binocular hold after the operation and the diplopia-strabismus-suppression cycle will be repeated. It is conceivable that when the vision of an amblyopic eye has been improved by occlusion, without fusion training being given simultaneously, diplopia will become troublesome, and the child will consequently either develop anomalous retinal correspondence or increase the angle of squint.

4. Suppression. When total or partial dominance is given to the image of one eye, and there is a loss of physiologic retinal rivalry, the usual cause is either incompatibility of the uniocular images or heterophoria.

In the latter, a small central suppression may prevent symptoms at first, but when compensation or adjustment can no longer be maintained, the effort becomes conscious and symptoms appear. The cure in this case consists of antisuppression treatment and the development of increased fusional range to overcome the heterophoria.

In the case of an alternating strabismus, suppression is both intensive and extensive, and requires treatments to obtain simultaneous cortical response to each uniocular impression. Sherrington proved the existence of the neural states of excitation and inhibition, which are believed to be due to electrical changes in the cortex. Inhibition may be of the intrinsic or adaptative type, as opposed to the extrinsic or antagonistic type, and in cases of amblyopia and suppression is probably of both types.

5. *Neurogenic anomalies* such as nystagmus, spasm, and so forth.

6. *Hyperphoria and hypertropia.* A vertical deviation of over five diopters is usually beyond the range of fusion, and can thus be considered a barrier to fusion.

7. *Loss of central fixation and false fixation.* These are further perversions of the amblyopic group.

8. *Deviation of the visual axes.* Strabismus, whether it is convergent or divergent, is a barrier to fusion since a correctly functioning extraocular musculature is a primary requisite. Whatever the etiology of the strabismus, the visual axes must be restored to approximate parallelism by operation. Nevertheless, it should be emphasized that the previous anomalies, such as amblyopia, suppression, anomalous retinal correspondence, and so forth, must be corrected and a fusion ability initiated before operative procedure, or the patient will be presented with straight eyes and a true or paradoxical diplopia, or a suppression which will cause him to squint again. The end organs should be capable of receiving the images, and then the two uniocular images must be compatible and capable of independent elaboration in the visual cortex. The facilitation of appropriate pathways and the integration of higher centers will then effect a correct motor response when the external musculature is finally adjusted.

A squint is a conditioned reflex and for its extinction requires not only the correction of muscular changes by operation, but also reconditioning by training.

Before final discharge, the patient should have good fusion range, and be able to converge correctly.

To reiterate, we have given the various theories and a definition of fusion, discussed the barriers to fusion, and the possibility of their removal by refractive correction, orthoptic treatment, and operation. To illustrate the importance of orthoptic training as being of therapeutic value in addition to its diagnostic uses, it will now be necessary to investigate the visual anlage of the individual, and the learning process.

Neuro-anatomy of vision

In the young child we have a condition of flux and an histologically proved anatomic network indicating a richly branching and interlacing central nervous system—fertile ground for the future formation of new associations and habits or reflexes.

Unlearned automatic reflexes are innately present, and they may be either physical reflexes which are not registered in consciousness—for example, the pupillary light reflex—or they may be psycho-reflex in nature and are registered in consciousness—for example, convergence. There are also learned or conditioned reflexes, of which an example is the accommodation-convergence linkage.

The inherited cellular adaptation may be modified by experience, and indeed neural tissue possesses the property of modification if only in a small degree. Of primary importance, however, is the possibility of the facilitation of present pathways and the

grounding or establishment of new connections between neurons—between receptors and effectors.

A response may be evoked or reinforced by changes and modification at the synapses, thus achieving a decrease in the threshold. Since the nerve impulse along a fiber is believed to be "all or none," the changes in the threshold must occur at the synapse; that is, at the point of excitation, by bioelectric potential and resulting ionization, or by certain physiochemical changes in the nerve cell.

It is conceived by recent experimentation that the mechanism of the transmission of nerve impulses across the synapse does not differ qualitatively from that of their conduction along the fibers themselves. It is only quantitatively greater at the synapse since the neuronal surface itself is greater here, and the chemical and metabolic changes associated with electric changes, which occur at the neuronal surface, show a greater manifestation here during nerve activity. Other neural theories which seek to explain conditioning are briefly that learned action occurs in closed neural chains, as opposed to direct neural chains, or that it depends on bioelectric fields for organization.

The quality of summation needs to be mentioned here, since it reflects on orthoptic training, which seeks to evoke responses by stimuli and association. Temporal summation occurs when two successive stimuli to the same nerve evoke a response even if the stimuli are too weak or the threshold too high for them to act individually. Spatial summation occurs when two stimuli are applied to two different afferent nerves which play upon the same reflex center. Summation is greater when they are applied simultaneously, and at least two simultaneous impulses are necessary to excite a neuron.

The learning process

We accept the conditioned reflex of Pavlov, as a true basis for the learning process, but since it has been proved that a conditioned response may be effected even when the cortex is destroyed, and considering that a simple chaining of conditioned reflexes will not adequately account for the patterning and integration of habits in their complex presentation, we may understand the neurologists' refusal to accept conditioning as a total explanation of neural behavior.

For a more complete understanding of the problem we must consider the functioning of the higher centers through the factors of interest and attention, and their superimposition upon the reflex foundation by means of association paths. Sherrington has shown the primary importance of the higher centers as modifiers and controllers of the reflexes.

Skilled reactions are controlled reactions, and any training is, therefore, a modification of the activity of the higher reflex centers through conscious control. The association systems which are concerned with the complex sensorimotor integration of adaptative behavior are capable of modification by training. The process of encephalization—or the dominance of the cortex which occurs in phylogenetic development—is indicative of learning possibilities, even ontogenetically.

Role of orthoptics in fusion

The role of orthoptics in the development of fusion is thus accomplished by the following physiologic and neurologic considerations:

1. The elicitation of response by the facilitation of neural pathways through the use of correct stimuli; the facilitation signifying a nonlearned increase in the strength of the response.

2. The elicitation of response by means of conditioned reflexes. New reflexes or responses may be conditioned by means of the fixation reflex (surely a primary reflex par excellence) and by kinesthetic re-

flexes. The direct and simultaneous stimulation of the two maculas, and hand and eye coördination are fundamental aids.

3. The consummation of the reflex arc is in itself a direct intrinsic stimulation to further response, especially if it is in the nature of a biologically superior response.

4. The elaboration of two uniocular images in the cortex and the arousing of the factors of attention and interest so that, with increased permeability of the association pathways, fusion is elaborated in a final synthesis.

SUMMARY

We have considered the theories of fusion and the necessary neural and physiologic factors. Reference has been made to the barriers to fusion and their removal by refractive, orthoptic, and operative means. The validity of orthoptic training on the basis of our present knowledge of the learning process is demonstrated and the attainment of fusion considered in the light of cortical neurophysiology.

DISCUSSION OF MISS EYLES' PAPER

GEORGE S. CAMPION, M.D.
San Francisco, California

The neuron component of the ocular-muscular apparatus has been somewhat neglected in our work because it is so poorly understood even by those best qualified to explain it to us. I think Miss Eyles has done an excellent piece of work in bringing together the many intangibles that form the basis of our present knowledge of how fusion is attained, and it is only by a sound knowledge of the physiology of vision and the associated neuron-anatomy that we can understand how fusion is made possible or impossible.

We must try to assign the most exact etiologic factor possible to each case of squint for if we are able, by a good history and a thorough examination, to find the etiology, we are well on the way to a complete physiologic cure.

True, some etiologic factors cannot be found and others cannot be removed and remain as permanent barriers. Still other barriers may be removed only after diligence and perseverance in the best of teaching techniques.

How diligent can you get? Certainly training should go on until all removable barriers are removed and the teaching phase given an intensive trial. For orthoptics becomes a teaching process only when there are two good eyes that are reasonably matched one to the other and an I.Q. high enough to learn new skills or relearn neglected skills.

As Miss Eyles has mentioned, if we assume there is a fusion center at some cortical or subcortical level we make everything very simple. Then, in the absence of a recognizable physical defect or recognizable functional defect, we can place failures into a comfortable fusion-defect group, dismiss them and work on the easy ones.

In the early days of orthoptics this group was a very large one, but it is dwindling in the face of better teachers and better techniques. I do not think the group will entirely disappear, but it will no longer be the wastebasket to catch all the failures from either side of the machine.

Most of the fusion-difficulty cases in those acceptable for training seem to occur in that group of alternators who had an early onset of squint—that is some time before the age of two—and who have been neglected. Many have had absolutely no fusion experience and have to be taught everything artificially. Their barriers to fusion are a fixed angle of squint, anomalous correspondence, deep alternating suppression, and complete comfort in their monocular world. The deviation should be corrected surgically in this group as early as possible, even before the child is capable of performing some of the tests you would like to do. Nothing is gained by waiting until he is capable of being tested for the deviation will have to be corrected in any case. The child is incapable of straightening his eyes—a mechanical barrier—even though he learns skills all the way up the binocular ladder.

If such an alternator is first seen at the age of 6 or 7 years, then preoperative training may be given to good effect if the angle is not so large as to make training all but impossible. In this latter case the last barrier to be removed will be the mechanical one of heterotropia and, needless to say, training should follow surgery as soon as possible and be as intensive as necessary to obtain binocular vision with fusion for casual seeing and reading.

Miss Eyles has pointed out that one small patient may harbor a whole nest of barriers to fusion, and it is fortunate that sometimes we can remove two barriers at once. Anti-suppression exercises are the same, basically at least, as antianomalous exercises and what a surprise occasionally is met when the surgical correction of a heterotropia also abolishes the anomalous correspondence.

Were I to be given a single choice of the many aids to fusion I would choose a good technician.

OPTIC ATROPHY IN DIABETES MELLITUS*

A REPORT OF THREE CASES IN ONE FAMILY

JOHN R. STANSBURY, M.D.
Dallas, Texas

One of the rarer ocular complications of diabetes mellitus is atrophy of the optic nerve. In a review of the literature, the precise pathogenesis of this phenomenon is infrequently discussed, the assumption being that the atrophy occurs following a retrobulbar neuritis and is, therefore, postinflammatory.

Duke-Elder states[1] that retrobulbar neuritis is a rare complication in diabetes, but by no means unknown. It attacks people at all ages, and the great majority of the victims are males. There is characteristically a sudden onset, with development of a central scotoma, which may clear or may persist indefinitely, resulting in some degree of permanent atrophy. As to the mode of origin of the optic neuritis, several theories are advanced. These include the existence of diabetic toxins; the rendering of the patient more prone to exogenous poisons, such as alcohol and tobacco; the possible etiologic factor of diabetes-induced arteriosclerosis; and, finally, some connection with diabetic acidosis, raising a theoretical parallelism between alcohol and acetone.

Actually, the type of optic atrophy occurring in diabetes mellitus is generally accepted as being secondary to an optic retrobulbar neuritis, the exact cause of which is poorly understood, but which is usually rather sudden and dramatic in onset, and which leaves the patient with more or less residual optic atrophy and loss of vision (usually central).

Rea[2] tabulates the ocular complications in 4,001 eyes of diabetics. Of this group, 27, or 0.65 percent, had an optic atrophy. In 914 eyes of nondiabetics, he found 4 cases, or 0.4 percent, of optic atrophy. These figures would bear out Duke-Elder's assertion that the condition of retrobulbar neuritis is a rare one in diabetes mellitus.

This paper is a report on three members of a family of nine siblings. These three each had severe, long-standing, and poorly controlled diabetes mellitus, and each had a slowly progressive primary optic atrophy. The other six children in the family, as well as the parents and grandparents, did not have diabetes and demonstrated no evidence of an ophthalmic disorder of any sort. In the histories of the three children afflicted jointly with diabetes and atrophy of the optic nerve, there is no hint of a clear-cut episode of optic neuritis, retrobulbar or otherwise, and the visual loss has been insidious and gradual in each instance.

It will be suggested that perhaps the relationship of diabetes to the optic atrophy in these cases is not necessarily contingent upon an actual "neuritis," (that is, an acute inflammatory reaction in the axones of the ganglion cells of the retina) with associated clinical symptoms and signs, but may instead be analogous to the degenerative process which occurs in tabes and taboparesis.

Although it is true that the pathologic process in neurosyphilis involving the optic nerve was once held to be a primary degeneration of the ganglion cells with consecutive atrophy of the nerve fibers, the consensus of opinion now favors a primary peripheral and interstitial neuritis (a "cirrhosis" involving the supportive tissue of the nerve), followed by an axone degeneration. In the strictest sense, therefore, the atrophy that occurs with tabes is secondary to a neuritis, retrobulbar in location. Clinically, however, this type of atrophy is readily

* From the Department of Ophthalmology, Southwestern Medical Foundation.

distinguished from the less insidious types, and the ophthalmoscopic picture is given the term of "primary optic atrophy" because there is no residual evidence of inflammation. If a retrobulbar neuritis, of whatever cause, occurs in the trunk of the nerve, there will be no ophthalmoscopic findings and the end result will also be "primary" atrophy. When the lesion is near the nervehead, the edema of the disc is marked and leaves behind, in the ensuing atrophy, those residual ophthalmoscopic traces of hemorrhage, exudate, vascular abnormality, and blurring of the disc margins that give the picture the name of "secondary" or "consecutive" optic atrophy.

Review of literature

The literature is not replete with discussion and opinion regarding the optic atrophy which occurs in diabetes. In three pages devoted to a discussion of the association of diabetic neuropathy and retinopathy, Rundles[3] discusses the retinal findings in his series of 125 cases, but does not mention optic atrophy. Burch[4] states that of 292 diabetics, one had optic atrophy, but does not elaborate.

O'Brien and Allen[5] studied the fundi of 555 patients under 31 years of age with diabetes mellitus. They summarized the retinal findings and found that four percent of their series showed retinopathy, but did not mention optic atrophy. McKee,[6] in 1941, analyzed 2,360 cases of diabetes mellitus from the ophthalmic point of view. Of this group, 476 persons had pathologic conditions of the retina which he felt to be more or less definitely related to diabetes, but there was only one case of atrophy of the optic nerve listed, and he apparently did not definitely ascribe this to diabetes.

As a matter or fact, Folk and Soskin,[7] in a discussion of diabetic ophthalmoscopic findings and of the differentiation between the findings in diabetic, arteriosclerotic, and albuminuric retinitis, stated that one of the criteria for diabetic retinitis is a "normal or nearly normal disc." While this actually had reference to the fact that, in the other two conditions, waxiness or edema of the disc serves to distinguish them, it does point up the fact that optic atrophy is a rare occurrence, and one not commonly associated with diabetes.

A specific reference to retrobulbar neuritis is to be found in a discussion by Frances and Koenig,[8] written in 1926. They stated that "Retrobulbar neuritis arising in the course of diabetes, the evident result of an endogenous toxin or toxins liberated during the disease, which exercises a selective action on the papillo-macular bundle of the optic nerve, is undoubtedly a clinical entity."

These authors felt that the precise toxins which attack the papillomacular bundle were not known, but that the ketone bodies (beta-oxybutyric acid, aceto-acetic acid, and especially acetone, along with some unidentified organic acids) might be the cause, and that the resultant amblyopia usually disappeared in from 3 to 8 months, the amelioration of the symptoms showing a definite relation to the disappearance of the ketone bodies from the urine.

Rönne is said to have described the pathologic process in the papillomacular bundle at necropsy of two patients, whom he had also studied clinically, as being a degenerative one, rather than a neuritis, and similar to that found in alcohol and tobacco amblyopia except for the presence, in diabetes, of "Kornchen cells," which are not found in the others.

Frances and Koenig concluded, after a case report, that glycosuric amblyopia, involving the central visual fields, the result of an endogenous toxin which is probably acetone, is a clinical entity.

Case reports

This recognized disease complex does not apply, however, to the three patients to be discussed herein, since the onset in their

cases was insidious rather than sudden, the absolute scotoma is peripheral rather than central, and the condition has not improved with better control of the diabetes, but rather has steadily grown worse (in one patient over an 11-year period).

CASE 1

History. I. J. T., a young woman, aged 21 years, was admitted to Parkland Hospital on January 26, 1947. This patient had been a known diabetic since the age of four years, but the onset of her visual difficulties occurred at the age of 12 years, when she found that she could not read fine print. By the time she was 17 years of age, she was unable to read school books; however, she was graduated from high school. At present she is a domestic. She states that she has little difficulty in performing housework but that she does not read any but the largest print and frequently stumbles and runs into objects.

Her past medical history, except for the severe diabetes mellitus, which has never been well regulated with insulin and diet, and the progressive visual difficulties, is essentially negative.

The family history is entirely devoid (with the exception of the two younger siblings) of diabetes or of significant visual disturbance. The grandparents were not examined, but there is no history suggestive of a hereditary type of optic atrophy. The parents do not have diabetes mellitus and the father, who is no known relation to the mother, is serologically negative with no history of treated lues. His visual apparatus, as well as his carbohydrate-metabolizing system, are normal. The mother was not able to report for examination, but she is not a diabetic and a recent communication states that an ophthalmic examination is essentially normal.

Eye examination. I. J. T. stated that her vision seemed to be appreciably worse after an attack of measles in 1941. The onset of visual disturbance was considerably before this, in 1936, at the age of 10 years. She stated her vision was better at night than during the day. Physical examination of this patient was essentially negative except for the eye findings. The pupils were round and regular (2.5 mm.) and reacted very sluggishly to light and accommodation, with no consensual reaction.

Vision was: R.E., 15/200, JO; L.E., 20/200, JO. Cycloplegic retinoscopy showed a refractive error of: R.E., −0.75D. sph. ⌒ +1.0D. cyl. ax. 180°; L.E., −1.0D. sph. ⌒ +1.0D. cyl. ax. 180°. The patient subjectively accepted: R.E., −1.0D. sph. ⌒ +1.0D. cyl. ax. 180°; L.E., −0.5D. sph. ⌒ +0.5D. cyl. ax. 180°, which brought the vision only to: R.E., 20/200, JO; L.E., 20/200, JO; hardly an appreciable improvement.

Funduscopic examination revealed the media to be clear. The peripheral fundus was normal with no hemorrhages, exudates, or vascular abnormality. Both optic discs were grayish-white, centrally, fading to white peripherally. The right eye demonstrated more pronounced pallor than the left. Both discs showed definite loss of substance. The disc margins were clear-cut and sharply demarcated (fig. 1).

Visual-field studies with a 5-mm. white target at 330 mm. revealed bilateral, quite regular constriction of from 10 to 30 degrees, somewhat more pronounced in the right eye, especially temporally (fig. a). Attempts to obtain color fields were not satisfactory, and it was found that the patient was red-green color blind, and recognized a solid-blue object with difficulty.

The blindspots with a 5-mm. target at one meter were elongated in a vertical direction. There were no isolated scotomas, and it was felt that the visual fields were not pathognomonic of any particular disease entity. The responses with a target smaller than 5 mm. were not conclusive. The intraocular pressure was: R.E., 18 mm. Hg (Schiøtz);

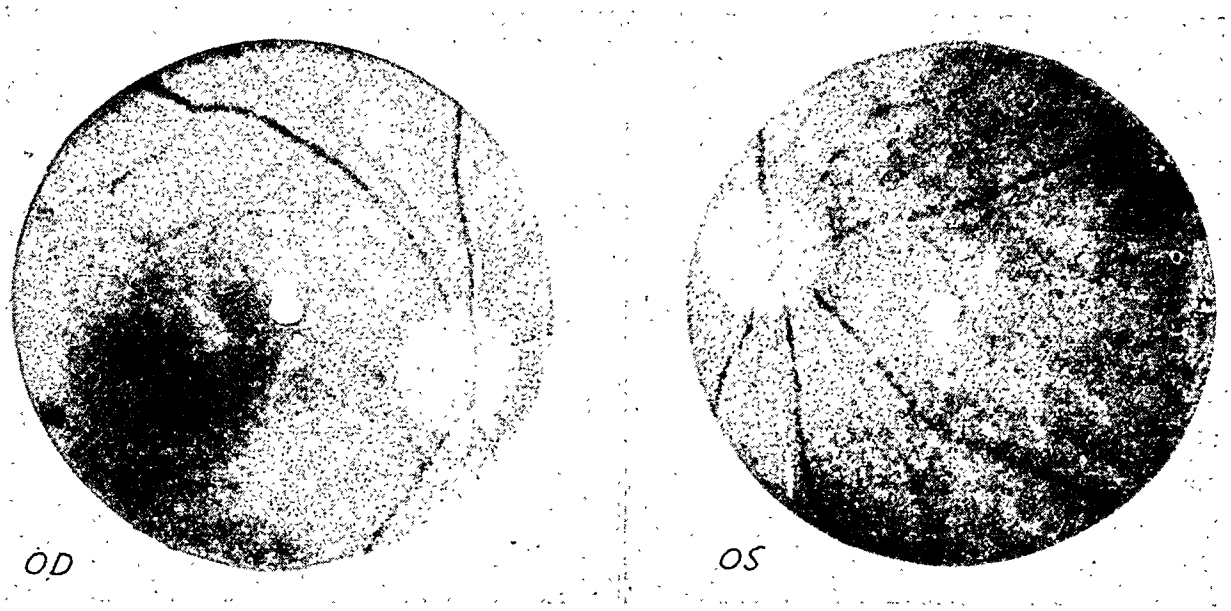

Fig. 1 (Stansbury). Fundi of *Case 1,* showing pallor as well as sharp outline of optic discs. Vision is: *20/200,* JO, O.U. The maculas normal.

L.E., 18 mm. General physical and neurologic physical examinations were entirely normal.

Laboratory reports. Blood studies revealed: Hb., 13.5 gm.; R.B.C., 4.21, W.B.C., 7,150, with normal differential. Urinalysis, sp. gr., 1.013; acid; sugar, 4 plus; negative acetone. The blood serology was negative; the fasting blood sugar, 277. Spinal fluid examination showed normal pressure, no cells. Wassermann and colloidal gold tests were negative. X-ray films of the optic foramina showed no constriction nor abnormality and the sella turcica was normal.

This patient was regulated on 40U protamine zinc insulin and 15U regular insulin before breakfast and 10U regular insulin before supper, and was discharged without

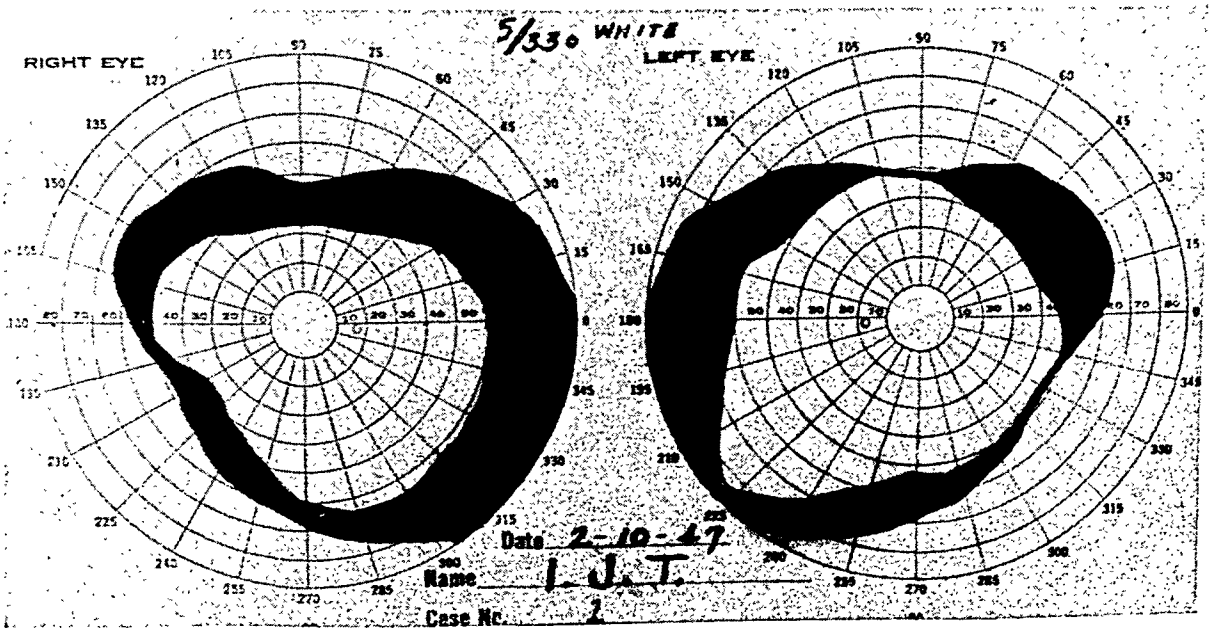

Fig. a (Stansbury). Peripheral fields of *Case 1,* 5/330 white.

other treatment. Intensive vitamin-B therapy had been employed since 1944, and it was advised that this be continued.

CASE 2

History. D. L. T., a girl, aged 14 years, was a sister of I. J. T. She had been a known diabetic since the age of seven years and was admitted to the hospital on February 4, 1947. This patient, a high-school sophomore, made excellent grades in her school work until one year ago, when she began to have trouble reading her lessons.

The patient's past medical history began with the sudden onset of loss of weight at the age of seven years, whereupon her parents diagnosed diabetes mellitus (having had previous experience with the first patient), and arbitrarily placed her on insulin and a diabetic diet. There was no history of diabetic coma, but there had been frequent episodes of mild insulin reaction. She had had diphtheria, measles, and mumps in childhood, and there was a history of recurrent furunculosis. Two years prior to admission, at the age of 12 years, she first noticed diminution of vision, particularly for near, with blurring of print and lacrimation. There was no complaint of difficulty with vision at night. Four weeks before her admission, she had been hospitalized elsewhere with left lobar pneumonia and left-sided pleurisy.

General physical examination revealed a well-nourished, prepuberty white girl, with no positive findings except for an auscultatory friction rub at the left 5th rib posteriorly. Neurologic examination was entirely normal.

Eye examination. Vision was reduced to: R.E., 20/200, J2; L.E., 20/200, J4. The pupils measured 4.5 mm., and were round and equal, with normal light and accommodative, as well as consensual, reactions. The media were clear, and the peripheral fundus, macula, and vascular tree were normal binocularly. The optic discs were flat and sharply demarcated, with a peripheral white ring fading to gray centrally, and had the typical appearance of a developing primary optic atrophy (fig. 2).

Retinoscopy with homatropine cycloplegia showed: R.E., −0.75D. sph., L.E., −0.50D. sph., but subjectively with: R.E., −0.75D. sph.; L.E., −0.25D. sph., vision remained only very slightly improved at: R.E., 20/200 J2; L.E., 20/200, J3.

The color vision was defective with the American Optical color charts, but the patient was able to distinguish and recognize red, green, and blue objects. The intraocular pressure was: R.E., 21 mm. Hg (Schiøtz); L.E., 25 mm. Visual fields (fig. b) showed moderate peripheral constriction, more marked temporally, for 5/300 white. Tangent-screen studies revealed only moderate enlargement of the blindspots, more marked on the right. The color-fields could not be examined satisfactorily due to the defective color-vision, but in general the form-fields with 5-mm. targets were larger for blue than for red and green, which was felt to corroborate the existence of neuroretinal rather than choroidal damage.

Laboratory studies showed the serology to be normal (Kline and Mazzini). C.B.C.: Hb., 10 gm., R.B.C., 3.8; W.B.C., 9,100; normal differential. Urine: sugar, 3 plus; 1.025, sp. gr.; acid reaction; negative acetone. Fasting blood-sugar, 190. The spinal fluid examination on February 5, 1947, revealed a normal pressure, but 3 segmented cells and 128 lymphocytes; on February 7th, two days later, the spinal fluid showed no segmented cells and 4 lymphocytes. The spinal fluid Wassermann and colloidal gold tests were negative. X-ray studies of the optic foramina and sella turcica were normal.

During her hospital stay, the patient developed an acute pleuritis and some parenchymal pulmonary consolidation which was thought to be an exacerbation of the previous episode and unrelated to her diabetes. She was felt to be adequately controlled at

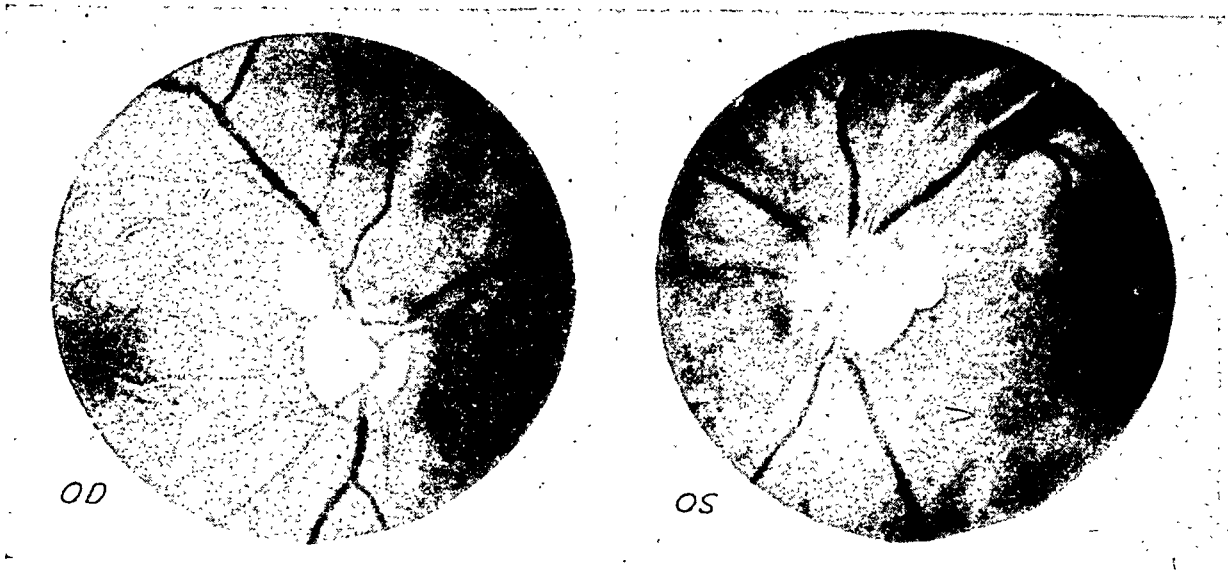

Fig. 2 (Stansbury). Fundi of *Case 2.* Vision is: R.E., 20/200, J2; L.E., 20/200, J3.

the time of her discharge on protamine-zinc insulin (40U) and regular insulin (15U) before breakfast, and regular insulin (10U) before the evening meal, in addition to a 1,390 calorie diet. On this regimen, the urine-sugar varied from 3 plus to a trace, with no acetone, and it was not felt possible to obtain better control. (Note: Information has been received that this patient has developed tuberculosis of the spine since this hospitalization.)

CASE 3

History. R. T., a boy, aged 13 years, was admitted to the hospital on February 4, 1947. He was a brother of patients reported in Case 1 and Case 2. The boy had been known to have diabetes since he was seven years of age when the mother tested his urine, found sugar, and arbitrarily placed him on insulin. He had never been taken to a physician for regulation and stated that he frequently experienced mild insulin reactions which were

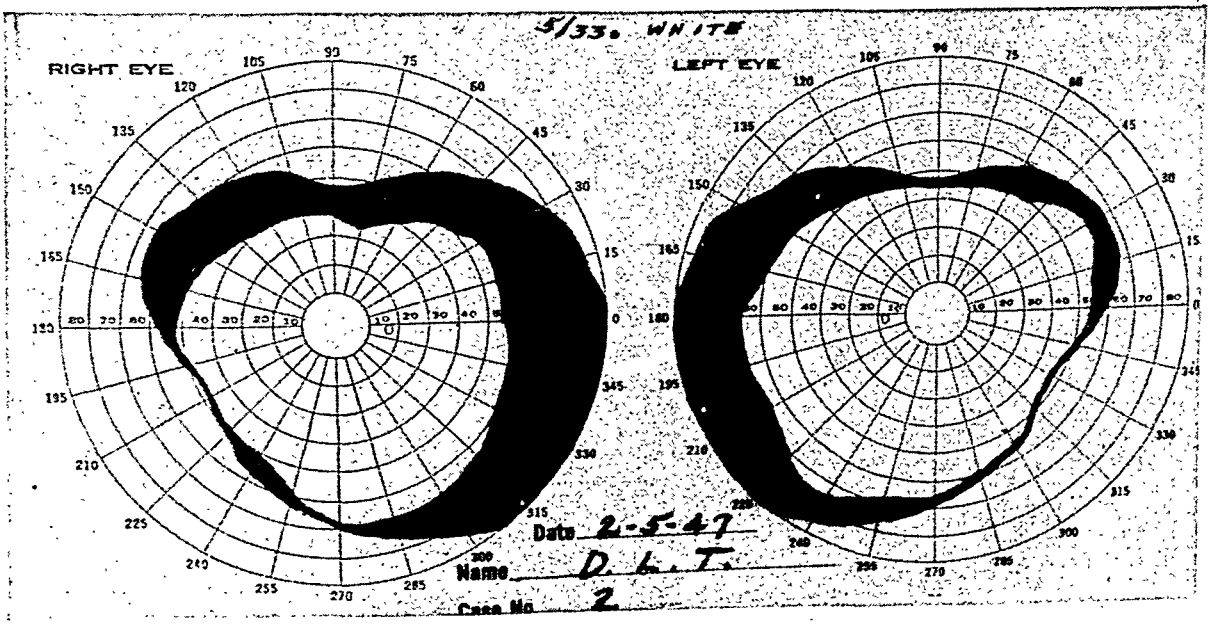

Fig. b (Stansbury). Peripheral fields of *Case 2.*

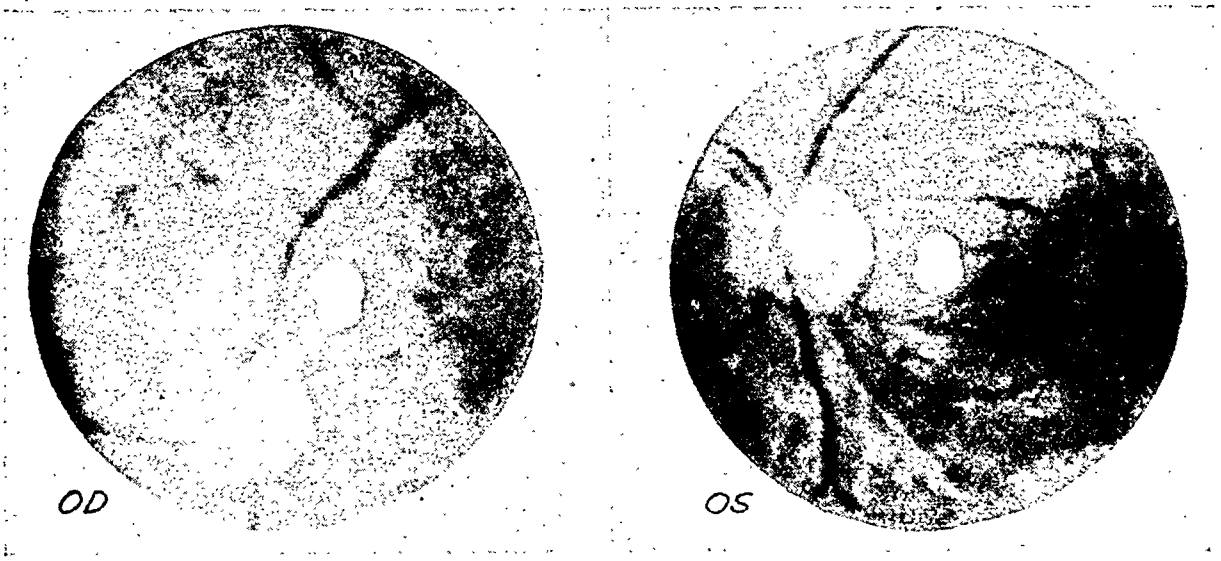

Fig. 3 (Stansbury). Fundi of *Case 3.* Vision is: R.E., 20/200, J6; L.E., 20/100, J6. The haziness of the disc margin on the right is an artifact.

relieved by drinking fruit juice or eating a piece of candy. Two years before admission, at the age of 11 years, he noticed the inability to read for prolonged periods without blurring of the print, and although in the seventh grade and not failing in his studies, he was conscious of slowly diminishing visual acuity. There was no difficulty with vision at night.

Eye examination. The past medical history was noncontributory, and general physical examination, with emphasis on the neurologic aspect, was entirely negative except for the ocular findings. The boy had not reached puberty. Vision was: R.E., 20/200, J6; L.E., 20/200, J6. Homatropine retinoscopy showed: R.E., +0.50D. cyl. ax. 90°; L.E., +0.25D. cyl. ax. 100°; but subjectively he accepted: R.E., plano; L.E., +0.25D. cyl. ax. 90° to make his best corrected vision: R.E., 20/200, J6; L.E., 20/100, J6. The pupils were round and equal (4 mm.), reacted to light and accom-

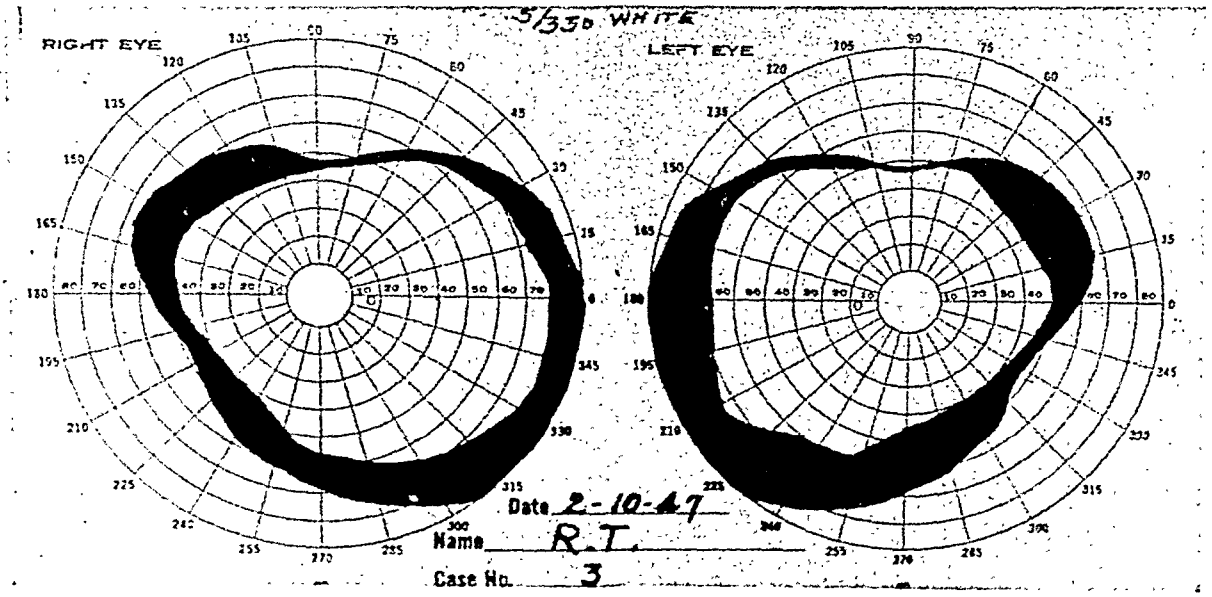

Fig. c (Stansbury). Peripheral fields of *Case 3.*

modation, and the consensual reaction seemed sluggish. The extraocular movements were normal, and the media clear. The peripheral fundi showed no evidence of hemorrhage, exudate, or vascular abnormality, but the appearance of the optic discs was quite similar to that of the other two patients. The margins were sharply demarcated, the physiologic cups wide, the periphery pale white (especially temporally) fading to gray centrally (fig. 3). One observer described debatable degenerative changes in the macular regions of this patient. The intraocular pressure was: R.E., 25 mm. Hg (Schiøtz); L.E., 27 mm. Visual fields in this case, too, showed nothing pathognomonic, but rather a concentric peripheral constriction, more marked temporally (fig. c). The color vision was defective, and attempts to outline the color fields were not successful. The blindspots of Mariotte were elongated vertically, more so on the right, but there were no central scotomas.

Laboratory studies revealed a negative serology. C.B.C.: Hb., 14; W.B.C., 6,700; normal differential. Urine: sugar, 2 plus; sp. gr., 1.025; acid; acetone negative. Fasting blood-sugar, 305. Spinal fluid on February 5, 1947, was clear; the pressure was normal, but there were 3 segmented cells and 120 lymphocytes; on February 15, 1947, a repeat examination revealed 3 segmented cells and no lymphocytes; spinal fluid Wassermann and colloidal gold tests were negative.* X-ray studies of the optic foramina and sella turcica were normal.

This patient's diabetes was regulated with 20U protamine-zinc insulin and 15U regular insulin before breakfast. His hospital course was uneventful, and he was discharged on a high-protein, high-vitamin diet.

* The spinal fluid findings in Case 2 and Case 3 were felt to represent a possible error in that both specimens with a high cell-count were collected by the same student on the same day, and in a later specimen, each patient showed a nearly negative cell-count. It must be admitted that the significance of the spinal fluid findings is not clear.

Comment

Of the remaining six children in this family whose ages were 23, 20, 17, 15, 11, and 9 years, respectively, the three oldest were available for examination. Vision in each of these siblings was: 20/20 J1, O.U., color vision was normal, and the optic nerves were normal to examination. In fact, there was no evidence of an ophthalmic pathologic condition or diabetes.

The father, aged 46 years, was examined and was found to be normal except for early presbyopia; the mother of these children (aged 40 years) and the three younger children were not available for examination, but there were no visual complaints, and all had been tested for diabetes and found to be free of signs or symptoms.

As has been stated, there was no known hereditary visual affection and no history of diabetes in the grandparents or the more remote ancestors. Generally speaking, this large family, with the exception of these three diabetic children, seems to be normal physically, and of sturdy stock. The father's occupation was that of a farmer.

Discussion

In considering the possibility that a causative factor other than diabetes might be responsible for the optic atrophy in these children, and in the absence of any indication that syphilis had played a part, the disease pattern of hereditary optic atrophy or "Leber's Syndrome" was given serious consideration.

This relatively rare condition, of unknown etiology but with a definite "hereditary tendency, affecting particularly males about the 20th year of life, . . . showing in its early stages fleeting evidence of optic neuritis, followed by a secondary atrophy which involves a serious impairment of central vision with retention of the peripheral fields"[9] . . . has several characteristic features. These are listed by Raaf and Bair[10] as: (1) A predilection for males; (2) average age of on-

set 23 years for males and 25 years for females (among Europeans); (3) rapid impairment of vision, with maximum disability within two months from the onset, and rarely with advancement of symptoms after six months; (4) patients are usually in good health, no other disease being characteristically associated with hereditary optic atrophy; (5) the sole complaint is usually diminution of vision, with the most common defect being a central scotoma, although peripheral defects are frequently seen; (6) color blindness is usually the only other symptom; (7) in early stages, the fundus may be normal or may show typical optic neuritis, optic atrophy supervenes, and the disc never regains its normal appearance; (8) from 10 to 29 percent of all patients show some subsequent improvement and, if the age of onset is early, the prognosis is better; furthermore, there is an inherited tendency to improvement; (9) in 93.6 percent of cases (European series) the disease was transmitted by the mother.

It will readily be seen that the majority of these criteria are not met by the three subjects of this paper.

Fisher,[11] in 1916, advanced the idea that Leber's optic atrophy is the result of hereditary changes in the pituitary gland, probably temporary in character, but clinical and X-ray studies have failed to bear this out, and the theory which blames irregularities in the growth of the sphenoid bone has not received much support. In the patients under discussion, there was no evidence of a primary pituitary disturbance, and the films of the skull did not reveal prominent clinoid processes or deep sella turcicas.

Pathologically, there is said to be[12] atrophy of the ganglion cells and nerve-fiber layer of the retina in Leber's disease, with the atrophy of the nerve limited to the papillomacular bundle and other parts of the nerve normal. There is destruction of the medullary sheaths but no inflammatory signs (this report records the autopsy findings in but one case), which leads its author to conclude that the underlying pathologic process is a primary neuronic (inherited) degeneration localized in the optic nerve, rather than a toxic retrobulbar neuritis secondary to neighboring sepsis and infected tissue which bears an inherent vulnerability.

Bhaduri[13] suggests that the condition may be embryologic, with a common germ-plasm defect in the anlage of the retina and the inner ear. In substance, however, it would seem that, by virtue of their failing to meet practically all of the criteria for hereditary optic atrophy, this syndrome can be excluded as a possible diagnosis in the patients herein reported.

In a further consideration of the differential diagnosis of these cases, any of the more remote causes for primary atrophy of the optic nerve must be considered. As has been stated, primary optic atrophy occurs subsequent to retrobulbar neuritis, when the inflammation confines itself to the trunk of the nerve and does not approach the nerve-head.

Duke-Elder[14] considers among the causes for retrobulbar neuritis followed by optic atrophy, the group of so-called "neurotrophic virus infections." These include disseminated (multiple) sclerosis, acute disseminated encephalomyelitis, neuromyelitis optica (of Devic), diffuse periaxial encephalitis (of Schilder), and herpes zoster. All of these are characterized by an extensive demyelinization of the optic-nerve fibers where these fibers are myelinated (hence retrobulbar), followed by degeneration of the axis cylinders, and finally a proliferative gliosis. In the subjects under discussion, the absence of positive neurologic signs, except ophthalmologically, along with the absence of clinical history and peripheral nerve damage, would appear to exclude this group of diseases.

In an exhaustive study concerning the relationship between Recklinghausen's disease (or multiple neurofibromatosis) and

gliomatous tumors of the optic nerve, Davis[15] makes the statement that many cases of unexplained atrophy of the optic nerve may be due to early tumors of the nerve, some of which may have been incorrectly diagnosed as retrobulbar neuritis.

Exophthalmos need not be present, but the diagnostic leads that are of value in establishing the presence of atypical neoplasms of the nerve are said to be subcutaneous nodules which are manifestations of the general condition, café au lait pigment patches on the skin, and certain typical changes, visible by X ray, involving the sella turcica and the optic foramina.

None of the three patients herein studied showed evidence of subcutaneous tumors, café au lait spots, skull changes visible to X ray, exophthalmos, or evidence of increased intracranial pressure, so that the possibility of tumor of the optic nerve being responsible for their optic atrophy seems remote.

These children were all three well nourished. The two younger siblings might be said to be somewhat retarded as regards pubertal changes. None of them showed evidence of an avitaminosis which might have produced an optic neuritis of the axial type. Since the onset of the visual disturbance, although occurring at about the same age in each patient, did not occur in the same calendar year, or coincident with an epidemic such as typhoid, influenza, and so forth, the possibility of an optic neuritis from endogenous toxins (other than diabetic) seems remote. External toxins, such as tobacco, alcohol, lead, arsenic and so on, were considered and then rejected as highly improbable due to the complete lack of contact. There was no evidence of adjacent infection, periorbital, intracranial, or in the paranasal sinuses, to produce optic neuritis and subsequent atrophy. As a matter of fact, two of the cardinal signs of optic neuritis were absent; namely, sudden onset and central scotomas. On the contrary, the progress had been very insidious and, although central vision was defective, the absolute scotoma was peripheral in each case.

It was suggested that, since each of these children had had frequent episodes of insulin shock, this alone might in some manner produce atrophy of the optic nerve. However, it was felt that, if this relationship existed, such a syndrome would be recognized and established.

Summary

To summarize, then, three children of a farming family of nine siblings have been shown to have had rather severe diabetes mellitus from early childhood and, in addition, each of these children has a pathologic condition of the eyes manifested by an absolute peripheral scotoma, a relative central scotoma, defective color vision, and a well-advanced primary optic atrophy (binocular), but no evidence of diabetic retinopathy.

The other six children in the family, as well as the parents and grandparents, are free of diabetes, and none shows evidence of optic atrophy or other ocular disease. The evidence may be circumstantial on these grounds, but from the standpoint of the selectivity of the optic atrophy, it would seem that, in these patients, there is a direct relationship between their diabetes and their visual symptoms.

A consideration of the possible etiology of the atrophy of the nerve, other than following a retrobulbar neuritis secondary to endogenous diabetic toxins, gives no clues, and an attempt has been made to rule out the common causes for retrobulbar neuritis and optic atrophy, including lues, exogenous toxins, the virus neuropathies, endocrine dysfunction, cranial malformation, tumor of the optic nerve, and particularly Leber's syndrome of hereditary optic atrophy. The weight of evidence in these patients seems to point to diabetes as the factor responsible for their eye-findings, but the pertinent history, as well as the clinical findings,

differs rather markedly from the usual case of this type in that there is no clear-cut episode of retrobulbar neuritis and the loss of central vision has been relative and gradual, the papillomacular bundle being only incidentally involved.

It is suggested that perhaps the underlying pathologic process in this group of patients is indeed a degenerative process—rather than an actual inflammatory "neuritis"—of the type that is said to occur in alcohol or tobacco amblyopia, but differing rather markedly in that the process here does not show a predilection for the papillomacular bundle, but rather involves the entire bundle of nerve fibers somewhere behind the globe and anterior to the external geniculate bodies. Furthermore, the process appears to be a particularly insidious one. Alternately, this might represent a "tabes-like" type of quiet neuritis and axone-degeneration.

In either case, the causative agent is not known, but it can be speculated that some type of endogenous poison, whether ketone-bodies or something else, occurring in the presence of active diabetes mellitus, is responsible for the condition. That there may be another, as yet unknown and undetermined, factor in this syndrome of optic atrophy and diabetes is a possibility. It seems reasonable to suppose that a joint defect in the germ plasm—some type of aberration common to the anlage of the pancreas and the visual organ—may be basically responsible for the presence of the two conditions of diabetes and optic atrophy in these patients, and this relationship could conceivably apply wherever these diseases coexist.

Conclusion

Optic atrophy can occur as a complication of diabetes mellitus. It is probably preceded by some type of retrobulbar neuritis, but it is suggested that in certain instances, the process may be primarily a degenerative one.

NOTES, CASES, INSTRUMENTS

AN OPERATION FOR SHORTENING A RECTUS MUSCLE

D. P. HORNBOGEN, M.D.
Marquette, Michigan

Operations for increasing the action of an eye muscle by advancement or resection are attended by the possibility of the sutures giving way and decreasing the amount of correction. This is especially true when the muscle is attenuated or stripped of its fascial covering.

In the Reese resection the pull of the sutures is in the direction of the muscle fibers making it easy for the sutures to slip toward the cut end. This is most likely to occur when tension is placed on the suture to draw the muscle into place against the stump before tying. It can still occur after the ends are in position and the sutures tied but is less apt to at this time, as some of the pull is now in a horizontal direction across the muscle fibers.

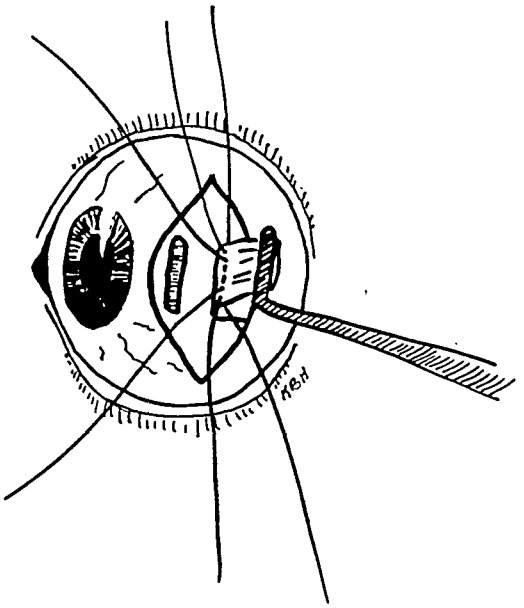

Fig. 1 (Hornbogen). The central mattress suture has the loop on the outside instead of the under surface of the muscle, and the conjunctiva is not included.

The modification here presented is one in which the pull of the suture is always across the muscle fibers and not with them. The muscle is exposed in the usual manner but not stripped of its fascial covering. A muscle forceps is applied near the insertion and the tendon severed leaving a stump of about 1.5 mm.

A central mattress and two wing sutures are placed in the muscle at the desired distance, as in a Reese operation, except that the central mattress suture has the loop on the outside instead of the under surface of the muscle, and the conjuntiva is not included (fig. 1). They are next passed through the stump. At no time during this stage should any pull by the sutures be exerted against the fibers. As tension is placed on the central suture to draw the muscle and the stump together, the assistant, holding the forcep attached to the end of the muscle, draws it toward the canthus making a V with the sutures at the apex (fig. 2). This puts all of the suture pressure across the fibers. The suture has such a firm hold on the muscle that it is not neces-

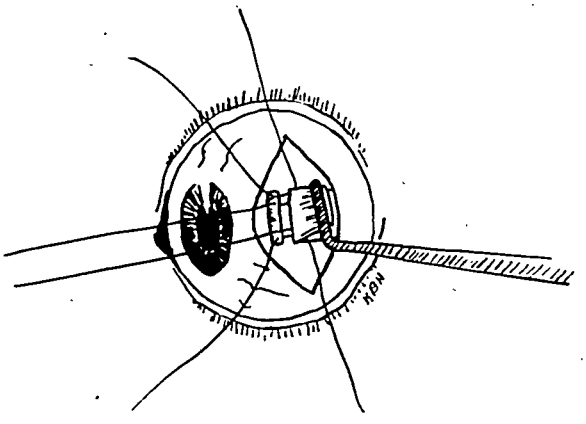

Fig. 2 (Hornbogen). As tension is placed on the central suture, it is drawn toward the canthus, making a V with the sutures at the apex.

sary to rotate the globe to bring the stump to the muscle.

The amount of force applied need be governed only by the breaking strength of the suture or by the amount necessary to tear through the bite of stump and episclera. The flap is held in this position until the sutures are tied and cut.

The forceps are removed leaving a flap of tendon beyond the sutured stump (fig. 3). This is now laid back, flat, along the muscle as far as it will reach and sutured to it at each edge. If the amount of shortening is large and the excess tendon is unduly long, a portion may be excised before it is sutured in position (fig. 4). The conjunctiva is closed separately. If one does not wish to bury the knot of the mattress suture, it can be carried through the limbal flap of conjunctiva and tied outside.

The suture material used can be that preferred by the individual operator. I have been using 4-0, 10-day, chromic gut for the mattress suture and 4-0 plain gut for the remainder.

This method is applicable to either the internal or external rectus. The thickening produced by the double layer of muscle is minimal and of no consequence and is not comparable to that produced by a tucking or a cinch operation. With this technique it is possible to mobilize the eyes earlier in the postoperative period.

BIPRONGED FORCEPS

AN INSTRUMENT FOR PLASTIC SURGERY

ALSTON CALLAHAN, M.D.
Birmingham, Alabama

In performing plastic procedures of the eyelids, it is frequently necessary for an assistant to apply forceps to areas immediately contiguous to that held by the surgeon. This is in order to prevent distortion in

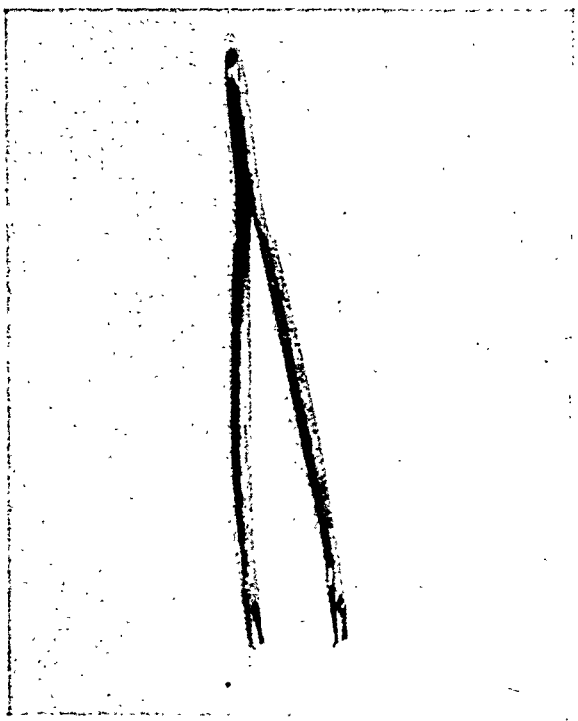

Fig. 1 (Callahan). Bipronged forceps for use in plastic eyelid surgery.

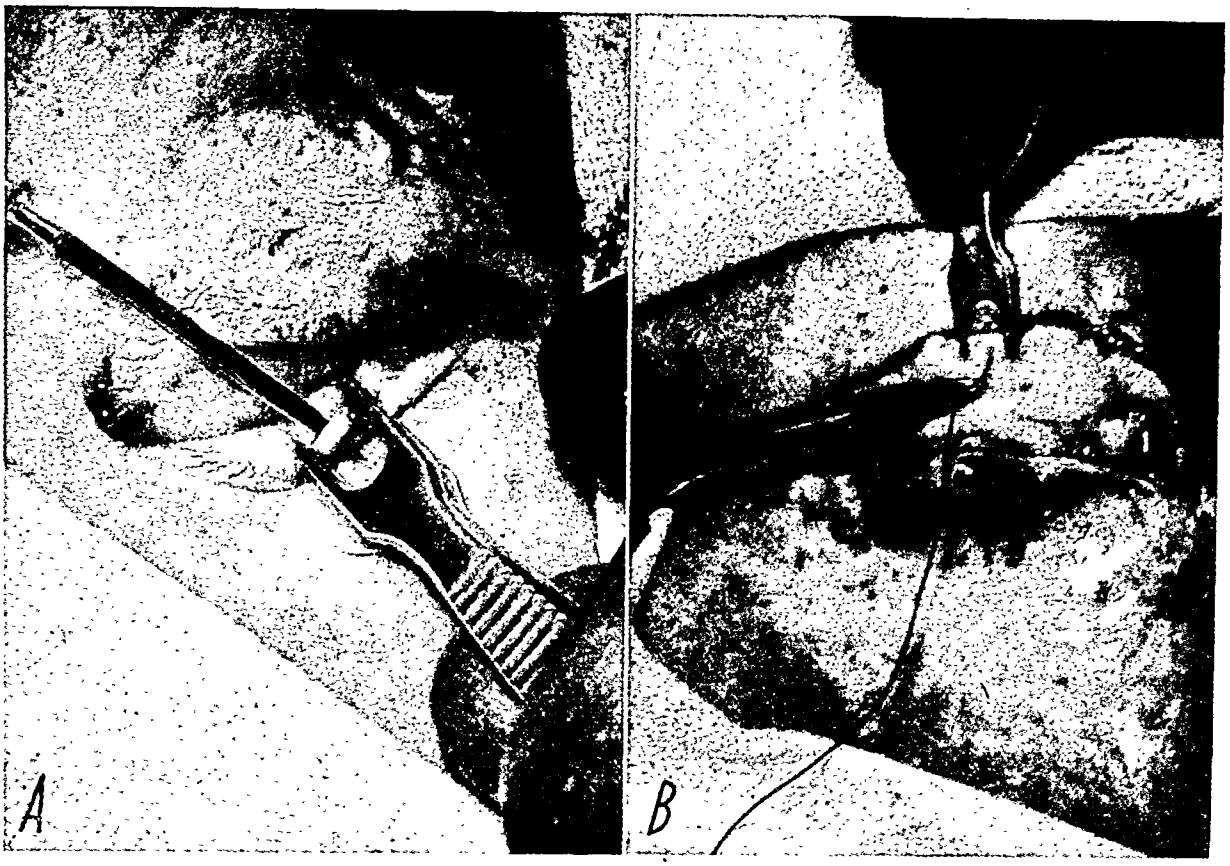

Fig. 2 (Callahan). (A) The bipronged forceps are holding the margin of the lower lid firmly, as a Graefe knife denudes a small rectangular area of transitional epithelium. (B) A free-skin graft is placed in position for the correction of ectropion. The bipronged forceps are holding the graft so that the first suture may be placed without difficulty.

making incisions and in placing sutures. The need for a bipronged forceps which would hold tissue firmly, without crushing, and would allow working space between the prongs, became apparent. This would allow smoother handling of tissue and free the assistant for cutting sutures, sponging of blood, and so forth.

An instrument was designed with prongs 8 mm. long, and the interspace 5 mm., fitted on the end of a handle similar to that of a Lester forceps (fig. 1). Each of the prongs on one side carries a small sharp tooth, which meshes between two teeth on the opposite prong. Denuding small rectangular areas for lid adhesions (fig. 2A) and placing sutures through a free skin graft (fig. 2B) are two of many technical procedures facilitated by its use.

FLEXIBLE CABLE SLIT CONTROL FOR BIOMICROSCOPE

LESTER STEIN, M.D.
Steubenville, Ohio

It has long been felt that control of the width of the slitlamp beam should be so facilitated mechanically that the biomicroscopist could alter the beam with utmost ease while examining pathologic details.

Of extant models of biomicroscopes, the Haag-Streit (Goldman),* and the Zeiss (Comberg)† are examples of geared control of the slit width. The simplified Universal model biomicroscope‡ lends itself to

* Goldmann biomicroscope (Haag-Streit, Berne, Switzerland).

† Comberg biomicroscope (Carl Zeiss, Jena, Germany).

‡ Universal biomicroscope (Bausch & Lomb Optical Co., Rochester, N.Y.).

incorporation of a flexible cable and knurled knob which will permit accurate, speedy slit-width readjustment without the fumbling in the dark which heretofore has inhibited alteration of the beam.

It is well known that the best results in visualizing the manifold optical changes of the ocular media are obtained with a combination of changing microscope focus, beam width, oscillatory field (Koeppe),[§] and panoramic sweeping of the beam across the field while employing the various modes of illumination. This type of optical scrutinization or "visual palpation" leads to definitive interpretation of the various refractive, reflective, and dispersive changes which characterize pathologic alteration of the ocular structures or media.

Direct focal illumination produces the finest optical delineation but unless the observer employs[‖] reciprocally the wide and narrow beam for observation and localization, he loses the full potentiality of biomicroscopy. The study of shadow formations ("optic reduplications"), vacuoles and bullae, deposits, and so forth, is enhanced by smooth control. Differentiation of extrasectional as well as sectional features in localization is helped by being able to widen and narrow the beam facilely. If students of the technique would learn at the outset to examine the eye with the various methods of illumination and with rapid beam-width control, considerable improvement in biomicroscopic technique would ensue.

Study of zonal discontinuity in the lens is benefited with ready control of the beam flux. After a survey of the lens with a wide beam, the transition to optic section for localization of details is smoother and more rapid in contradistinction to the present method of reaching to the slit housing for the slit-control screw and then twisting it to obtain the requisite narrowing. It is small wonder that the busy practitioner, unconcerned with the minutiae of biomicroscopy, may allow the slit to rust into fixation at one wide width. To help him as well as beginning students, I offer this suggestion for modification of a domestic biomicroscope.

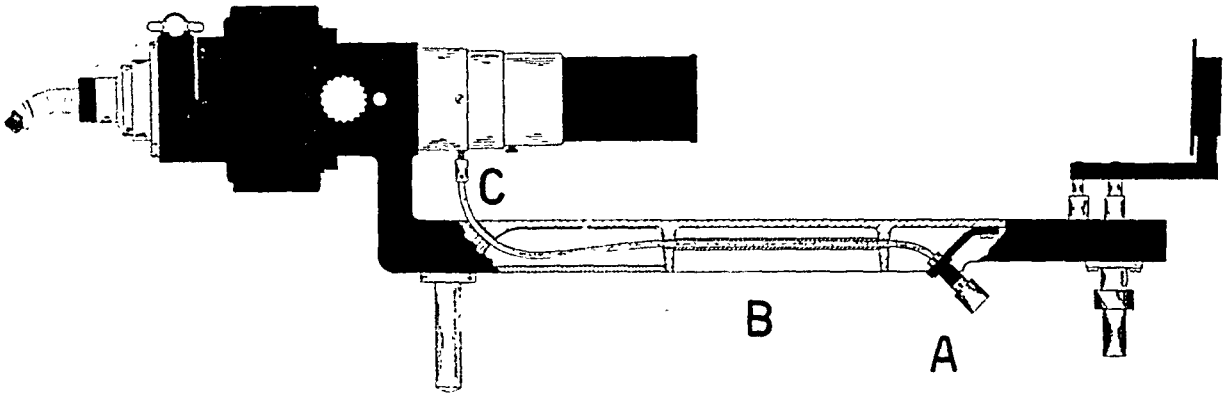

Fig. 1 (Stein). Cross-sectional view of apparatus.

The knurled knob is placed (fig. 1-A) at the distal extremity of the illuminating arm in proximal juxtaposition to the Arruga screw at such an angle as to be readily available to the controlling fingers of either the right or left hand. By means of a flexible cable affixed within the matrix of the illuminating arm (fig. 1-B), rotation of the knurled knob results in corresponding rotation of the inverted slit-control screw to which the cable is fastened (fig. 1-C), leading to alteration of the width of the corneal parallelepiped, lens prism, and optic section.

TOTAL DISAPPEARANCE OF THE IRIS DUE TO ESSENTIAL ATROPHY*

JENNER HU, M.D.
Chengtu, Szechwan, China

Apparently all cases of essential atrophy of the iris reported in the literature showed only holes or partial defect. A total disappearance of the iris, as far as we know, has not been reported before. We were fortunate enough to observe such a case recently.

Sun Chuan-Min, a man, aged 31 years, apparently had normal eyes when he was young, since neither his parents nor his friends ever made any remarks about them. His vision in both eyes was always good. Four years ago he suffered from a severe eye inflammation, which was probably trachoma. Since then his vision has been poor. Even three years ago he could read with the left eye alone.

On examination, both eyes were found to have trachoma, with scars in the conjunctiva of the upper tarsus and a thin total pannus. The right eye showed a normal anterior chamber, iris, and fundus. The left eye had a white macula on the temporal side of the cornea and had no iris at all. The depth of the anterior chamber could not be estimated. On the nasal side, the ciliary process could be seen projecting against the equator of the lens. On the temporal side, the corneal macula obstructed the view of the deeper structures. However, the golden glistening equator of the lens could be seen with focal illumination. The fundus was normal. The papilla was pink, the central vessels appeared normal, and there was no evidence of glaucoma. Vision was: R.E., 2/60; L.E., 1/60. The slitlamp examination was somewhat hindered on the temporal side by the corneal opacity and revealed a total absence of the left iris.

* From the Department of Ophthalmology of the West China Union University.

The visibility of the entire equator of the lens made the absence of the iris especially conspicuous.

We have to consider three possibilities for this absence: (1) Congenital aniridia. (2) Traumatic expulsion or extraction of the iris. (3) Essential atrophy.

As the patient's parents never mentioned anything about any anomaly of the left eye and as congenital aniridia would have been very conspicuous even in the darkly pigmented Chinese eye, since such an eye would have certainly shown a red pupillary reflex in the dark, it would seem that congenital aniridia was not present. That the patient had had good vision and could read with the left eye even as recently as three years ago further strengthens this contention. The second possibility, that of injury, is excluded by the negative history and by the clinical examination which did not reveal any sign of violence or scar.

Without doubt we have here a special case of essential atrophia iridis in which the disappearance of the iris tissue progressed so rapidly and so extensively that the last iridic fibers became invisible.

Essential atrophy of the iris is, as a rule, monocular as is exemplified in our case where the change was confined only to the left eye.

The tension of the right eye was 7 mm. Hg (Schiøtz) and that of the left eye, 16 mm. Hg. That the latter figure was much higher than the former again emphasizes the correctness of our supposition. The low tension in both eyes was probably due to the increased permeability of the cornea due to the pannus. Anyhow, the tension in the left eye was more than double that in the right.

If we take into account the probable permeable condition of the corneas, we may say that there was a definite relative glaucoma in the left eye. We know that in the later stages of essential atrophy the tension goes up. As a rule, it is at that time that a large part of the iris tissue is already resorbed. No doubt we have here in our case the cardinal sign necessary for the diagnosis of essential atrophy of the iris.

Concerning the cause of this increase in tension, there is much difference in opinion. We do not believe that the diminished surface of the iris due to the defects causes the resorption of the aqueous. We feel that the increase of tension may be due in early cases to the remnants of the fine fibers of the iris which are seen in some cases as white felt in the neighborhood of the holes of the iris or on the surface of the lens. These fibers may obliterate the gaps of the pectinate ligament and hinder the filtration in a way similar to that found in cases of glaucoma following degeneration of the zonular lamellae. Histologic examinations of cases with advanced glaucoma showed that the root of the iris was drawn to the pectinate ligament.[1]

Fine and Barkan's case[2] exhibited the most advanced degree of atrophy involving both eyes in a 9-year-old boy. The strands left formed a V-shaped figure in the right eye and an irregular X-shaped figure in the left eye. Duke-Elder[3] has summarized all the literature on this subject quite thoroughly. Rones reported a case where the iris showed an ectropion of the pigment epithelium; such an ectropion was apparently not present in our case.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

COLORADO OPHTHALMOLOGICAL SOCIETY

December 20, 1947

DR. MAURICE MARCOVE, *presiding*

FAMILIAL NODULAR DYSTROPHY

DR. WILLIAM M. BANE presented three cases of corneal dystrophy showing the deposits typical of Groenow's familial dystrophy including striations, small and large, round and oval deposits, ring-shaped opacities, and larger, white fluffy deposits. These cases were in the same family—the mother, Mrs. N., aged 39 years; a daughter, Betty, aged 14 years; and a son, John, aged 10 years. The youngest boy, aged 9 years, had normal vision and the corneas showed no signs of the disease. The mother stated that her mother and maternal grandmother, both deceased, had eyesight not improved much by glasses, and that she has two sisters living who have an eye condition similar to hers. Two brothers have no eye trouble. She and her family came from Iran. It seems safe to presume that the sisters and the mother and grandmother also had this same type of corneal dystrophy.

Mrs. N. states that, when examined 11 years ago in England, a diagnosis of punctate keratitis and vitreous opacities was made. The true condition was apparently not recognized. Betty and John had poor vision but never wore glasses and were never previously examined. Although examination with the corneal microscope revealed in each case a picture typical of the disease as described by previous observers, each of these three cases also showed a different picture. There were more striations in the 10-year-old child, the development of more nodules in the 14-year-old child, and more of the fluffy white deposits in the mother. It was also noted that, in the mother, there was more involvement of the deeper layers of the cornea than in the children. William Zentmayer in his article for the Jackson Birthday Volume, said that the disease was apparently limited to adults; whereas, Duke-Elder states that the earliest known cases begin about 10 years of age, although in one child aged five years, some early signs had been noted. The 10-year-old boy in this family had so much involvement of each cornea that it seems fair to believe that his eyes became involved when he was 8 or 9 years of age, or even younger.

Discussion. Dr. Harry W. Shankel quoted Berliner as saying that cases of corneal dystrophy are seen as early as five years. The cases herein presented are especially interesting in that they are seen in the typical stages of the various decades of life; in the youngest child, there are spots in radiating lines; in the older girl, these spots have coalesced somewhat; and in the mother they are seen in large groups of nodules. Dr. Marcove said that this is purely a degenerative disease and not at all infectious. It differs somewhat from Groenow's original report which was of an epithelial dystrophy.

CHORIORETINITIS DUE TO TOXOPLASMOSIS

DR. JAMES STRONG presented a white woman, aged 31 years, who had first been seen four months before complaining of blurring of right vision. She had had a similar attack four years before lasting five months and again three years before lasting three weeks. Examination revealed vision to be 20/25, O.U. The left eye seemed to be quite normal throughout. The right eye showed numerous keratic precipitates on the cornea, and the aqueous was quite full of cells. The iris, pupil and lens were normal.

The vitreous was hazy. An active area of chorioretinitis about 1 by 2.5 disc diameters in size was seen about 2 disc diameters above and temporal to the macula. Disc and vessels were normal.

The patient was started on atropine drops and penicillin by mouth, but the described signs became worse. Penicillin, 300,000u. in wax, was begun daily with no benefit. She was then hospitalized and given typhoid therapy alternating with calcium gluconate intravenously. She improved remarkably for a while and then became much worse again. She was given a course of gold sodium thiosulphate and improved considerably. In the meantime, a cataracta complicata had begun to develop. Vision was 20/200. One month ago she received a whole blood irradiation after which the lens cleared entirely, and the aqueous beam became almost imperceptible. X-ray films of the chest and an exhaustive physical examination were normal. A laboratory test for toxoplasmosis will be done soon.

Discussion: Dr. Ralph Danielson asked about the possibility of brucellosis and added that toxoplasmosis is a probability but not likely since it is seen mainly in children and only healed lesions are seen in adults. Dr. Walter Ohmart said that the negative X-ray films and Mantoux test did not finally rule out tuberculosis which this could well be. Dr. W. H. Crisp said that the probability of tuberculosis is so likely that, as a therapeutic measure, the patient should be at absolute bed rest for many weeks. Capt. A. Schultz suggested a therapeutic test of streptomycin, 1 gm. daily by injection or by iontophoresis, as it is given at Fitzsimons General Hospital with very good results. Dr. John C. Long stated that he was quite opposed to the use of gold empirically and quoted Hill of Richmond who reported the loss of both corneas after its use. Dr. Leonard Swigert repeated that the case seemed typically tuberculous and suggested a series of old tuberculin along with small doses of X ray with which he had had very good results in two cases of Eales's disease.

Dr. Strong (closing) agreed that all signs pointed toward tuberculosis but said that the internist on the case had insisted that infection could not possibly be present with all the performed tests being negative. Brucellosis tests had been negative. X-ray films of skull had shown reduction in brain convolutions which pointed toward toxoplasmosis. (Two weeks later, Dr. Strong received the report that this patient was strongly positive for toxoplasmosis.)

Bitemporal hemianopsia

Dr. James Strong presented a 23-year-old white woman who complained of headaches, blurring of vision, and eyestrain of six months' duration. In addition, she had had increased thirst for the past month. Examination revealed 20/20 vision, O.U., easily correctible to 20/15. Funduscopy was entirely normal except for blurring of disc margins in right eye. Visual-field studies revealed slight enlargement of each blindspot with moderate bitemporal hemianopsia. X-ray films of the skull were negative. Repeat of fields one month later showed that the hemianopsia had disappeared entirely. Impression: Optic neuritis.

Discussion. Dr. Marcove suggested that in optic neuritis of sufficient extent to blur disc margins, it would be most unusual to have 20/15 vision; therefore, the diagnosis is most unlikely and there must be some type of intrancranial pathologic condition. Dr. Long added that there should be a sedimentation rate and a spinal puncture to rule out an infection such as arachnoiditis.

Congenital glaucoma

Dr. Walter Ferer presented a 12-year-old Spanish boy who was admitted to Colorado General Hospital complaining of poor vision in the right eye during most of his life. The condition had been diagnosed as having hardening of the eyes but had received very little treatment. Examination

revealed vision to be: R.E., 20/400, incorrectible; L.E., 20/30, correctible to 20/20. Tension was 38 mm. Hg (Schiøtz) in the right eye and 34 mm. in the left. The corneas were large and prominent and measured 13 mm. The cornea of the left eye was clear, while that of the right was cloudy with many tears in Descemet's membrane. The irides were somewhat atrophic and the pupils were oval and reacted to light and accommodation. Anterior chambers and lenses were normal. The left disc was normal, while the right disc was deeply cupped and atrophic. Gonioscopy showed the right chamber angle to be entirely obliterated in all its circumference, while the left was obliterated only in patches. In the hospital, the tension of the left eye was easily controlled with pilocarpine and that of the right was not controlled at all with either pilocarpine or D.F.P.

Discussion. Dr. Marcove said that this case was presented for two reasons: (1) To seek surgical opinion as to type of operation to perform since something beyond medical treatment should be given, this would be a choice between goniotomy, trephination, and cyclodialysis; (2) to describe the drug D.F.P.

This drug was first discovered in a wargas plant where it was noted that those exposed to it became miotic and remained so for at least 10 days. At the University of Pennsylvania, it was found that the chemical was di-isopropyl fluorophosphate. It will soon be available commercially and is believed to be a tremendous advance in the medical treatment of glaucoma—especially secondary glaucoma. It was used at first in 0.1-percent solution but this seemed to produce too much spasm and 0.05-percent solution appeared to be much more practical. The drug stimulates the parasympathetics and its action is more prolonged than that of other miotics; however, it takes 2 to 3 days to commence its action after eserine or pilocarpine has been used. It is used in peanut oil and is unstable in water or mineral oil.

Dr. Danielson said that he had had a case almost identical with this one which was first seen when the patient was five months of age on which he had done a bilateral iridencleisis with very satisfactory results after three years. Dr. Tom Van Bergen said that at the University of California Clinics, the operation of choice in these cases is cyclodialysis.

Complication to streptomycin

Capt. A. Schultz (by invitation) said that since October, 1945, streptomycin therapy has been used at Fitzsimons General Hospital on slightly more than 500 patients with tuberculosis. In this group only one case with a visual-field defect was noted as a complication. This is a presentation of the case.

Mrs. M. L., a 31-year-old white woman, with pulmonary tuberculosis came to the Eye Clinic at Fitzsimons General Hospital, on October 20, 1947, complaining of sudden loss of vision in upper visual field of the right eye two days previously.

Her past history revealed that in July, 1946, a diagnosis of pulmonary tuberculosis was made. Her sputum was positive. The X-ray examination showed minimal infiltration of the right lower lobe. Cavitation was not found. She was treated with phrenic crush and pneumoperitoneum. The latter treatment consisted of the injection of about 800 cc. of air into the peritoneal cavity, five days before the onset of her visual symptoms. On August 28, 1947, parenteral streptomycin was begun, using 2 gm. daily in four divided doses. On October 18, 1947, 52 days after streptomycin had been started, the patient had sudden visual complaint, preceded by severe occipital headache. Streptomycin was discontinued on October 20, 1947.

Eye examination. On the first examination on October 20, 1947, visual acuity in the right eye was 20/30, correctible to 20/20; in the left eye, 20/20. The pupils were equal and regular, reacted well to light and accommodation. There was no diplopia. Slitlamp

examination was negative. Ophthalmoscopic examination of the right eye revealed the media to be clear, disc normal, retinal arteries generally attenuated, superior vessels slightly, inferior vessels moderately. The macula was normal, as was the periphery. The patient could not see the ophthalmoscopic beam in the inferior retina. The left eye was normal throughout. There was no caliber irregularity of arteries.

Visual field. Right eye, absolute altitudinal defect for 3/300 white and 3/1000 white up to a bright light through midline, sparing macula. There was a relative area in entire lower half of field for 3/330 and 3/1,000 white.

Color sense. She could recognize 10/1,000 blue within 10 degrees of macula inferiorly in the right eye, but no red or green. The left eye was normal.

Therapy. Immediate therapy consisted of 50 mgm. sodium nitrite, I.V., (Nitroscleran) and 50 mgm. q3h, I.M., for 24 hours. Hourly massage of the eye was ordered. The following day it was felt more energetic therapy was indicated since the vascular spasm and field defect persisted. The ciliary ganglion was anesthetized with 2 cc. of 2-percent novocaine injected retrobulbarly. A paracentesis of the anterior chamber was performed. An injection of 100 mgm. sodium nitrite, I.V., was made concurrently. Dicumarol was started, keeping the prothrombin time at 40 to 50 percent of normal; 660 mgm. rutin were given daily. The latter two drugs were given on the premise that a thrombus might be present at the bifurcation of the central retinal artery.

Course. Under this regimen, the field defect improved and recognition of colors returned. On October 23, 1947, three days after onset, ophthalmoscopic examination of the right eye disclosed about one diopter of papilledema with enlargement of the blindspot. Visual acuity remained at 20/30 in the right eye, correctible to 20/20 until November 7, 1947, 19 days later, when visual acuity in the right eye was found to be 20/100, uncorrectible. No new ophthalmoscopic findings were present. Previous therapy was continued. Four ampules of amyl nitrite were inhaled, improving vision to 20/70 in the right eye. This was repeated on alternate days and in two weeks visual acuity in the right eye was 20/30 uncorrected. The final examination on December 2, 1947, showed visual acuity of the right eye to be 20/30, correctible to 20/25; left eye, 20/20.

Ophthalmoscopic examination of right eye showed the media to be clear; disc was of normal size, shape, and color except for a slight temporal pallor; the previous elevation had disappeared. The arteries of superior retina were nearly normal in caliber, A-V ratio was 2:3. The inferior retinal arteries showed generalized attenuation but were not as constricted as at the time of first examination. A-V ratio, 1:3. Macula and peripheral fundus normal. Left eye entirely normal.

Visual field. Visual-field studies showed the right eye to have a normal peripheral field for 3/330 white. Central field (3/1,000 white) showed normal physiologic scotoma, but a 2 by 5 mm. vertical relative scotoma was present just nasal to the fixation point. This was a remnant of the previous superior scotoma. Color fields for 10/1,000 red, green, and blue, were almost normal.

The patient has had no recurrence to date. Drug therapy was discontinued on November 20, 1947. No more streptomycin has been given. Pulmonary tuberculosis improved under the relative short course of streptomycin therapy.

Discussion. Dr. Long said that intravenous ether has been used in arterial emboli in legs and it might have been useful here. Dr. Marcove said that he felt that the ganglion cells of retina die after 3 to 4 hours. It was unusual that in this case amyl nitrite benefited after 17 days.

Morris Kaplan,
Secretary.

SOCIEDAD OFTALMOLOGICA DE MADRID

June 26, 1947

Entropion of the lower lid

Dr. Marin Amat presented his operative procedure, consisting of: (1) An incision parallel to the ciliary border and some 5 mm. from it, including the skin and the orbicularis muscle; (2) resection of the muscle fibers if they protrude in the wound; and (3) placement of the suture points (which is the fundamental part in the procedure) so that the needle point penetrates successively the lower (cutaneous) lip of the wound, deep enough to include the thickness of the broad ligament, and the upper (cutaneous) lip of the same wound. In addition some auxiliary steps are taken when necessary.

This method, in addition to its simplicity and rapidity of execution, has the great advantage in that the sutures can be removed a day or two after the operation, giving a perfect functional and cosmetic cure.

Discussion. Dr. Mario Esteban said that in order to have an operation for entropion give desirable results it is always necessary to look for a base to give firm support to the sutures, a matter which is as easy in the upper lid as it is difficult in the lower lid. In the lower lid where the tarsus is narrow and flexible we can only find tarsal support if we make the incision and the line of suture very near to the free border. Sometimes the best way to achieve this is simply to make a deep lineal cauterization parallel to the ciliary border.

The usual operations with or without excision of a cuneiform strip or an elliptical piece, and with sutures placed beneath in superficial planes, are of uncertain results in the lower lid. Sometimes the skin will slip upwards and nothing will have been accomplished. Other times there will be a shortening and descent of the lid, but no eversion of its border and the eyelashes.

I believe that the procedure described by Dr. Marin Amat obviates the first of these inconveniences. As for the second, one must be careful to give the suture threads an adequate direction so that when tying, the palpebral border will be drawn forward and not downward.

Dr. Marin Amat concluded by thanking Dr. Esteban for his discussion. He added that this procedure, which he had used many times, does not give safe results and that the cure is obtained much later after elimination of the scab and cicatrization by second intention. The effect of the suture is so great that one must estimate it carefully so as not to produce an ectropion.

Pseudoneoplasms of the orbit

Dr. Diaz Gomes and Dr. Marin Amat discussed two cases of this condition, one of a chronic inflammatory type and the other of a hydatid cyst.

The first case is that of a 48-year-old woman who showed an enormous exophthalmos (10 mm.) of the right eye which was not reducible, did not pulsate, and had developed slowly. All biologic tests (Wassermann, the reactions of Weinberg and of Cassoni) were negative, as well as X-ray studies. A very extensive Krönlein operation showed an extensive flat neoplasm in the orbit, situated between the bony and muscular pyramid. It completely covered the latter on the outside, above and within.

The cure was rapid with proper position of the globe in the orbit, return of vision, and disappearance of the intense papillitis that had existed. There only remained a slight immobility of the globe and ptosis of the upper lid. Histopathologic analysis showed that it was a case of chronic inflammatory nature of the acinous glandular ty[illegible] (lacrimal gland) with infiltration of lymphocytes, plasma cells, and histoid elements.

The second case was that of a boy, aged 16 years, who had an exophthalmos (6 mm.) of the left eye for several months, irreducible and without pulsation, with almost complete loss of sight and a very intense papillitis. It was thought this might

be an intraorbital neoplasm, perhaps of the optic nerve, in view of the age of the patient and the early loss of vision.

In order to expose the neoplasm freely, a transfrontal surgical procedure was undertaken, which confirmed the presence, at the vertex of the orbit above and within the optic foramen, of a hydatid cyst the size of a chestnut. This was perfectly and fully removed. The postoperative course was satisfactory. The patient left the hospital without exophthalmos, without diplopia, with normal ocular motility, with a vision of 6/6, and with complete disappearance of the papillitis. There was a perfect anatomic and functional cure.

The extensive surgical procedures permitted to remove completely the neoplasms, in the first despite its extension and in the second despite its depth, are factors which are essential in operations of the orbit. Dr. Diaz Gomez made a few additional observations. In the first place it is very useful in order to diagnose the exact localization of the tumor and therefore to determine the best way to approach it, to get exact visualization of all the structures by means of injecting in the orbit some opaque medium of contrast to the X rays, a medium which would be harmless to the eye and the other intraorbital structures. He added, "I have read somewhere about this procedure, but do not remember where nor the details and I will be grateful to any of you gentlemen who can enlighten me on this."

The second point is that the transfrontal route could even be improved, in the sense of avoiding loss of the superior orbital border with disagreeable cosmetic consequences, as well as the difficulties which the resection places on the muscles which are inserted there. I believe this could be avoided by omitting to resect a strip of the orbital border, and, if this is not possible, it might be possible to insert a strip of bone afterwards to replace the lost bone, similar to the other procedures we do in cranioplasty.

Discussion. Dr. Bartolozzi congratulated Dr. Marin Amat and Dr. Diaz Gomez for their very interesting paper. The orbit is a closed box and to diagnose what takes place there is one of the most difficult things in ophthalmology. For this reason many times the only solution is to open up the box in the manner which Dr. Diaz Gomez has done with such brilliant results. It is evident that it is difficult to diagnose correctly many cases of exophthalmos especially when one lacks sufficient experience.

I recall a case of exophthalmos seen with Professor Carreras and diagnosed by him as having a chronic inflammatory origin. In this case, there was no antecedent factor except an old trauma to the frontal region. Could this be one of those rare cases where the process was due to a late hemorrhage caused by changes due to a very old trauma? At times, several years may elapse between the trauma and the hemorrhage. Only a surgical intervention could have cleared this up.

With reference to the suggestion of Dr. Diaz Gomez on the possibility of obtaining radiographs of the orbits with their contents visualized by means of a contrast medium, this work has already been realized. Finally, I agree with Dr. Diaz Gomez on the desirability of trying a plastic reconstruction of the roof of the orbit in cases where it is necessary to remove it in the course of the operation, since this would improve the appearance of this region and the function of the musculature.

Dr. Marin Amat thanked Dr. Bartolozzi for his discussion and added that the Krönlein operation which Dr. Diaz Gomez performed on the first patient is not the limited, circumscribed operation which we oculists do, but it is a much more extensive operation, with removal of the entire external wall of the orbit and, in addition, a large part of the roof of the orbit down to the sphenoidal fissure, so that the full contents of the orbit can be explored and the extensive tumor can be removed. In his second case, the transfrontal approach, he mobilized a

very extensive piece of bone periosteum and muscle, leaving it to adhere by its lower-external portion. Resection of the whole roof of the orbit leading to the exposure of the frontal lobe of the cerebrum and all orbital contents affords a large field of observation by means of which it is not only possible to remove the hydatid cyst from the apex of the orbit but also to perform total extirpation in cases where it invades the cranial cavity.

Facial paralysis with hysterical manifestations

Dr. Bartolozzi presented a clinical case characterized by the association of facial paralysis with typical hysterical manifestations. It is a case of a young woman, aged 18 years, who suddenly showed the following symptoms: deviation of the mouth towards the right side, impossibility of closing the left eye, pain in the left half of the head, and marked loss of vision of the left eye. The first examination showed a left, total facial paralysis, anesthesia of the regions supplied by the ophthalmic and superior maxillary branches of the trigeminus, limitation of movement of the left eye (downward, downward and inward, and downward and outward), marked loss of vision of this eye (fingers at half a meter) and slight loss in the right eye (7/10). The visual fields were restricted in both eyes, more marked in the left. The fundus was completely normal. Other tests, ocular and general, were negative. Not being able to ascribe such a complex picture to some definite process, it was suspected that the case presented a superposition of an hysterical process upon an organic picture. When the test was properly made, a typical "fatigue" field was obtained. Concurrently there was a rapid improvement in visual acuity.

Discussion. Dr. Marin Amat congratulated Dr. Bartolozzi and confirmed the extreme symptoms outlined, mentioning the frequency with which hysterical manifestations are superposed on organic diseases. This frequency is even more manifest in diseases of the nervous system, necessitating a careful discrimination between the functional or hysterical symptoms and those due to an organic or anatomic lesion.

When the second pair of cranial nerves (optic nerves) are affected at the same time with another pair of cranial nerves, as in the case of Dr. Bartolozzi, the functional examination will remove all doubts and will disclose the hysterical manifestations superposed on an organic lesion. In cases where vision is retained, the problem is simple, assuming that the hysteria shows the triad described by Charcot—a spreading of the personality, reduced field of consciousness, and a reduced field of vision.

One should emphasize that the constriction of the field of vision is one of the most constant phenomena of ocular hysterical manifestations. The constriction is concentric and regular and has certain characteristics which help to reveal it. These are: an inversion of the red with reference to white; the displacement curves of Foerster, and the fatigue curves of Wilbrand, or the fatigue spirals of Von Reuss, the outlines and isopters of which constitute true spirals like those which Dr. Bartolozzi has shown in his patient. In addition, the concentric reduction of the visual field shows a constant variability not only from day to day but from one moment to another. These are typical changes in the visual fields of hysterical and neurasthenic patients.

On the other hand when there is loss of visual acuity (amaurosis) the diagnosis is also not difficult (pupillary reflexes and fundus being normal). However, there are exceptional cases where there could coexist an amaurosis due to an organic lesion in the cortical centers of sight (as uremia or lead poisoning, principally) when it becomes necessary to resort to the other symptoms of these affections in order to complete the diagnosis.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 664 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE REBATE CASES

By this time everyone knows that 3,221 ophthalmologists in the United States have been charged in the antitrust suits brought by the government against the Bausch and Lomb Optical Company and four subsidiaries and the American Optical Company with violating the Sherman antitrust law by accepting rebates. That the number is so large should occasion little surprise, for it has long been known that the practice of accepting rebates by ophthalmologists is extensive, hoary with age, and has almost become a tradition or at least an accepted custom.

This custom arose in the very early days of American medicine when almost every physician and surgeon accepted rebates from drug stores, undertakers, and orthopedic supply firms, as well as from opticians. Fee splitting between physicians and surgeons was common and widespread. Specious arguments in favor of such practices have been advanced from time to time among the doctors themselves. That they were uncomfortable about it, to say the least, is shown

by the fact that their patients knew little or nothing about what went on behind the scenes.

Physicians of every specialty, furthermore, took hypocritical pleasure in condemning openly and officially in their societies and special organizations these usages as unethical. As has been said before, it was like Congress and the people during Prohibition days, voting dry but drinking wet. We look back on those evil days of national hypocrisy with no pleasure to our conscience.

Fee splitting still goes on, but certainly in a very subdued and gradually disintegrating form. The optical rebate practice is the last to remain of these unethical ways of getting something for nothing by exploitation of the patient. Thanks to government action it, too, appears to be on the way out. Unfortunately, the great science of ophthalmology and all ophthalmologists in this country are smeared and stained with muck in the process. The price will be worth it if the cancer is excised.

Among the 3,221 ophthalmologists named in the suit are members of all the ophthalmological organizations of this country, including the American Board of Ophthalmology. These are our friends and respected colleagues. Many of them are our leaders whose contributions to our science are noteworthy and significant, whose service to their patients is of the highest quality, and whose personal conduct is above reproach. We know that they and the rest of us deep in our hearts have hated the rebate practice that has so many roots in our professional lives and that has become so firmly established through effective outside pressure and reluctant inner complacence.

A widespread custom, handed down from generation to generation of ophthalmologists, endorsed and engaged in by so many of our past leaders and present prominent figures, overwhelmingly seductive to our young men just getting started in practice and eagerly fostered by optical firms, cannot be expected to be easily changed, especially by courageous, individual voluntary action.

It is significant, therefore, that 92 members of the Chicago Ophthalmological Society named in the antitrust suit have accepted a consent decree recently entered in the Federal District Court at Chicago. Under the terms of the decree, the ophthalmologists, while not admitting receipt of rebates from the optical companies on the sale of spectacles to their patients, consent to be enjoined against accepting such rebates and to remove themselves from any further proceedings in the antitrust suit against the optical companies.

The stipulation stated that the physicians are in agreement in condemning rebates by optical companies, that they affirm that they are not accepting such rebates, and pledge themselves not to accept any rebates or credits from dispensers. The order that was issued also provides that other doctors named in the suit may voluntarily become parties to the consent decree by signing the stipulation.

The action taken by the members of the Chicago Ophthalmological Society is a welcome and wholesome sign of moral progress. It means that they will no longer be glorified optometrists, but true doctors of medicine. It means that they will practice ophthalmology unfettered by commercial chains. It means considerable financial loss to their pockets, but it means increasing confidence, love, and respect from their patients, and quiet nights of respect for themselves.

Derrick Vail

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjuctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

1

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Spring, K. H., and Stiles, W. S. **Apparent shape and size of the pupil viewed obliquely.** Brit. J. Ophth. 32:347-354, June, 1948.

After photographing pupils at varying angles the authors found considerable individual variation in the apparent position of the pupil at oblique angles of view. For all pupil sizes the relative apparent vertical diameters at different angles are the same. At a given angle the ratio of horizontal to vertical diameters may be taken as a linear function of the apparent pupillary diameter for normal view.

Orwyn H. Ellis.

2

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Braley, A. S. **Experimental studies in inclusion blennorrhea. Isolation of a virus.** Tr. Am. Ophth. Soc. 45:432-461, 1947.

It is assumed that a new unknown virus was isolated, which however may represent a variant of the virus of inclusion blennorrhea. Because of the manner in which the inclusion blennorrhea was handled in passing through the mouse brain it is quite possible that a mutation of the virus may have occurred, which transformed an atypical virus into a typical one. This virus could then give rise to a follicular conjunctivitis in baboons in which there might be an immunity to further innoculation with the inclusion blennorrhea from a patient. If we consider a virus to be a mutation from bacteria by loss of their ability to synthesize artificial media then it would appear probable that a mutation of an atypical virus could be brought about.

It is concluded that the virus of inclusion conjunctivitis as it occurs in the human was not grown, but a variant which was a true virus was produced from the atypical virus of inclusion blennorrhea.

David O. Harrington.

VEGETATIVE PHYSIOLOGY, BIOCHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Estable, J. J. **The ocular effect of several irritant drugs applied directly to the conjunctiva.** Am. J. Ophth. 31:837-844, July, 1948. (2 figures, 14 references.)

Palm, Eric. **On the passage of ethyl alcohol from the blood into the aqueous**

humour. Acta ophth. 25:139-164, 1947.

The purpose of this work was to investigate how a lipoid-soluble substance would pass into the eye. Ethyl alcohol was chosen as the typical substance. It was injected into animals, the changes in the alcohol concentration in the blood and the aqueous humour were measured at intervals and the two curves thus obtained were measured. Alcohol passes through the membrane that separates the blood from the aqueous at so high a rate that diffusion in the anterior chamber cannot be regarded as taking place immediately and consequently the rate of penetration cannot be determined precisely. The penetration rate is estimated to be approximately one-third to one-half of the rate at which heavy water enters the eye. Alcohol enters the eye more rapidly than any other substance than water; for example at five to eight times the rate of urea. The comparison was suggested that the membrane that separates the blood from the eye functions, as far as permeability is concerned, as a porous lipoid membrane. The high rate of penetration of alcohol as compared with that of previously investigated lipoid-insoluble substances shows that the conditions that prevail in the eye are similar in this respect to those in the central nervous system and differ fundamentally from those found in the other tissues of the body.

F. H. Haessler.

Pirie, A., Schmidt, G., and Waters, J. W. **Ox vitreous humour. 1. The residual protein.** Brit. J. Ophth. 32:321-339, June, 1948.

The authors review the scanty literature on vitreous residual protein, and present their methods of procedure. Partition chromatographs of hydrolysates of commercial gelatin, cornea gelatin, vitreous humour residual protein and a mixture of glycine, proline and hydroxyproline showed striking similarities in the pattern exhibited by the first three. It was evident that all three contained roughly comparable amounts of proline, hydroxyproline, glycine, glutamic and aspartic acids, and alanine. This evidence was sufficient to suggest that the vitreous humour protein might be a member of the collagen gelatin group. X-ray photographs of vitreous humour residues, both in the unstretched and the stretched state were taken. The general agreement of the spacings of the X-ray reflections with those of oriented collagen fibers provides additional support for the view that the protein of the vitreous humour belongs to the collagen class. For further identification the action of collagenase which digests only collagen and reticulin of proteins was studied. A preparation of the enzyme readily dissolved the isolated residual protein of the vitreous humour. This again suggested that the protein was of the collagen class. The structure of the vitreous humour, which may perhaps be considered as a network of submicroscopic fibers, has a firmer, more stable arrangement than a colloidal gel.

When comparing the swelling curve of ox cornea collagen with the vitreous as a whole, acidity or alkalinity was found to have the exactly opposite effect. The effect of salts on the volume of washed vitreous humour residues was studied. The salts were found to depress shrinkage, and in general the valency effect of the anion was more clearly apparent. Ox vitreous humour has been shown to have a great deal more hexosamine than the humours of other animals. This indicates that the hyaluronic acid content of ox vitreous humour is greater and this probably explains its greater rigidity.

Vitreous cannot be considered as uniform, but must be made up of at least two structures, the collagen-like network and the hyaluronic acid and protein jelly. Liquefaction of the humour follows enzymic hydrolysis of the network, and therefore one may say that this network is essential for maintenance of a normal

vitreous humour. The relationship of the network to the jelly is of prime importance. Orwyn H. Ellis.

Spring, K. H., and Stiles, W. S. **Variation of pupil size with change in the angle at which the light stimulus strikes the retina.** Brit. J. Ophth. 32:344, June, 1948.

No abnormally high pupillomotor effect resulted from rays that entered near the edge of the dilated pupil, and hence were incident on the retina at an angle with the normal. Thus, for practical purposes the part of the pupil through which light enters the eye is not a factor in determining size of the pupil. Orwyn H. Ellis.

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Freusberg, O. **Muscular spasm of accommodation or transitory lenticular myopia in a swampfever-like toxemia.** Klin. Monatsbl. f. Augenh. 112:304-308, 1947.

The clinical syndrome of high fever, nausea, marked albuminuria and transitory myopia was observed among German troops stationed in the swamps of northern Finland. The author denies the possibility that this myopia could be due to a central or peripheral toxic stimulation of the accommodative mechanism, because the myopia does not disappear under the influence of a mydriatic and because of the lack of a simultaneous miosis. He regards the myopia as a lenticular one due to changes in the refractive index in the lens, similar to the transitory myopia in diabetes and in sulfonamide poisoning. (References.) Max Hirschfelder.

Harms, H. **The distribution of the light sense in the retina.** Klin. Monatsbl. f. Augenh. 112:353-357, 1947.

The light sensitivity of various meridians of the retina during light and dark adaptation was investigated by the author. In light adapted persons the fovea is found to have the highest sensitivity, whereas the peripheral parts show ten to fifteen times lesser sensitivity. The greatest decrease takes place within a radius of 20 degrees from the center of the retina. The fovea centralis of dark adapted persons shows less light sensitivity than its immediately adjoining region, usually 5 to 15 degrees from the point of fixation. The relative increase of light sensitivity in dark-adapted persons is more marked within this intermediate zone than it is in more peripheral parts. Individual differences in the various persons tested were noted during the experiments. (References.) Max Hirschfelder.

Jaeger, A. **A new instrument for checking the visual acuity in reduced illumination.** Klin. Montsbl. f. Augenh. 112:346-353, 1947.

A "nightvision selector (Nachtsehwähler)" is described which has the advantage of greater flexibility during the examination of acuity in low grade illumination. The instrument permits a change in the intensity of the illumination as well as a change in the size of the test letters. The article describes the use of a luminous foil for gauging the intensity of illumination, the arrangement of the illuminating lamps, and the test charts used. It also contains the arrangement which provides for constant light adaptation which precedes the test for vision in reduced illumination. In practice the test is taken by several persons at once, who sit 5 m. from the test object and are exposed to illuminated test signs of 0.005 lux and 0.0005 lux intensity for 10 seconds after various time intervals. After 15-minute dark adaptation and with 0.0005 intensity 61 percent saw about 0.09, 30 percent 0.06 and 8 percent less than 0.05. (References.) Max Hirschfelder.

Katz, J. **A new method for exact determination of visual acuity.** Klin. Monatsbl. f. Augenh. 112:341-346, 1947.

A method for exact determination of visual acuity by means of rotable Landolt rings is described. The method excludes the influence of guessing by making mathematical allowance for results which are subject to guess. Twelve observations of each of two to four Landolt rings of various sizes are the basis of the method. The article contains the mathematical calculations which make the method an exact one. Max Hirschfelder.

Kessler, J. **Instrument for the measurement of depth perception.** Klin. Monatsbl. f. Augenh. 112:339-341, 1947.

Two discs of glass, one of which is transparent, the other translucent, are arranged so that the distance between them can be varied. The transparent glass bears points arranged to make a letter or number, the other has an irregular arrangement of dots. A source of light is placed behind them. The measure of depth perception is the smallest angle of separation under which the patient can recognize the figures on the anterior disc.

Max Hirschfelder.

Swan, K. C. **Some aspects of studying binocular vision.** Am. J. Ophth. 31:845-852, July, 1948. (3 figures, 5 references.)

v. Tschermak-Seysenegg, A. **Is Fraunhofer correct?** Klin. Monatsbl. f. Augenh. 112:358-360, 1947.

The arrangement of slit and prism for the dispersion of light into spectral colors puts red to the left, blue to the right side. The letters A to H signifying the Fraunhofer lines are arranged in the same manner. England and America follow the opposite orientation and arrange the spectroscope so that blue is on the left, red on the right. According to the author, this is done to have the lower wave length on the left, the higher one on the right and, in this way, have an increasing mathematical series instead of a decreasing one. The author proposes a compromise which would retain the original arrangement by Fraunhofer which is still in use in continental Europe, but which would introduce the usage of the Hertz oscillation numbers which are low for red and high for blue.

Max Hirschfelder.

5

DIAGNOSIS AND THERAPY

Heinz, K. **The totally reflecting prism as an adjuvant in ophthalmoscopy.** Proc. Ophth. Soc. Vienna p. 90, Dec. 11, 1944.

By the use of a rectangular prism with reflecting hypotenuse surface it is possible to examine even the most distant periphery of the fundus of the human eye. Neither the patient nor the examining physician have to change their mutual positions during the examination. It is sufficient to turn the prism in different angles in order to visualize the distant sections of the periphery of the fundus. The instrument is of value in localizing retinal holes. F. Nelson.

Kirby, D. B. **Instruments for cataract surgery.** Tr. Am. Ophth. Soc. 45:423-432, 1947.

Detailed specifications for a complete set of matched instruments for cataract surgery is presented. All the instruments have balanced cylindrical handles so that each instrument has the same feel, grip, length, weight, size and balance. The article is photographically illustrated.

David O. Harrington.

Koch, F. L. P. **Pupillometry: a comment.** Tr. Am. Ophth. Soc. 45:415-422, 1947.

The various techniques of pupillometry and pupilography are reviewed in considerable detail. The characteristic components of the normal light reflex are listed and the application of pupillometry to diagnosis is discussed.

David O. Harrington.

Moehle, Walter. **Corneal scissors.** Am. J. Ophth. 31:864-865, July, 1948. (1 figure.)

Sloan, L. L. **A note on plastic test objects for perimetry.** Am. J. Ophth. 31:861-862, July, 1948. (1 table.)

6
OCULAR MOTILITY

Coachman, E. H. **A common extraocular muscle imbalance.** Eye, Ear, Nose and Throat Monthly. 27:175-179, April, 1948.

The author emphasizes the necessity for prolonged occlusion to detect the total muscle imbalance because momentary screening will not bring out latent phorias. In the vertical phorias, especially, this is essential for complete correction and relief of symptoms.

Orwyn H. Ellis.

Critchley, C. F., and Cameron, A. J. **Exophthalmic ophthalmoplegia treated with prostigmin.** Lancet 1:751, May 15, 1948.

A 33-year-old woman with exophthalmic ophthalmoplegia was treated with daily injections of 0.125 g. of prostigmin for two months. The exophthalmos and ophthalmoplegia improved and the dose of prostigmin was reduced. In two weeks one eye became more protuberant, 0.125 g. was again given, and the proptosis subsided. After about seven months the prostigmin was withheld. A month later the proptosis appeared to have decreased a little more and the function of the eye was otherwise within normal limits. (References.) Bennett W. Muir.
